In the future, capsid-targeted viral inactivation (CTVI), which involves the use of the viral capsid protein containing a deleterious enzyme such as a nuclease, could be used to bind native viral protein.<sup>94</sup>

There is also the future possibility of imidazolepyridines, which have a potent in vitro activity against CSFV, being used for treatment.<sup>95</sup> The reduction of CSFV transmission to untreated pigs has been shown by the pestivirus inhibitor BPIP.<sup>96</sup>

#### CONTROL

Strategies for Control Have Been Reviewed.<sup>97</sup>

The methods used in the control include **eradication** and control by **vaccination**. Both modeling and real-time prediction have been described. In areas where effective barriers to reintroduction of the disease can be established, eradication of the disease by slaughter methods is feasible and usually desirable. In contrast, in areas where the structure and economics of the pig industry require considerable within-country and across-border movement of pigs, it may not be practical or economically feasible to institute a slaughter eradication program. The establishment of a highly susceptible population in a high-risk area is unwise. If repeated breakdowns occur, the restriction of movement of pigs within the quarantine areas creates considerable management problems for pig owners, and they may, as a result, eventually become noncooperative in the program. In these areas, control and possibly even eradication by vaccination is the approach of choice, and this method is used in some countries, such as the Philippines. The Commission for the European Communities has declared its policy, supported by appropriate community legislation, to eliminate hog cholera without vaccination. A full discussion of the possibility of using vaccination in the future has been outlined. A computerized framework for the risk assessment for CSF has been produced. In Germany, there are big risks with regard to the import of pigs, the presence of wild boar populations, and the import of pig meat. A retrospective spatial and statistic simulation to compare two vaccination techniques with the nonvaccination scenario in the Dutch 1997/1998 CSF outbreak showed that both emergency vaccination techniques would hardly have been more efficient.

In the following discussion, general procedures are described first, followed by a description of the immunizing products available.

#### Control of Outbreaks in Hog Cholera-Free Areas

Modeling for the control of CSF in such areas has been described, and a simulation model for low- and moderate-density pig areas has been described.<sup>98</sup> A simulation of an outbreak of CSF in Denmark suggested that the outbreak would be of fewer than 10 cases and last less than 2 weeks on average,<sup>99</sup> although in some cases it may be longer lasting, and a large epidemic would result. Any outbreak would have a considerable cost to the export industry. A modeling study suggested that movement restrictions have had the dominant effect on control strategy for CSF and that preventive culling only became relevant under imperfect compliance.<sup>100</sup>

In areas where the disease does not normally occur, eradication by slaughter of all in-contact and infected pigs is possible and recommended. The pigs are slaughtered and disposed of, preferably by burning. All herds in the area should be quarantined and no movement of pigs permitted unless for immediate slaughter. In areas with high pig densities, control strategies depend on highly effective identification and recording systems, which provide information on herd inventories and animal movements, and thus herd epidemics can be traced back to their origin. Recent experiences with epidemics of swine fever in Belgium and the Netherlands found that with the current eartag with manual recording and use of a documentation system, most epidemics could not be traced back to their origin. The tracing and removal of carrier herds prevents these herds from becoming infectious and prevents the spread of disease at an early stage.

All vehicles used for the transport of pigs, all pens and premises, and all utensils must be disinfected with strong chemical disinfectant such as 5% cresylic acid. Contaminated clothing should be boiled. Entry to and departure from infected premises must be carefully controlled to avoid spread of the disease on footwear, clothes, and automobile tires. Legislation prohibiting the feeding of garbage or commanding the boiling of all garbage before feeding must be enforced. This eradication procedure has controlled outbreaks that have occurred in Canada and Australia and has served to maintain these countries as free from the disease.

#### Control Where Hog Cholera Is Endemic

One of the major problems in Europe is the wildlife reservoir in the wild boar population. A retrospective analysis of oral wild boar vaccination in the Eifel region of Rhineland-Palatinate has been described.<sup>101</sup>

In areas where there is little risk, there are few positive animals; where there is a high risk, many animals may be positive. In Switzerland 179 of 528 boars in a risk area were positive. The oral vaccination of wild boar described in Germany had no risk for the

establishment of a persistent wild boar CSF infection. However, it was shown that more than 50% of the wild boar did not feed on the vaccination baits and therefore did not become immune. There is evidence from wild boar studies in Italy that the level of infection in the free population gradually reduces in any case. When wild pigs with maternal antibodies contract live CSF virus, they have transient clinical signs, but the disease is not lethal. Infected wild boars could therefore play a very big part in the transmission of a natural outbreak. The vaccination studies in wild boar were reported recently and showed that after the fifth vaccination, there was no viremia, no virus excretion, and no postmortem virus recovery. Oral vaccination of wild boar usually reduces the presence of CSF, but only a low number of wild boars (30% to 35%) become seropositive. The isolated case in Israel in 2009 showed the problem of transfer of virus from wild boar.<sup>102</sup>

After CSF occurred in wild boar in north-eastern Bulgaria, it was decided to trap them; 124 were removed from the area, and of these, 119 were trapped. Further outbreaks of CSF were prevented.<sup>103</sup>

In endemic areas, control is mostly a problem of selecting the best vaccine and using it judiciously. In Asia almost all the control is vested in the use of vaccines and their proper use. Most problems are caused by policy failures or changes in demographics, whereas most of a vaccination policy should be determined by the epidemiology of the disease. Much can also be done to keep the incidence of the disease low by the education of farmers, whose cooperation can be best assured by a demonstration that eradication is both desirable and practicable. Once farmers are motivated to act, the greatest stumbling block to control, failure to notify of outbreaks, is eliminated. Education of the farmer should emphasize the highly contagious nature of the disease and the ease with which it can be spread by the feeding of uncooked garbage and the purchase and sale of infected or in-contact pigs. The common practice of sending pigs to market as soon as illness appears in a group is one of the major methods by which hog cholera is spread.

Vaccination in the EU finished in 1990 mainly because of the difficulty of differentiating infected and vaccinated animals. The exception is as an emergency vaccine or as bait for wild boar. Vaccination of wild boar has been carried out in France and Germany to reduce the shedding of the virus by the vaccinated boars. Outside the European Union, there is widespread use of the Chinese live C-strain vaccine and a biotech CSF E2 glycoprotein subunit marker vaccine.

There are two sorts of vaccine:

1. The first group is the classical live group containing attenuated virus, and these are preferred. Live, virulent-virus vaccines produce a solid immunity

within just a few days and give lifelong protection. The reaction to live-virus vaccine may be severe, and the susceptibility of pigs to other diseases may be increased. Eradication of the disease is impossible while the use of this type of vaccine is permitted. Commercially available modified live vaccines are able to induce complete protection in vaccinated pigs, but several factors, including maternal immunity, age of primary vaccination, vaccination protocol, and complications caused by other pathogens, can affect the effectiveness in the field.<sup>107</sup>

2. There is a recently developed second group of live vaccines aimed as marker vaccines based on the E2 protein, but these are still undergoing development. The marker vaccine strategies have been reviewed.<sup>108</sup> There appears to be no complete protection against congenital infection, they do reduce transmission of the virus, but they seem to last only about 1 year. They have the potential to allow tests to be used to differentiate between naturally infected and vaccinated animals. They may also fail in the face of natural infection. Recent further developments of these marker vaccines possibly include a chimeric vaccine in which one of the genes has been replaced by a BVD gene and a second vaccine in which a DNA vaccine expresses the E2 protein after entering the host cell and others with E2 peptides.

There are also several other vaccines: the E2 subunit marker vaccines expressed in baculovirus, E2 subunit vaccines, a chimeric BVDV-CSF marker vaccine, and a recombinant PRV vaccine expressing CSFV glycoprotein that is protective for both diseases.

A safe glycoprotein E2 vaccine expressing an ORFF virus recombinant has been described.<sup>104</sup> Protective efficacy of a CSF virus C-strain deletion mutant was described,<sup>105</sup> but the commercially available E2 ELISA was unsuitable as an accompanying test.

The strategy of exchanging specific epitopes between pestiviruses is useful, as was shown<sup>106</sup> when parts of the E2 gene were replaced by the corresponding sequence from a BDV strain.

When an outbreak occurs in a herd, the immediate need is to prevent infection from spreading further. This can be best achieved by removing the source of infection and increasing the resistance of in-contact animals by the administration of hyperimmune serum or one of the available vaccines. Removal of the source of infection necessitates the following:

- Isolation of infected animals—this was highlighted in the recent Dutch outbreak.
- Suitable hygienic precautions to prevent the spread of infections on boots, clothing, and utensils

- Disposal of carcasses by burning
- Disinfection of pens—the pens should be scraped, hosed, and sprayed with 5% cresylic acid solution or another suitable disinfectant. The choice of serum or vaccine may depend on local legislation and will depend on circumstances. Pigs in the affected pen should receive serum (20 to 75 mL, depending on size), and pigs in unaffected pens should be vaccinated. Pigs receiving serum only will require active vaccination at a later date if a strong immunity is to be achieved.

### Hog Cholera Eradication

The elimination of hog cholera from a country where it is well established presents a formidable problem. Before the final stage of eradication can be attempted, the incidence of the disease must be reduced to a low level by widespread use of vaccination and enforcement of garbage-cooking regulations.

One of the most important problems encountered in eradication programs is the clinically normal “carrier” animal, and steps need to be taken to avoid the sale of all pigs from infected premises. A procedure that has been particularly effective in the control of this and other diseases of pigs is the complete prohibition of all community sales of feeder pigs. There are obvious political difficulties in such a prohibition, but despite their usefulness as marketing agencies, community sales continue to be a major source of swine infections. When the occurrence of virulent hog cholera has been eliminated, further necessary steps include the prohibition of use of any vaccine and serologic studies to detect low-virulence carrier states.

The eradication of swine fever in the United Kingdom in 1986 was an important achievement. Control was radical in that all herds in which the disease was diagnosed were slaughtered and all carcasses burned or buried to avoid missing atypical cases and recurrence through the swill cycle. The two focal points that became apparent were the need to avoid vaccination and the need to diagnose accurately. Vaccination was not permitted because it was not completely effective, produced “carriers,” and encouraged the development of mild and chronic forms of the disease. The need to diagnose accurately led to changes in diagnostic procedure as the campaign progressed. As the proportion of classical epidemics declined, there was increasing dependence on serologic and antigen-detection tests. The program in the United States, which currently appears complete, is an equivalent achievement.

### Immunization Methods

There is a common neutralizing epitope on envelope glycoprotein E2 of different pestiviruses, which may have implications for the

development of DIVA vaccines and serologic diagnosis of CSF.<sup>109</sup>

Very few pigs possess natural immunity to hog cholera, and until the introduction of the serum-virus method of vaccination, an outbreak of the disease in a herd meant that the herd would be eliminated. The situation changed rapidly thereafter, and it can be safely claimed that the development of the swine industry in the United States would have been impossible without the protection that the serum and virus provided. On the other hand, the dangers inherent in the use of fully virulent or partially avirulent virus do not recommend their use and have led to a continuing search for safe methods of immunization. The ideal vaccine should retain strong immunogenicity but should be completely avirulent, even for pregnant sows, the fetus, and young or stressed pigs. It should be stable in the degree of attenuation and should not persist in the vaccinee or transmit from the vaccinee to in-contact pigs. Killed vaccines are safe and do not directly spread virus, but, in general, they engender only a limited immunity. Live vaccines provide a longer-lasting immunity but frequently have not met the criteria listed previously.

### Serum-Virus Vaccination

The serum-virus vaccination produces an immediate, solid, and lasting immunity when properly administered to healthy swine. The virus, produced by collecting blood 6 to 7 days after artificial infection, is injected SC in 2-mL doses followed immediately by serum in doses graduated to the size of the pigs and varying from 20 mL for suckling pigs to 75 mL for adults. Overdosing with serum will not prevent the development of immunity. Vaccination is performed at any age after 4 weeks. Because of the availability of safer vaccines, this method is not recommended.

### Attenuated Vaccines

The first attenuated vaccine was the Chinese lapinized vaccine (C-strain), which induced antibody- and cell-mediated immunity. C-strain-vaccinated pigs produce interferon-gamma at about 9 days postvaccination, and it is a potent inducer of type 1 T-cell responses with significant levels of proinflammatory cytokines.<sup>110</sup> There are certain CD8 cells that play an important role in the protection derived from the C strain vaccine, particularly in the early period before the presence of neutralizing antibody occurs.<sup>134</sup>

CSF infection results in the rapid onset of leucopenia, and it was shown that this affects the T cells. The inability to prime IFN- $\gamma$ -secreting virus-specific T cells may be attributable to their depletion before activation or to the phenomenon of apoptotic cell-induced dendritic-cell-mediated suppression.<sup>111</sup> It may also be that the affected dendritic cells have a deranged cytokine production that overexpresses IFN- $\gamma$  and TNF- $\alpha$ .<sup>112</sup>

The most notable development has been the introduction of the first generation of marker vaccines against CSF. These are E2-subunit vaccines that protect pigs by inducing high levels of neutralizing antibodies to E2 after vaccination. A serologic test against E<sup>rns</sup> was approved within the European Union.<sup>55</sup> However, this test also detects antibodies against E<sup>rns</sup> from ruminant pestiviruses and therefore produces cross-reactivity in diagnostic tests.<sup>113</sup> E2 glycoprotein contains epitopes that produce neutralizing antibodies, which confer protective immunity and are frequently used for designing DIVA vaccines.<sup>114</sup> The E2 glycoprotein is the major antigenic protein exposed on the outer surface of the virion that induces the main neutralizing antibody, and there are differences between the E2 of the vaccine and field strains of CSF.<sup>115</sup> There are conserved residues, and these may be useful in the development of future diagnostic tests and marker vaccines.

A live attenuated antigenic CSF marker vaccine involving a positive antigenic marker in E1 and a negative marker in E2 has been designed.<sup>116</sup>

A yeast-expressed CSF virus glycoprotein E2 was also shown to produce a protective response.<sup>117</sup>

There has been the rational design of a CSF C-strain vaccine virus that enables the differentiation between infected and vaccinated animals.<sup>118</sup> These findings provide the molecular basis for the development of a novel, genetically stable, live attenuated CSF DIVA vaccine. Some C-strain vaccine virus is not detected by C-strain-specific RT-PCR as a result of a point mutation in the primer binding site.<sup>119</sup>

The efficacy of marker vaccine candidate CP7\_E2alf in piglets with maternally derived C-strain antibodies was studied.<sup>120</sup> It provides early protection against lethal challenge infection with CSF virus after both intramuscular and oral immunization.<sup>121,122</sup> It was shown to be effective in preventing mortality, severe clinical signs, and pathologic lesions in 5- or 8-week-old pigs, positive for maternal antibodies derived from sows vaccinated 4 weeks before farrowing, with one dose of C-strain vaccine. The vaccine was able to produce stable antibodies that led to protection for 6 months after vaccination.<sup>123</sup> The primary replication site in vaccinated animals is the tonsils. It persists for up to 63 days after oronasal administration, and it also allows the use of DIVA in the serologic tests.<sup>124</sup> It was confirmed as a promising marker candidate for oronasal vaccination for both wild boar and domestic pigs.

Enhanced immunity to CSF was described after inducement by prime boost immunization using an alphavirus replicon-vectored DNA vaccine and a recombinant adenovirus,<sup>125</sup> and it is able to produce cell-mediated immunity.<sup>126</sup>

Attenuated vaccines include tissue culture vaccines attenuated by repeated passage through tissue culture of porcine or other origin, lapinized vaccines produced by repeated rabbit passage, and vaccines from mutant strains. Many of the early vaccines of this type were not stable and could cause disease when not used in conjunction with serum. Furthermore, transmission to in-contact pigs, especially with porcine origin vaccines, and fetal disease following vaccination of pregnant sows have been problems. Attenuated vaccines are in wide use in Europe and Asia and include the Chinese or LPC and GPE strains. Recently, a safe and efficacious CSF marker vaccine based on the E2 protein (major immunogen) of the virus has been developed. This protein has neutralizing antibodies, and it is also conserved. It can be used where there is an endemic problem and also after the outbreak. It also prevents or reduces drastically the problem of transplacental infection. Experimental nontransmissible marker vaccines have also been developed. Highly passaged preparations are antigenically stable and show no evidence of reversion. They produce a very limited viremia, or none, and no leukopenia or clinical illness. Protection is evident within 5 to 10 days of vaccination. Piglets from nonimmune sows can be vaccinated within the first 2 weeks of life. Because the presence of maternal immunity can interfere with effective immunization, the vaccination of piglets from immune sows should be delayed until at least the second month. The French Thiverval strain is a cold mutant strain that has lost its virulence but retained good immunogenicity. Vaccination of piglets even with 10 times the regular dose produced no clinical illness and virtually no viremia. A single IM vaccination will produce resistance to challenge by 5 to 10 days, and immunity persists for 3 years. Colostral immunity will protect piglets for periods up to 2 months after birth. When given to pregnant sows, even the highly attenuated strains have the ability to cross the placenta and produce fetal infection even though no clinical evidence of this may be manifest. Consequently, it is recommended that replacement gilts be vaccinated at least 2 weeks before mating and that recently vaccinated animals be kept separate from susceptible pregnant sows.

In the Netherlands, the control of swine fever has relied on a slaughter policy on affected farms plus an emergency vaccination program in which all pigs over 2 weeks of age in areas of risk are vaccinated. The mass vaccination program is followed by supplementary vaccination of pigs at 7 to 9 weeks of age and revaccination of breeding gilts when they reach 6 to 7 months of age. The serologic response of piglets born from vaccinated sows is best at 9 to 10 weeks of age rather than at 5 to 6 weeks of age. A vaccine-induced neutralizing antibody titer

of less than 32 is adequate to provide protection against clinical disease and to prevent virus transmission.

In the future, a recombinant adenovirus expressing the E2 protein of CSF virus may be useful as a candidate vaccine for preventing CSF.<sup>127</sup> Another possibility is the use of synthetic RNA corresponding to the nucleotides 1130 to 1148 of the CSF virus targeting the nucleocapsid protein, which was shown to inhibit viral replication.<sup>128</sup>

Modification of the glycosylation of the E1, as for the other E proteins, could be useful for the development of CSF live-attenuated vaccines.<sup>129</sup>

Oral vaccination of backyard pigs against CSF with bait vaccine was proven to be useful in an emergency-type situation.<sup>130</sup>

### Inactivated Vaccines

Inactivated vaccines are usually prepared from the blood or tissues of infected pigs. Crystal violet vaccine has been the most widely used of this type and was used in the United Kingdom before eradication but never gained full acceptance in the United States. It is completely safe, but its immunogenicity is poor. Immunity does not develop until 12 days after vaccination. Its duration is short, and booster injections are required for maintenance. Vaccinated sows may still develop fetal infection when exposed to virulent virus, and there is a danger that the use of this vaccine in enzootic areas may in this way induce virus carriers. The production of immune antibodies to the blood components of the vaccine may result in the occurrence of isoimmune hemolytic anemia in some breeds. For these reasons inactivated vaccines are not in common use.

Wild boar populations in some countries have risen considerably, particularly in Germany. It is seemingly harmless in wild boar. It can be confined to certain areas until eliminated.<sup>131</sup> Routine vaccination around an area of infection has been proposed as a method of control.<sup>132</sup> Only then can the DIVA qRT-PCR be used to separate vaccinated from field cases.

### AFRICAN SWINE FEVER

African swine fever (ASF) is an OIE List A disease. It is on the move and dangerous.<sup>1</sup>

For many years only the Pirbright, Spanish, Portuguese, and South African groups have been interested in the virus, with limited resources to pursue a vaccine, but with the incursion into Europe, this has changed. It is indistinguishable in the field from classical swine fever because both are hemorrhagic diatheses, and it is just as contagious. It is responsible for a highly fatal disease in domesticated pigs. It is the greatest limitation to the development of the pig industry in Africa.<sup>2</sup> However, it is associated with a totally different virus. It is also very important because of its spread into Europe, because of its economic effect, and because of the difficulties of control in wild pig populations and eradication in the face of no effective vaccination. It has no public health significance. An online training course put together by a consortium of experts working on ASF is offered through the link <http://asforce.org/course/>.

## SYNOPSIS

**Etiology** Large icosahedral cytoplasmic DNA virus.

**Epidemiology** Disease of major threat to pig-producing countries. Occurs in Africa, western and eastern European countries, Caribbean countries. High morbidity, high case-fatality rate in classic form; low-virulence form less fatal. In Africa, transmitted by argasid tick from wild pigs to domestic pigs. In Europe, transmitted by direct contact with infected pigs and wild and feral pigs. Antibodies in colostrum of recovered sows provide passive protection to piglets.

**Signs** High fever, purplish skin, depression, anorexia, huddling, disinclination to move, weakness, incoordination, nasal and ocular discharges, diarrhea, vomiting, abortions, death in a few days. Historically, highly virulent forms; in recent decades, subacute and chronic forms common, with fever, depression, and lethargy; recover in few weeks but remain persistently infected; chronic cases are intermittently pyrexemic and become emaciated, with soft edematous swelling over joints and mandible.

**Clinical pathology** Severe leukopenia and lymphopenia. Detect antigen or serologic tests.

**Lesions** Marked petechiation of all serous surfaces, lymph nodes, epicardium and endocardium, renal cortex, bladder; edema and congestion of colon and lungs. Renal hemorrhages are considered pathognomonic.

**Diagnostic confirmation** Identify virus in tissues.

### Differential diagnosis list:

- Hog cholera
- Erysipelas
- Salmonellosis

**Treatment** None.

**Control** Identification of affected pigs, slaughter, and quarantine premises.

Establish disease-free areas.

## ETIOLOGY

It is associated with a DNA virus that is the sole member of the family Asfarviridae and as such is the only known DNA arbovirus. It is a large icosahedral virus that contains a linear, double-stranded DNA genome (170 to 190 kbp). The viral genome may encode for 165 genes and encodes for approximately 113 virus-induced proteins and over 28 structural proteins in intracellular viral particles, most with an as yet unknown function. The variable ends of the genome contain five multigene families, and the large differences in these between the different isolates may account for the large differences in antigens that are seen between the various isolates. There are large differences between the genomes of isolates from different regions and types of pig<sup>3</sup> and between virulent and avirulent viruses. Morphologically, it is similar to the iridoviruses but resembles the pox viruses in genome construction and gene expression. There are different forms from highly lethal to subclinical with different field strains and tissue-culture-adapted strains. These are recognized by restriction fragment length polymorphism (RFLP), and protein p72 recognizes all viral groups. Partial p72 gene characterization allows genotyping of field strains. It does not produce neutralizing antibodies, and therefore there is no serotypic classification, but 22 ASF genotypes have been identified using partial sequencing from the p72 gene.<sup>4</sup> Genotype 1 is West African, which also circulated in Europe in the previous outbreaks, and the other 21 are East African. The strain at present circulating primarily in Russia is also an East African strain. It grows well in porcine bone marrow and buffy coat with the production of syncytia.

## EPIDEMIOLOGY

Because there is no vaccination as yet, the presence of antibodies always denotes infection, and these antibodies appear early and last for long periods. There is high genetic variability, which seems to be related to the sylvatic cycle present in the region and may be responsible for the complex epidemiology in the region.<sup>4</sup>

## Geographic Occurrence

### Africa

African swine fever is indigenous to the African continent, where it affects wild pigs. These include warthogs, bush pigs, and escaped (feral) forest hogs, which act as reservoirs of the virus, which cycles between the pigs and the ticks. Wild pigs in some areas are free of infection, and consequently the

disease is not endemic in all areas. It was always considered to be a disease of sub-Saharan Africa but over the years has reached new areas. It is endemic in over 20 sub-Saharan countries. It reached Cuba (1971 and 1980). In 1978 outbreaks occurred in Malta, Brazil, and the Dominican Republic and in 1979 in Haiti. It reached Madagascar and Mozambique in 1994, Kenya in 1994, Ivory Coast in 1996, Benin in 1997, and Togo and Nigeria in 2001. The Kenyan outbreak seemed to be maintained in the domestic pigs without sylvatic hosts. The Nigerian strain was 92% to 97% homologous to the strains from Uganda, the Dominican Republic, and Spain. The serious worry was the appearance of the virus in Madagascar in 1998. Although studies showed a seropositivity of only 5.3%, infection of wild pigs produced no clinical disease. With virulent strains, infection in the domestic pig is almost always fatal. Since its recognition, occurrence of the disease in South Africa has been cyclical, with periods of 10 to 12 years of clinical disease and then an absence of disease. Until 1957, ASF had not occurred outside the African continent. To the rest of the world it represented the most formidable of the exotic diseases of swine, a disease that had to be kept within its existing boundaries at all costs.

## Europe

In 1957, it spread from Africa to Lisbon and then to Spain in 1960; France in 1964; Italy in 1967, 1969, and 1993; Malta in 1978; Belgium in 1985; and the Netherlands in 1986. It was eradicated from the Iberian Peninsula in 1964.

In Malta (1978), the disease resulted in the death or slaughter of the entire population of 80,000 pigs within 12 months of the diagnosis. This is one of the few examples where a country had to slaughter an entire species of a domestic animal to eliminate a disease. The source of infection was thought to be pork imported from Spain, which was fed to only one boar. Once the official diagnosis was made, all animals on affected farms were slaughtered. Animals that had direct commercial contact with infected herds were also slaughtered, and the disease was declared eradicated in September 1985.

In Spain, the disease had been present since 1960, but the implementation of regulations for eradication adopted in 1985 made it possible to divide the country into an ASF-free region and an infected region. Since 1995, Spain and Portugal have been declared free from the disease, although there was an isolated outbreak in Portugal in 1995. This has resulted in a marked change in the distribution and incidence of the disease.

Europe has remained free after the eradication from Iberia, with one exception, Sardinia, where the disease is endemic in the Central Highlands, although it decreased from October 1994 to March 1996. In a

survey in 1998, 45 of 82 municipalities in the province of Nuoro in Sardinia were found to have ASF. In 2010 there were 87 cases in Italy, the principal reasons being the extensive pig farming and the occurrence of wild boar. The partial confinement farms have less seropositivity than the free-range farms, and those in total confinement have only 20% of the level of the free-range farms.

### The Recent Disease Outbreak

On the basis of sequence studies,<sup>5</sup> it is likely that the virus in Georgia originated from East Africa (Mozambique or Madagascar) and went by boat (uncooked pork) to the Black Sea and then to the port of Poti in Georgia. In 2007 ASF was recognized in Georgia. It killed all the pigs within 5 to 10 days<sup>6</sup> and remains as virulent now. It then spread rapidly to the Caucasus<sup>5</sup> and then rapidly to Armenia, Azerbaijan, and the Russian Federation. It has reached the Ukraine and now has reached the northwestern areas of Russia near the Baltic States and the Barents Sea. It is currently circulating out of control in both domestic and wild pig populations.<sup>7</sup> There are two populations at risk: the low-biosecurity population (backyard pigs, etc.: 77%) and the high-security domestic pigs (23%). The disease has spread widely in the southern part of the Russian Federation, and since 2011 a secondary endemic center has shifted to the center of the country.<sup>8,9</sup> In 2010, pigs were dumped at a poultry manure storage site just 30 km from St. Petersburg and 100 km from the EU border with Estonia, but where the pigs came from is unknown. It is a risk being near to one of the largest ports in Russia, and it must be ensured that trucks emanating from these ports are properly disinfected. This present virus is genotype 11, and nearly all the cases are acute cases, as you would expect in a naïve, susceptible population.

In June 2013, the Russian authorities reported outbreaks in backyard pigs along the border with the Ukraine and in wild boar in the Smolensk region north of Moscow. Belarus also reported ASF in backyard pigs in the Grodno region in the west of the country. This is of danger to the European Union because this is close to the border with Lithuania, where there have been cases in the wild boar as a result of transborder movements. It is a threat to the European Union because of wild boar, backyard pig keeping, illegal entry of meat from infected pigs into the food chain and possible import into the United Kingdom, and swill feeding. Three-quarters of all ASF events are reported between June and November in the backyard sector, whereas a quarter of wild boar outbreaks are reported in May and June when there is an increasing population. The virus has also been found in illegally disposed carcasses and meat-processing plants. Low temperatures do not destroy the virus, and chilled meats are a source of infection where

swill feeding is practiced. A model has been developed for the spread of ASF into the European Union during the high-risk period.<sup>10</sup> One of the key suggestions is that spread during the high-risk period is likely to be limited especially if the high risk period is short. There is a risk of ASF being transported into the European Union through transport-associated routes (returning trucks, and waste from planes and ships), and this risk has been examined.<sup>11</sup> The study showed that the risk through transport-associated routes was low, except for in some countries, such as Lithuania and Poland, and the returning trucks were the highest risk. The risk of introduction of live pigs was highest in Poland,<sup>12</sup> particularly in November and December, and from the Russian Federation. The ASF virus found in Georgia can replicate efficiently in ticks.<sup>13</sup> An epidemiologic update has been provided.<sup>14</sup>

In early 2014, ASF was discovered in wild boar in Lithuania less than 200 km from the Polish border. It is likely to be the result of movement of infected animals from affected regions in Belarus.

### Species Affected

Only pigs are affected; domestic pigs of all ages and breeds are highly susceptible, but the virus can be passed in tissue cultures of rabbits, goats, and embryonated hen eggs. The three African wild species (warthogs, giant forest hogs, and bush pigs) are resistant to infection, but European wild boar are susceptible.

Until recently, the occurrence of the disease in Africa was limited to explosive outbreaks in European pigs that came in contact with indigenous African pigs. These outbreaks tended to be self-limiting because all pigs in affected herds died or were destroyed, but after a number of years the disease became enzootic in domestic herds. Surveys of the disease in countries such as Malawi illustrate the changing behavior of the disease over a period of years. The virus, which was introduced to Europe in 1957, was capable of persisting in European pigs, and after a period of several years in which the disease was epizootic, a change to an enzootic character occurred. The outbreak in Cuba was of a comparatively virulent form.

When the disease occurred in the Caribbean region, it posed a major threat to the large swine industry of the United States principally because of the possible spread of the virus to the feral swine population in Florida. The feral swine population in Florida is the largest in the United States and is of major recreational and economic importance to hunters, trappers, taxidermists, and dealers who sell feral swine to hunting clubs. The feral swine in Florida are descendants of domestic swine that were allowed to run wild. Experimental inoculation of these pigs with virulent isolates of the virus will cause fatal disease.

### Morbidity and Case Fatality

Early in the history of African swine fever, the morbidity rate could be as high as 100%, and the case-fatality rate was also often over 90%. However, a decrease in the virulence of the virus occurs with time in enzootic areas, and the case-fatality rate may now be as low as 2% to 3%.

### Methods of Transmission

There are three main methods of transmission cycle. Firstly, a wild pig/soft ticks/domestic pigs cycle; second, a domestic pig/tick cycle without warthogs; and third, a domestic pig/pig cycle.<sup>15</sup> Local spread and outdoor production facilities in association with wandering wild boar may be the most common methods of transmission.

In Africa, the method of transmission of the disease from the reservoir in wild pigs to the domestic pig has been the subject of considerable interest. Infection is primarily transmitted to domestic pigs via the argasid tick *Ornithodoros moubata*. The viremic warthog is a source of infection for the ticks. The virus can be maintained in warthog-associated argasid ticks by a transstadial, transovarial, and sexual (male to female, but usually not vice versa) transmission mechanism. It needs to replicate in the midgut epithelium of the tick for successful ASF infection of the tick. The tick is relatively restricted in its habitat, and if contact between domestic pigs and wild pigs and their burrows is prevented, transmission can be prevented. The virus can be maintained in these ticks for long periods in the absence of fresh sources of infection, with a low level of viremia lasting a long time. The young warthogs in the burrows are infected early on, and thus they act as reservoirs and vectors of infection. Sporadic outbreaks may thus occur in endemic areas when the virus spreads from infected ticks or warthogs to domestic pigs. In some areas where infected warthogs are common but where *O. moubata* is apparently absent, *O. savignyi* may be a natural field vector of the virus. It is also found in *O. porcinus*. The ASF virus replicates to a high titer in the developing cells of the egg of the tick. Ticks infected with ASF virus also have a higher mortality than uninfected ticks.

The long-held belief that the source of the virus in primary epidemics of African swine fever in southern and eastern Africa is the carrier, wild pig, is not tenable. It is postulated that infected ticks are transported to the vicinity of domestic pigs either by warthogs or on the carcasses of warthogs.

In Africa, the virus is maintained primarily by a cycle of infection between warthogs and soft ticks (*Ornithodoros moubata*). The virus does not have an apparent effect on either warthogs or ticks, and it is only when infection of domestic pigs occurs that the virus produces disease. Indeed, most warthogs are aviremic but seropositive. The tick

has a wide distribution in Africa south of the Sahara, and its main habitat is in burrows that are inhabited by the warthog. There is a good correlation between antibodies in warthogs and the presence of ticks. Newborn warthogs can become infected soon after birth if bitten by infected ticks, and the consequent viremia would be high enough to infect previously uninfected ticks feeding on them. It is also found in the bush pig (*Potamochoerus porcus*), which, following infection, may be viremic for 35 to 91 days, and these also transmit the infection to ticks.

In Europe there is direct transmission between sick and healthy animals irrespective of whether they are domesticated or wild or feral animals. In **Spain and Portugal**, the methods of spread are contact between neighboring farms and the introduction of infected pigs either during the incubation period or as persistently infected virus carriers. During the last 20 years, an increasing number of outbreaks occurred in which clinical disease was not readily recognized. The mortality rates decreased, and a wide range of clinical disease occurred, ranging from acute to chronic and including apparent recovery to normal health. The major consequence of the emergence of these less virulent forms of the virus was the development of persistently viremic carriers and a large population of pigs with inapparent infection. The African swine fever virus may persist in the pig population by persistent infection in recovered pigs for several months, during which time the virus must be reactivated before transmission can occur. The virus can also persist by reinfection of recovered pigs in which the virus replicates without producing clinical disease, and transmission occurs by excretion and by infected blood and tissues. Wild boars in Spain carry the virus without clinical signs.

The **European vector** of the virus is the soft tick *O. erraticus*.<sup>16</sup> It can maintain and transmit the virus for at least 300 days. In various areas of Spain, *O. erraticus* was found in 42% to 64% of the pens occupied by pigs. Following the outbreak of the disease in Spain, abandonment of these pig pens has resulted in the elimination of most soft ticks infected with the virus. The adults and large nymphs can survive for about 5 years or longer in the soil of pig pens when animals occasionally enter them. There is a relationship between the persistence of the disease and the distribution of the tick in Spain. Hungry tick populations may transmit the virus when feeding in the winter, but populations that have continuous access to pigs do not feed until the pig pens reach a temperature of 13° to 15°C (55°–59°F). The development from larva to adults takes 2 to 3 years. In a recent study of the ticks (*O. erraticus*) from farms in southern Portugal, two types of ASF were isolated. One produced the acute, 100% fatal disease, and the other just a low viremia in pigs.

In **Sardinia**, the major factors involved in the spread of the disease are related to the following factors:

- Mountainous terrain in which pigs may range freely in previously infected areas
- Movement of pigs that may survive infection and mingle with other herds
- Introduction of infected pigs from unknown sources into healthy herds because of the uncontrolled movement of pigs
- Feeding of waste food containing meat from infected pigs

The virus has been experimentally transmitted to healthy swine by *O. coriaceus*, an argasid tick indigenous to the United States. The potential arthropod vectors of the virus in **North America and the Caribbean basin** have been examined. Most *Ornithodoros* spp. of ticks that will feed on pigs may be capable of acting as vectors of the virus, and the possible existence of potential vectors among the other blood-sucking arthropods should not be ignored. The soft tick *O. (Alectorobius) puertoricensis* found on the Caribbean island of Hispaniola (Haiti and Dominican Republic), where African swine fever was endemic from 1978 to 1984, was experimentally able to transmit the virus from infected to susceptible pigs. The *O. coriaceus* tick is able to harbor and transmit the virus for more than 440 days, passing it transstadially from the first nymphal stage to the adult, sustaining it through at least four molts. *O. puertoricensis* has all of the prerequisites for becoming a true biological vector and reservoir of the virus.

Once established in domestic pigs the disease can spread rapidly. Virus is present in high titer in nasopharyngeal excretions at the onset of clinical signs and is present in all organs and excretions in acutely sick pigs. In experimentally inoculated domestic pigs, the virus is present in substantial amounts in secretions and excretions of acutely infected pigs for only 7 to 10 days after the onset of fever and is present in the greatest amount in the feces. The virus can persist in the blood of some recovered pigs for 8 weeks and in the lymphoid tissues for 12 weeks. Feces are the environmental contaminant most likely to spread the infection, but blood is also highly infective, and transmission could occur by contamination of wounds created by fighting. Infection occurs via oral and nasal routes, and with the short incubation period once the disease is established in a herd, it spreads rapidly by direct contact. Infection among domestic pigs can also reputedly be spread by the following activities:

- Indirect contact by infected pens
- Ingestion of contaminated feed and water
- Feeding uncooked garbage containing infected pig material

Transmission via the hog louse *Haematopinus suis* is also probable. An important source of infection is the recovered pig,

which may remain persistently infected and a carrier indefinitely. Pigs that have recovered from the Western Hemisphere isolates (Brazilian and Dominican Republic) may be persistently infected and are resistant to experimental challenge.

Little is known as yet about the transmission of the virus by ticks in eastern Europe. However, all *Ornithodoros* spp. ticks tested so far have been susceptible to ASF virus and are therefore potential biological vectors.

## Risk Factors

### Pathogen Factors

The ASF virus is a multiclonal population of viruses in which all combinations of at least four markers (hemadsorption, virulence, plaque size, and antigenicity) are found. This may explain the epidemiologic observation that when the disease was confined to Africa and the Iberian Peninsula in the early 1960s, the viruses isolated were highly virulent to swine, but in subsequent years mortality decreased and subacute and chronic infection became more common. Experimentally, moderately virulent ASF virus obtained from the Dominican Republic, when inoculated into pigs, results in an acute febrile illness along with viremia and a transient neutrophilia from which the pigs recover. The Malta 78 isolate of the virus experimentally produces a clinical syndrome similar to that of the African isolates of the virus.

A huge amount of research is continuing apace into the genes and the proteins produced from the expression of these genes, but these are beyond the scope of this text. However, recent studies of ASF have suggested that the virulence may depend on their ability to regulate the expression of macrophage-derived cytokines, which in turn regulate T-helper type 1 cells (Th1) and T-helper type 1 cells (Th2) responses and control the host protective responses. The less virulent cultures of ASF with macrophages produce more TNF- $\alpha$ , IL-6, IL-12, and IL-15, whereas virulent strains inhibit their production. The ASF virus also affects chemotactic responses and phagocytic capacity and causes a reduction in the release of toxic oxygen radicals.

The virus is very stable at pH 4.0 but not so stable at levels above or below this. It is highly resistant to putrefaction, heat (it will survive 2 hours at 56°C [133°F]) and dryness and survives in chilled carcasses for up to 6 months and at 4°C (39°F) for 2 years. It survives in serum for 6 years at 5°C (41°F). Probably 0.5% to 0.66% of all the genes of ASF are not connected with virus replication but are important for viral transmission and survival in the host. It is inactivated by 1% formaldehyde in 6 days and by 2% sodium hydroxide in 24 hours.

## Immune Mechanisms

Antibodies against the ASF virus occur in the colostrum of sows previously infected

with the virus and are transferred passively to nursing pigs. Experimentally, passively transferred virus-specific immunoglobulins alone will protect swine against lethal infection with a highly virulent homologous strain of the virus. The antibody-mediated protective effect is also an early event that effectively delays disease onset. The construction of blocking antibodies by some of the viral proteins probably prevents the complete neutralization of the virus by antibodies.

Pigs infected with virulent or attenuated virus may recover and resist challenge exposure with virulent homologous and, under certain conditions, heterologous viruses. Although pigs develop antibodies that are detectable by different tests, virus-neutralizing antibodies have only recently been demonstrated against viral protein p72. However, it has recently been suggested that p30, p54, p72, and p22 proteins are not associated with neutralizing antibodies. The sera from pigs that have been infected and are resistant will inhibit virus replication, but the nature of the inhibition is not understood. Neutralization of virulent virus isolates in both Vero cell cultures and swine macrophages using swine immune sera has been demonstrated. Experimental exposure of pigs to a low-virulent field isolate of the virus results in a range of virus-induced specific cellular responses.

The virus induces strong *in vitro* blastogenesis of primed blood mononuclear cells, when less virulent but live virus isolates are used. Pigs recovering from an acute infection with the virus have significant levels of virus-specific cytotoxic T-lymphocytes after *in vitro* stimulation. Viral protein p36 induces a helper T-cell response in mice. Resistance to infection appears to be related to the level of antibody-dependent cell-mediated cytotoxicity. Virus-specific blastogenic and cytotoxic T cells are prime candidates for the cells inducing and conferring protective immunity against challenge with the virus, suggesting that cellular-based mechanisms are highly important.

In persistently infected animals the virus may be shed into the environment for at least 70 days.<sup>17</sup>

The incubation period varies widely from 4 to 19 days depending on the isolate and the route of infection. Infected domestic pigs begin shedding the virus before they are showing clinical signs. The virus is shed in large amounts from all excretions and secretions. Surviving pigs demonstrate a long-term viremia, and virus may be recovered.

## **PATHOGENESIS**

The virus replicates in the monocytes and macrophages of the lymph nodes nearest the point of virus entry to the body. It is often the tonsils and respiratory tract and replicates in the lymphoid tissues of the nasopharynx before the occurrence of a

generalized viremia, which can occur within 48 to 72 hours of infection and is followed by secondary replication in the lymph nodes, spleen, lungs, liver, and kidney. The viremia may begin after 4 to 8 days and may last for weeks because there are no neutralizing antibodies.

Infectivity and contact transmission develops at this time and continues for at least 7 days. Pigs inoculated with field isolates of the virus from the Western Hemisphere develop thrombocytopenia with a characteristic pattern. Infected pigs become thrombocytopenic over a 48-hour period after 3 to 4 days of illness. After several days of thrombocytopenia, the platelet count returns to baseline level even with a continuing viremia. Experimentally, the virus causes hematopoiesis in bone marrow, which coincides with macrophage activation, and bone-marrow function is not impaired. Membrane proteins on the surface of permissive cells act as receptors for ASF, and specific interactions take place at this site. ASF is associated with red blood cell membranes and platelets. The subacute form is characterized by a transitory thrombocytopenia.

The effects of ASF are primarily hemorrhages and apoptosis. A newly found protein (p54) encoded by the virus has just been shown to be the first that directly induces apoptosis. The disease is characterized by apoptosis with abundant lymphocyte, particularly B-cell, death. Both T and B cells, particularly in the spleen, are affected as early as 3 days after infection, with the apoptosis being induced by cytokines or apoptotic mediators released from ASF-infected macrophages. In all probability there is an intracellular pathway triggered at the same time as the process of virus encoding. It is probable that the inducers of apoptosis are balanced by the inhibitors of apoptosis.

Tissue necrosis and generalized endothelial cell infection are not features of the disease caused by isolates of moderate virulence.

The virus causes hemorrhages through its effect on hemostatic mechanisms by affecting vascular endothelium. After about 4 to 5 days the vascular damage extends to the basement membranes, and death ensues, usually because of the serious edema and hemorrhage. The mechanisms related to hemorrhage consist of the following:

1. Activation and extensive destruction of monocytes and macrophages—serum TNF- $\alpha$  and IL-1 $\beta$  increase in the serum. The lymphocytes also appear to have decreased activity. Apoptosis of thymocytes has been reported.
2. Disseminated intravascular coagulation
3. Infection and necrosis of megakaryocytes—many apoptotic and also pyknotic and karyorrhectic megakaryocytes can be seen, which are induced either by cytokine damage or

peripheral destruction of platelets.

Between 0.2% and 9.5% of cells may be affected. Early in the infection there is prolongation of coagulation times as a result of inhibition of fibrin formation; later, thrombocytopenia develops. The thrombocytopenia and coagulation defects lead to the development of the following:

- Hemorrhage
- Serous exudates
- Infarction
- Local edema
- Engorgement of tissues

All clinical forms of the disease are characterized by extensive hemorrhage at necropsy, and it is this feature that often establishes a presumptive diagnosis in the field. A highly virulent virus produces renal hemorrhage as a result of intense endothelial injury, facilitated by phagocytic activity. With strains of moderate virulence, hemorrhage is a consequence of an increase in vascular permeability with diapedesis of erythrocytes. Activation of platelets by the virus may also contribute to increased permeability. After 4 to 5 days the basement membranes are affected, which leads to pulmonary edema, and this results in death.

The virus mainly infects cells of the mononuclear phagocyte system and also impairs lymphocyte function. Pulmonary intravascular macrophages demonstrate intense TNF- $\alpha$  and IL-1 $\alpha$  activity, which coincides with the pulmonary edema, neutrophil sequestration, and fibrin microthrombi. The lymphopenia that is so characteristic of the disease is attributable to a significant increase in lymphocyte death by apoptosis (programmed cell death). In the experimental disease, there is marked apoptosis of lymph node lymphocytes, and this occurs in both compartments of cortical tissue but is more intense in diffuse lymphoid tissue (T area). The peripheral lymphopenia is associated with T-lymphocyte depletion. There is no evidence of virus replication in lymphocytes in the lymph nodes, but there is a high rate of viral replication in macrophages in diffuse lymphoid tissue compared with the low rate in lymphoid follicles. In summary, there is lymphoid tissue impairment and programmed cell death of a high percentage of lymphoid and monocyte/macrophage cell populations. This accounts for the lymphopenia and the state of immunodeficiency. There are also a variety of proteins encoded by the virus that are apoptosis inhibiting proteins. Experimentally, the virus also causes activation and degranulation of platelets from day 3 after inoculation onward, coinciding with activation of the mononuclear phagocyte system and virus replication in monocyte/macrophages. Virions of the virus also appear in the platelets, which suggests that platelets assist in disseminating the virus within the body, especially in subacute infections. Probably 95% of the infectivity of

blood is in the form of virus adsorbed to the red blood cells.

The virus can cross the placenta, replicate in fetal tissues, and cause abortion. However, the pregnancy failure is probably the result of the effects of the virus infection on the dam more than from direct viral damage to the placenta or fetus.

The reasons for the lack of viremia in wild African pigs is unknown, as is the higher resistance of European wild boar to ASF.

## CLINICAL FINDINGS

The disease occurs in acute to chronic forms. When it occurs as a new infection (epidemic), it is often acute, but it is subacute to chronic when endemic. In the acute form of the disease the animals die in an acute state of shock characterized by a disseminated intravascular coagulation with multiple hemorrhages in all tissues. The incubation period after contact exposure varies from 4 to 19 days depending on virus dose and the route of infection, but only 2 to 5 days in experimental infections.

Most often the morbidity is 40% to 85%, and the mortality may be as high as 90% to 100% when a virulent virus is involved but may be only 20% to 40% in less virulent outbreaks.

A high fever (40.5°C [105°F]) appears abruptly and persists, without other apparent signs, for about 4 days. The fever then subsides, and the pigs show marked cyanotic blotching of the skin, depression, anorexia, huddling together, disinclination to move, weakness, and incoordination. Extreme congestion and discoloration of the hindquarters with difficulty in walking are early and characteristic signs. Coordination remains in the front legs, and affected pigs may walk on them, dragging the hindlegs. Tachycardia and serous to mucopurulent nasal and ocular discharges occur, and dyspnea and cough (sometimes up to 30%) are present in some pigs. Diarrhea, sometimes dysentery, and vomiting occur in some outbreaks, and pregnant sows usually abort. Purple discoloration of the skin may be present on the limbs, snout, abdomen, and ears. Abortion may occur in all stages of gestation about 5 to 8 days after the infection commences or after 1 to 2 days of fever. Death usually occurs within a day or two after the appearance of obvious signs of illness, and death is often preceded by convulsions. Subacute is characterized by thrombocytopenia, leucopenia, and numerous hemorrhagic lesions.

High fever and varying degrees of depression and lethargy are observed during the acute phase, but some pigs continue to eat; the case-fatality rate is usually less than 5%; the fever subsides in 2 to 3 weeks; and the pigs return to full feed and grow at a normal rate. Recovered pigs have no lesions suggestive of the disease but may be viremic for several weeks. These persistently infected

pigs would pass routine antemortem inspection at slaughter and potentially infectious offal and carcass trimming could be fed unknowingly to other pigs. Chronic cases are intermittently febrile, become emaciated, and develop soft edematous swellings over limb joints and under the mandible.

Diagnosis depends on clinical signs (which are not distinguishable in the field from acute PDNS or CSF), postmortem examination (it is said that button ulcers and “turkey egg kidney” are less common rare in ASF, but this cannot and must not be relied upon), and, most important, on diagnostic tests to rule out CSF and confirm ASF. **A definitive diagnosis is only obtainable by exclusion of CSF and confirmation of ASF by laboratory testing.**

## CLINICAL PATHOLOGY

### Hematology

As in hog cholera, there is a fall in the total leukocyte count to about 40% to 50% of normal by the fourth day of fever. In particular, there is the emergence of immature cells and atypical lymphocytes in the host blood following ASF infection, but the mechanisms are as yet unknown.<sup>18</sup> There is a pronounced lymphopenia and an increase in immature neutrophils. In chronic cases there is hypergammaglobulinemia. Clotting times are increased from about 4 days postinfection. Thrombocytopenia is detectable from day 6 to 9. Serum concentrations of C-reactive proteins, serum amyloid A, and haptoglobin have been measured<sup>1,9</sup> and all increased significantly in pigs inoculated with either ASF or CSF. Pig major acute-phase protein and apolipoprotein correlate with the clinical course of experimental ASF infection.<sup>19</sup>

### Diagnosis

The viremia persists, as do the antibodies, for long periods of time; therefore, diagnosis is best achieved by parallel detection of antigen and antibodies.<sup>20</sup> Pen-side tests are just around the corner.

### Detection of the Virus

The safest and most commonly used techniques are PCR, direct immunofluorescence (DIF), and the hemadsorption (HA) technique, which is used in reference laboratories. DIF and HA should be used with other techniques because they both can produce false negatives.<sup>20</sup> The original PCR techniques have also been developed to include novel real-time PCR,<sup>21</sup> universal probes,<sup>22</sup> and loop amplification systems. More recently, a genotyping microarray has also been developed.<sup>26</sup>

Antigen can be detected by the fluorescent antibody technique in tonsil and submandibular lymph node within 24 to 48 hours of infection and elsewhere once generalization has occurred. The indirect fluorescence antibody and direct fluorescence

tests are commonly carried out on pooled visceral fluid samples.

## Serologic Tests

The ELISA is frequently used to screen large numbers of samples because it is easily automated, and many tests have been developed, including a recombinant that works well in poorly preserved sera.<sup>23</sup> Antibody to the virus may be detected within 7 days of infection. The ELISA is highly sensitive and specific and can be automated for screening large numbers of sera. It has been developed for a variety of ASF proteins, such as p73 or p30. More than 90% of infected pigs can be detected by the demonstration of specific antibodies against the virus. An immunoblotting assay is a highly specific and sensitive test that is easy to interpret, provides an alternative to immunofluorescence, and can be carried out in less than 90 minutes under field conditions. Complement testing is also a possibility. The inadequate storage or transport of sera may lead to samples being kept at high temperatures for long periods, and up to 20% of these may be false negatives by ELISA. All blood samples should be held at 4°C before testing and if incorrectly stored or handled should be tested by immunoblotting. A monoclonal antibody immunoperoxidase test is also useful for screening purposes.

To confirm positive or ambiguous ELISA results, immunoblotting, indirect immunofluorescence, and immuno-peroxidase techniques are used. The first two used together will confirm ASF in over 90% of infected animals.<sup>20</sup>

## NECROPSY FINDINGS

Gross changes at necropsy resemble closely those found in hog cholera, except that in the acute ASF, the lesions are more severe. The pathology varies with virulence of the virus but is essentially extensive hemorrhages and lymphoid tissue necrosis in the acute cases. In the subacute and chronic cases, the lesions may be minimal or absent. The lesions are most pronounced in the spleen, heart, lymph nodes, and kidneys. In many organs there is a hyperemia or edema, with fibrinous microthrombi. The most common gross findings are swollen and hemorrhagic gastrohepatic and renal lymph nodes, often so badly affected that they may resemble the spleen; subcapsular petechiation of the kidneys; ecchymoses of the cardiac surfaces and various serosae; and pulmonary edema with hydrothorax. There may be hemopericardium. The renal hemorrhages are considered almost pathognomonic and are a consistent lesion following inoculation of pigs with the virulent or moderately virulent virus. Splenomegaly is usual, but in contrast to hog cholera, splenic infarcts are rarely seen. There may be congestion of the liver and gall bladder and petechiae in the bladder. Hydrothorax is not unknown. There may be

congestion in the meninges, in the choroid plexuses, and on the brain. The gallbladder is edematous and hemorrhagic, but this is not a pathognomonic lesion, as sometimes thought. In chronic cases the lesions are essentially the same but also include pericarditis, interstitial pneumonia, and lymphadenitis. There is severe submucosal congestion in the colon, although button ulcers in the large intestine are less common than in hog cholera.

It is said that button ulcers and “turkey egg kidney” are less common but this must not be relied upon.

Histologically, the lesions are more diagnostic. The virus causes destruction of the mononuclear phagocyte system and then infects megakaryocytes, tonsillar crypt cells, renal cells, hepatocytes, and endothelial cells. Postcapillary venules undergo hyalinization and endothelial swelling. Destruction of monocytes/macrophages is visible in the lymph nodes, the spleen, and the bone marrow. In the liver, there is extensive destruction of hepatocytes. Marked karyorrhexis of lymphocytes is visible in both normal lymphoid tissues and in the infiltrating population of cells within parenchymatous organs. Encephalitis may be present with lymphoid infiltration of the leptomeninges, but is generally less severe than that of hog cholera. In recovered animals the presence of virus and antibody simultaneously (persistent infection) can cause the formation of immune glomerulonephritis.

Diagnosis depends on laboratory diagnosis because it cannot be determined on clinical signs and pathology.

As for hog cholera, the diagnostic testing to confirm ASF tends to be restricted to specialized laboratories.

### Samples for Confirmation of Diagnosis

Samples can be collected on filter papers to detect antigen and antibody,<sup>20</sup> and oral fluids have also been used to detect antibody.<sup>24</sup>

- Histology—formalin-fixed spleen, lung, lymph nodes, kidney, liver, colon, cecum, brain (light microscopy). The virus can be detected by immunohistochemistry, particularly in the tonsil,<sup>25</sup> or ISH.
- Virology—spleen, kidney, submandibular and abdominal lymph nodes, tonsil, and bone marrow should be collected for fluorescence antibody test and PCR. Direct immunofluorescence and hemadsorption are reliable, as are a range of PCR tests, including a TaqMan. A PCR has also been developed that can be used on a blood sample on filter paper and also a plaque assay. The PCR developed using the p72 protein will enable detection of ASF within 5 hours

of clinical sample submission and full characterization of the virus within 48 hours. A new RT-PCR using the universal probe library has been described.<sup>22</sup>

### SEROLOGY

The immunity to ASF is unknown. Surviving animals are persistently infected, and viremia persists in spite of high levels of antibody as a result of high levels of incomplete antibody. Antibodies first appear after 10 days. Most of the virus is bound to erythrocytes. There is an absence of neutralizing antibodies and a huge variation in viruses. Cell-mediated immunity may be important in the immune response to ASF and in the protection against reinfection. The serologic responses have been described.<sup>28</sup>

The presence of anti-ASFV antibodies is indicative of infection because a vaccine is not available. ELISA is the most useful method for large-scale investigation of outbreaks, and the new methods are not affected by the quality of the samples.<sup>23,29</sup>

### DIFFERENTIAL DIAGNOSIS

The disease is easily confused with hog cholera, and very careful examination is required to differentiate the two. Clinically, the illness is much shorter (2 days versus 7 days) than in hog cholera. Gross necropsy changes are similar to but more severe than those of hog cholera. The marked karyorrhexis of lymphocytes characteristic of African swine fever (ASF) is not observed in hog cholera. Differential diagnosis must rely on laboratory testing. In the past, differentiation has been achieved by the challenge of hog cholera-susceptible and immune pigs with suspect material. More recently, reliance has been placed on the demonstration of hemadsorbing activity with virus from suspected outbreaks grown on pig leukocyte tissue cultures. But hemadsorbing activity may be weak, delayed, or even absent, and there is sometimes difficulty in isolating virus from subacute or chronic cases in enzootic areas. Demonstration of antigen by fluorescent antibody staining will allow diagnosis of acute cases. For chronic cases, serologic testing has been recommended, and with the use of more than one test a high degree of accuracy can be achieved. Several sensitive laboratory tests for detection of the virus in tissues and serum antibody are now available. Enzyme-linked immunoabsorbent assay (ELISA) tests are highly sensitive. Radioimmunoassay tests are also sensitive, and isolates of the virus may be titrated in swine monocyte cultures using a microtechnique. In the lymphocyte response test to virus infection, there is a cytolytic effect on the lymphocytes; the effect is greater on the B-lymphocytes than on the T-lymphocytes. Pigs with demonstrable antibody should be considered as chronic carriers of the virus because it is doubtful that true recovery ever occurs.

### TREATMENT

There is no treatment for ASF.

### CONTROL

Immediately restrict pig movements. There is no vaccine for ASF as yet, but ASF has been eradicated before from countries without the use of a vaccine.

Slaughter affected pigs and their ticks as quickly as possible.

The control and eradication of ASF is difficult because of the following factors:

- Lack of an effective vaccine
- Transmission of the virus in fresh meat and cured pork products
- Recognition of persistent infection in some pigs, particularly wild feral pigs, and possibly warthogs and bush pigs
- Clinical similarity of hog cholera and African swine fever
- Recognition that in some parts of the world soft ticks of the genus *Ornithodoros* (*erraticus*, *moubata*, *porcinus* *porcinus*) are involved in the biological transmission of the disease and can remain carriers for long periods (possibly 5 years)

Prevention of introduction of the disease to free countries is based on the prohibition of importation of live pigs or pig products from countries where African swine fever occurs. Strict application of the prohibition has prevented the spread of the disease from enzootic areas within South Africa. If a breakdown does occur, control must consist of prevention of spread by quarantine, slaughter of infected and in-contact animals, and suitable hygienic precautions. The need for close contact between pigs for the disease to spread and the ease with which this can be prevented by the erection of pig-proof fences facilitate control. Conversely, the disease is virtually uncontrollable when pigs from a number of farms have access to communal grazing. The virus is highly resistant to external influences, including chemical agents, and the most practical disinfectant to use against the virus is a strong solution of caustic soda. Contaminated sites can remain infective for periods exceeding 3 months. These factors and the persistence of the virus in recovered pigs probably contributed to the difficulties encountered in the eradication program in Portugal, where the disease was stamped out but reappeared in 1960. However, the most important factor appears to have been the indiscriminate use of attenuated vaccines, which fostered the development of carrier pigs. In this outbreak, very little was seen in the form of clinical signs.

In Spain in 1985, a comprehensive nationally coordinated program for the eradication of the disease was begun, and substantial progress had been made. Before 1985, the only method of control of the disease in Spain was depopulation of herds with clinical disease. The current eradication program consists of the following:

- Depopulation of herds with clinical disease
- Serologic surveillance of all sows and boars in every herd
- Improvement of sanitary conditions of housing
- Improved hygiene (safe disposal of manure, vehicle disinfection, insect and rodent extermination)
- Veterinary control of all swine livestock transfers (with individual identification of every animal moved for finishing or breeding purposes)
- Health certification of every animal used for herd replacement
- Destruction of every seropositive animal
- Formation of mobile veterinary field teams exclusively dedicated to support the program

Following introduction of this program, it has been possible to divide Spain into a disease-free region (the criteria is a minimum of 2 years without the disease) and an infected region. Eradication of the disease in Spain occurred by 2001. In 1991 the Spanish government claimed that 96% of the Spanish territory was free of ASF. The calculated benefit–cost ratio is estimated to vary from 1.23 to 1.47, depending on the intensity of the program. A reduction in the funding for control would result in a benefit–cost ratio of 0.97, making the program unprofitable.

It has been shown that the use of chemical disinfectants containing at least 2% citric acid for porous surfaces is effective in removing ASF<sup>30</sup> and foot and mouth disease (FMD), whereas 2000 ppm of sodium hypochlorite will disinfect ASF but not FMD.

In a study of the risk factors for ASF in major pig-producing areas in Nigeria 1997 to 2011,<sup>31</sup> it was found that the presence of an infected pig farm in the same area and an abattoir will increase the likelihood of ASF infection of farms. Vermin and birds are also a risk. Strict food and water control, immediate separation (isolation) of sick pigs from healthy pigs, and the washing and/or disinfection of farm equipment will assist in reducing the chance of infection. Region-based control and farm-based biosecurity will help control ASF in Nigeria. Biosecurity is the likely key to successful control in Africa.<sup>2</sup>

### Vaccines

The prospects for the development of vaccines have been discussed,<sup>32</sup> and the key factor is that knowledge of the antigens that encode the dominant protective epitopes recognized by CD8+ T cells is lacking at present.

It is difficult to make a vaccine because of the large size of the virus and the many proteins in the genome. Many of these alter the immune response.<sup>20</sup> It is also variable. The host response to the virus is very complex, with only partial protection produced by neutralizing antibodies.<sup>33</sup> Several different

vaccines have been used, including an ineffective inactivated-virus vaccine and modified live-virus vaccines.<sup>34</sup> The modified live-virus vaccines provide some protection, but the results following their use have been neither satisfactory nor safe, and they have the two disadvantages of confounding laboratory tests and producing “carrier” pigs. The cell-mediated immunity component is very important.<sup>27</sup> The administration of individual recombinants proteins and/or DNA only gives partial protection.<sup>32</sup>

## PORCINE CIRCOVIRUS-ASSOCIATED DISEASE

Originally, the condition associated with porcine circovirus type 2 (PCV2) was called *postweaning multisystemic wasting syndrome* (PMWS), but we now know that PCV2 is associated with a wider spectrum of conditions now referred to as porcine circovirus associated disease (PCVAD). PCV1 was known for some time beforehand in tissue culture but has always been considered nonpathogenic. Infection with PCV2 is necessary for PMWS to develop, but one or more cofactors are necessary to facilitate this.<sup>1</sup>

The other diseases in PCVAD include porcine dermatitis and nephropathy syndrome (PDNS), reproductive disorders, enteritis, proliferative and necrotizing pneumonia, and the porcine respiratory disease complex (PRDC). Only once has congenital tremor been linked to PCV2, so it is no longer regarded as a PCVAD.<sup>2</sup>

Two initial features of the disease are the effects on the lymph nodes of the pig and the lack of response of the condition to antibiotic therapy.<sup>3</sup>

Very simply, the disease occurs where there is a high serum viral load (compared with nonaffected pigs) and where there is a lack of neutralizing antibody. In other words, if there is a successful immune response, it limits PCV2 replication and avoids clinical disease.

PCV2 is one of the three viral diseases that destabilize the enzootic bacterial diseases in a herd.<sup>1</sup> It is a cause of considerable economic loss.

### ETIOLOGY

Circoviruses are relatively new, probably having existing for only around 500 years.<sup>4</sup> PCV has the highest mutation rate reported for any DNA virus and approaches the higher rate of genetic change seen usually in RNA viruses.<sup>5</sup> PCV2 belongs to the genus *Circovirus* of the *Circoviridae* family (includes PCV1) and is described as the prime causative agent of PMWS.<sup>6</sup>

Porcine circoviruses are small but powerful,<sup>7</sup> and PCV1 and PCV2 have similar genomic organization, with two ambisense open reading frames (ORFs) flanking the origin of replication.<sup>7</sup>

PCV2 has been retrospectively identified by serology in swine populations as an asymptomatic infection at least 25 years before the first case of PMWS, and a recent study of the genome showed that the archival PCV2 was avirulent, as is the new PCV2, as a result of mutational events within a

sequence of nine base nucleotides in the nucleocapsid gene of PCV2.<sup>8</sup>

The experimental reproduction of the disease and its occurrence under field conditions are usually associated with a number of risk or triggering factors.<sup>9</sup> It has been suggested that PCV2 is a necessary but not sufficient cause of the condition of PMWS.<sup>1</sup>

A novel porcine circovirus-like agent P1, also associated with wasting disease, has been isolated with 896 nucleotides.<sup>10,11</sup> No single viral cofactor has yet been identified.<sup>12</sup> Different isolates may vary in virulence,<sup>13</sup> but PMWS has been produced in gnotobiotic pigs following exposure to various amounts of PCV2a and PCV2b<sup>14</sup> without the presence of any detectable infectious cofactors.

There are two subtypes, 2a and 2b, with sequence differences mostly found in the capsid region,<sup>15,16</sup> and the antigenic profiles are not identical.<sup>15-19</sup>

The current classification scheme for grouping viruses is complicated by genetic recombination.<sup>20-23</sup>

## GENOME STUDIES

The viruses are the smallest known mammalian viruses. The details of the genome and the virus proteins produced have been described.<sup>7</sup> The PCV2 genome is a circular, single-stranded DNA with a size of 1766 to 1768 nucleotides that contains three major ORFs.<sup>19</sup>

ORF1 encodes the replicase proteins *rep* and *rep'* involved in virus replication. They bind to specific sequences within the origin of replication located in the 5' intergenic region, and both are essential for viral replication.<sup>24-26</sup>

ORF2 encodes the viral capsid (*cap*) protein, which has the ability to bind to the host cell receptor.<sup>19,27,28</sup>

ORF3 encodes a protein that is involved in PCV2 apoptosis,<sup>29,30</sup> and in vitro ORF3 is found within ORF1. The ORF3 proteins of both PCV1 and PCV2 induce apoptotic cell death<sup>31</sup> and code for a 105 amino acid protein that causes apoptosis of PCV2 infected cells<sup>32</sup> but is dispensable for virus infection.<sup>33</sup>

An ORF4 has also been detected in PCV2 productive infection.<sup>34</sup> It is not essential for PCV2 replication but plays a role in the suppression of caspase activity and regulating CD4+ and CD8+ T-lymphocytes during PCV2 replication.

The signature motif<sup>25</sup> discriminating between 2a and 2b lies within the virus capsid protein, which often contains virus pathogenicity characteristics. There are several genotyping studies.<sup>16,29,35-37</sup>

Genetic variation and newly emerging genotypes in China have been described,<sup>38</sup> and 19 isolates were identified in three genotypes, 2a, 2b, and 2d. PCV2d was a new genotype for China, and PCV2b had become the predominant genotype. The subtypes described in Asia (2d and 2e)<sup>39,40</sup> may belong to the previously described groups (a, b, or c), depending on classification interpretation.<sup>41</sup>

In a recent study, the complete genome sequence of a novel PCV2b variant was described in cases of vaccine failure in animals with PMWS,<sup>42</sup> and this was similar to the reported Chinese PCV2d strain.

A new natural PCV2 virus with a very low incidence was identified in Quebec in September 2008, in which it was found that the virus contained the ORF1 of PCV1 and ORF2 of PCV2a; using the nomenclature of Segales et al.,<sup>65</sup> it was decided to call this virus PCV1/2a.<sup>43</sup>

It is to be noted that very small differences in the amino acid sequence may result in major changes in the pathogenicity of the virus.<sup>13</sup>

## TRANSCRIPTION

Little is known about the cellular events triggered by infection with PCV2 in PMWS. Several porcine genes were found to be up-regulated in lymph nodes and also in PK-15 cells. At least five have been identified.<sup>7</sup> It has recently been shown that PCV2 induces the activation of NF- $\kappa$ B by phosphorylation and degradation and subsequent translocation of NF- $\kappa$ B p65 from the cytoplasm to the nucleus. Many of the events point to intracellular signaling and endocytic pathways.<sup>7</sup>

## EMBRYO INFECTIVITY

Embryonic cells are susceptible to infection but not while in the zona pellucida. Extensive replication in embryos leads to death and resorption in utero.<sup>44</sup> In fetuses of 40 to 70 days of gestation the virus replicates mainly in the heart, followed by the liver, lymphoid tissue, and lungs;<sup>45</sup> with increasing age of the fetus, the replication decreases. After birth, replication is mainly in the lymphoblasts and the monocytes.<sup>46</sup>

## VIRUS IMPORT

Internalization is slow and inefficient via endocytosis. Clathrin-mediated endocytosis also plays a part. No substantial replication was found in lymphoid cells but rather in endothelial cells particularly aortic endothelial cells, gut epithelial cells, and fibrocytes<sup>47</sup> by an increase in *Cap* and *Rep* proteins. The glycosaminoglycans heparin, heparin sulfate, chondroitin sulfate A, and keratin sulfate serve as attachment receptors.<sup>28</sup> After internalization, PCV2 is localized in endosomes.<sup>48</sup> A dynamin- and cholesterol-independent, but actin- and small GTPase-dependent pathway allows PCV2 internalization in epithelial cells that leads to infection, and clathrin-mediated PCV2 internalization in epithelial cells is not followed by a full replication.<sup>49</sup> Disassembly involves serine proteases.<sup>48</sup>

## REPLICATION

Upon infection, in step 1 the viral ssDNA genome is converted by host cell factors into a dsDNA replicate form that serves

as a template. Further complex processes occur,<sup>26,50,51</sup> and only *Rep* and *Rep'* are essential for viral replication in mammalian cells.<sup>24</sup> PCV2 replication is impaired by inhibition of the extracellular signal-regulated kinase (ERK) signaling pathway,<sup>52</sup> which indicates that it is involved in PCV2 infection and beneficial to PCV2 replication in cultured cells.

Six cellular proteins were found to react with *cap* and three with *rep* in a study of the interactions of the replication proteins and the capsid protein of PCV1 and PCV2 with host proteins.<sup>53</sup> It appears that only the *rep*, *rep'*, and *cap* genes are responsible for replication. It has been proposed that PCV replicates by means of a rolling-circle melting-pot mechanism.<sup>24</sup> The *rep* and *cap* genes are oriented in the opposite direction, resulting in an ambisense genome organization. An intergenic region between the 5' ends of the *rep* and *cap* genes forms a stem-loop structure containing the origin of virus replication and the replication factors between PCV1 and PCV2. Replacement of the replication factors of PCV2 with those of PCV1 greatly enhances the viral replication in vitro.<sup>54</sup> Reactive oxygen species regulate the replication of PCV2 via a NF- $\kappa$ B pathway.<sup>55</sup>

Viral replication is enhanced by stimulation by mitogens (Con A or pokeweed mitogen) but does not depend strictly on whether a cell is in mitosis.<sup>56</sup> Monocyte-derived dendritic cells enhance cell proliferation and PCV2 replication in concanavalin A-stimulated swine peripheral blood lymphocytes in vitro.<sup>57</sup>

A recent study has shown that ORF1-dependent but not ORF2-dependent differences are important for in vitro replication of PCV2 in porcine alveolar macrophages singularly or coinfecting with PRRSV.<sup>58</sup> The PCV2 ISRE sequence not only plays a role in the whole viral genome in vivo and in vitro but also works in the *Rep* promoter. It plays a significant role in the viral replication efficiency and regulation of IFN- $\alpha$ -mediated PCV2 replication in PK-15 cells.<sup>59</sup> PCV2 could trigger autophagosome formation and enhance autophagic flux in PK-15 cells and thereby increase replication.<sup>60,61</sup> PCV2 replicates in lymphoblastoid cells, and viral infection could result in the lysis of infected cells.<sup>62</sup>

## GENOTYPES

Early studies focused on differences in genotype,<sup>16,29,63,64</sup> and further studies have led to the naming of the two major genotypes, PCV2a and PCV2b.<sup>65</sup> Since then, a new genotype has been added, and the three PCV2 genotypes have been designated PCV2a, PCV2b, and PCV2c.<sup>41,65</sup> In this system, the ORF2 sequences are assigned to different genotypes when the genetic difference between them is at least 0.035.<sup>65</sup>

PCV2a is divided into five clusters (2A to 2E), whereas PCV2b is divided into three

clusters (1A to 1C).<sup>16</sup> PCV2c was identified in pigs from Denmark.<sup>66</sup>

Some countries have detected a shift from PCV2a to PCV2b on sequencing studies.<sup>66-68</sup>

An association between the genotype shift from PCV2a to PCV2b and the sudden increase of PMWS has been suggested. The genotype shift was reported from Switzerland and Denmark in 2003,<sup>66,68</sup> in Canada in 2005,<sup>69</sup> and in the United States in 2005.<sup>15</sup> In Spain, it was reported in 2011 in cases from 1985 to 2008.<sup>70</sup> In Korea, the shift occurred in 2002 or even earlier.<sup>71,72</sup> In England, there appeared to be a shift from PCV2a to PCV2b at the time as an outbreak of PMWS on a farm.<sup>73</sup> PCV2a may have been associated with non-PMWS-affected farms, and it is the switch to 2b that has been associated with the upsurge in PMWS. This may also mean that 2a is less virulent than 2b. In Australia, where PMWS has not been seen, only 2a has been reported.<sup>66</sup>

PCV2b is currently the most prevalent form of the virus in naturally occurring infections.<sup>29,66,74-77</sup>

Recombination between lineages in natural populations of PCV2 in Hong Kong and China has been shown.<sup>78</sup>

Evidence for recombination between PCV2a and PCV2b has been found.<sup>79-81</sup>

In the study from the United States, PCV2a and PCV2b were found in the tissues of the same infected pig.<sup>79</sup>

Forty strains from China were sequenced from 2004 to 2008,<sup>82</sup> and they could be grouped into four genotypes based on their genetic distances and phylogenetic trees. PCV2a, PCV2b, PCV2d, and PCV2e were found, but the Danish type PCV2c was not found. The study also showed that PCV2b had become the most common type in China. Since this study,<sup>82</sup> the existence of 2d and 2e has been discounted on the basis of classification studies.<sup>41</sup>

An emerging recombinant cluster from 2b (recombination between the 2a and 2b strains within the ORF2 gene) has been shown to be circulating in China and other Asian countries.<sup>83</sup>

Multiple strains of PCV2 have been found in the same pig in China,<sup>84</sup> and this coexistence may contribute to the development of more severe clinical signs in coinfecting pigs.

There is a high degree of heterogeneity of PCV2 within a geographic region in both domesticated and wild boar populations.<sup>85,86</sup>

During 2012, a new variant PCV2 strain designated mPCV2 was identified in the United States,<sup>42</sup> and it was found to be more virulent than the traditional 2a and 2b strains.<sup>87</sup> This mPCV2b strain appears to be present in Europe and based on limited data appears to be replacing other PCV2b strains in Southeast Asia and North America.<sup>88</sup> It also has significance in that this variant has also been found in possible vaccine failure cases.<sup>89</sup>

Dual heterologous PCV2a/2b infection induces severe disease in germ-free pigs when given 7 days apart. PCV2a or PCV2b when administered singly or in combination with keyhole limpet hemocyanin appeared to be of equal virulence.<sup>90</sup> Gross lesions were more severe in heterologously infected pigs than in 2b/2b infected pigs, and these were more severe than in 2a/2a infected pigs.

## EPIDEMIOLOGY

Other than the mouse,<sup>91</sup> nonporcine species are not susceptible.

PCV2 can be considered to be enzootic throughout the world and becomes epizootic when there is a significant increase in mortality.<sup>92</sup> Initially, the viruses isolated (1997–2006) were PCV2a, but there was a shift on a global scale to PCV2b, except in Korea, Japan, and Australia.<sup>66</sup> PCV2b was isolated in Korea from 2005 to 2007,<sup>93</sup> and in Japan (isolates from 2006–2007), the change from PCV2a to 2b occurred very quickly.<sup>76</sup>

In a study of 148 PCV2 isolates, 63.5% were PCV2b.<sup>16</sup> In Ireland, 5/6 isolates were PCV2a, but the other one, associated with increased mortality, was a PCV2b.<sup>74</sup> The most recent discovery of a PCV2 was probably in Australia<sup>94</sup> and was a PCV2a, but the criteria for the Australian definition of PMWS were not met,<sup>95</sup> possibly because a PCV2b has not yet been found.

Many epidemiologic studies have suggested that the shift from PCV2a to PCV2b has been associated with an increase in PMWS infections.<sup>64,66,67,69</sup>

A new emerging genotype subgroup within the PCV2b dominates the PMWS epidemiology in Switzerland.<sup>68</sup>

In North America, the shift occurred later and may have been initially in South and Latin America, and then followed importation of infected animals into North America.<sup>75,96</sup>

In a study in Canada, most of the strains were PCV2a, but PCV2b was also found, and in a few cases both types;<sup>64,97</sup> for example, one pig had both 2a and 2b in the liver.<sup>98</sup>

In a study of the prevalence of 2a and 2b in pigs with and without PMWS in Korea, it was found that there was a significant increase over time in animals with PCV2b that had and did not have PMWS.<sup>71</sup>

In the United States, the emergence of novel mutant PCV2b associated with PCVAD (PCV2b was first seen in 2005 to 2006) was described<sup>67</sup> and was found to be 99.9% identical to a mutant virus found in China.<sup>89</sup>

A similar progression from PCV2a to PCV2b has been seen in Asia, in both China<sup>39,99</sup> and in Korea.<sup>100</sup> The genetic diversity of PCV2 from pigs in Korea has been described,<sup>100</sup> and there are two main groups and four subgroups (1A, 1C, 2D, and 2E). Most cases from PMWS-affected herds were in group 1, whereas cases with no clinical signs of PCV2 infection were within group 2.

It is not just the variations in the genotype of the virus that may be related to the pathogenicity of the virus;<sup>101</sup> the dynamics of PCV2 infection in a herd are strongly influenced by management and husbandry,<sup>102</sup> with everything that favors early infection being particularly important, such as the size of the pens and cross-fostering.

## Wild Boar

It has been found in Transylvanian wild boar (in a Hungarian study), where 13.5% proved to be positive for PCV2 by RT-PCR.<sup>107</sup> It was found in wild boar in Poland<sup>108</sup> in over 70% of animals and was found to be of either 2a or 2b genotype.

PMWS has been described in wild boar in several countries, including the United States, Brazil,<sup>111</sup> Germany, Croatia,<sup>112</sup> Greece,<sup>113</sup> and Italy.<sup>114</sup>

## Prevalence

The prevalence varies considerable from country to country and survey to survey, often with results between 40% and 80%, but it may be as low as 23% in Japan<sup>103</sup> on PCV2 antigen detection or viral DNA, even though 50.45% of the farms were positive (65/129 farms). One of the other conclusions was that it may exist in several forms, including an epidemic form or a subtle endemic or sporadic form. The prevalence was 50% in Taiwan and 8% in Korea.<sup>104</sup> It has been found in 30% to 40% of archived tissue in the United Kingdom and in 10% in the United States.

In a study in the United States of 185 farms, it was found that 82% of the farms were positive for PCV2, and only 2.45% were positive for PCV1.<sup>105</sup> It was found in Cuba in 2010.<sup>106</sup>

It has also been found in 50% of animals in Spain<sup>109</sup> and in 43% in the Czech Republic.<sup>110</sup> PCV2 infections associated with PMWS are only sporadically present in the Czech Republic,<sup>115</sup> although positive serology for PCV2 was widespread. The spread of PMWS in Sweden has been described,<sup>116</sup> and the change from an exotic to endemic disease was described.

In a study of seven PCVAD-affected farms, the risk of PCVAD was increased by early PCV2 infection but significantly decreased when pigs were born to PCV2-seropositive sows.<sup>117</sup> Nonaffected animals also had higher titers earlier than piglets that developed PCVAD<sup>118</sup> and higher PCV2 viremia.<sup>119</sup>

## Environmental Survival

The virus is extremely difficult to eradicate from the environment because it has an ability to resist the environment and therefore increase its survival time.

It is resistant to pH 3.0, chloroform, and temperatures of 70°C (158°F) for 15 minutes.<sup>120-122</sup> Animals exposed to nondisinfected trailers for 2 hours became viremic

and seroconverted, but no seroconversion or viremia was found after disinfection using one of four protocols.<sup>123</sup>

It has been suggested that because of its survival in the environment, animal-to-animal contact is not necessary for its spread.<sup>124</sup>

### Transmission

Both vertical and horizontal transmission is possible. Multiple routes of transmission to piglets in the presence of maternal immunity have been described.<sup>125</sup> Piglets are regularly infected with PCV2 in utero and are under constant challenge by PCV2 through contact with infected sows and a contaminated farrowing environment. Maternal immunity did not affect PCV2 transmission to piglets or the viral load in sows. This emphasizes the importance of maternal infection in early infection in newborn piglets.

As fetuses near term, the replication of the virus takes place in the cells of the monocyte-macrophage series.

### Horizontal Transmission

It is transmitted principally by the oronasal route. The widespread distribution in the lymphatic system, respiratory system, urogenital system, and gastrointestinal system suggests that it may be present in all secretions and transudates. It is also present in colostrum,<sup>126</sup> milk, and semen.<sup>127</sup> It was found in the macrophages of the mammary ducts within 3 days.<sup>128</sup>

A study showed that the virus was shed in similar amounts by the nasal, oral, and fecal routes,<sup>118</sup> and in sows until at least 27 days,<sup>129</sup> or 209 days postfarrowing.<sup>130</sup> The maximum level of genomic load was detected at 28 days postfarrowing (5 to 7 log<sub>10</sub> genome copies/mL) and steadily decreased until 209 days postfarrowing.

In a study of five experimentally infected gnotobiotic pigs, there were between 6 and 12 log<sub>10</sub> PCV2 genome copies/mL in the serum and liver.<sup>131</sup> In one study, infectious PCV2 was detected in colostrum samples and milk samples. Anti-PCV2 IgA was found in high levels in colostrum and milk. Infectious PCV2 may be present in milk and colostrum of naturally infected sows even in the presence of neutralizing antibody.<sup>132</sup> Shedding of PCV2 in milk has been shown from experimentally infected sows.<sup>129</sup> The animals excreted from day 1 until day 27 of lactation. There is also the possibility of PCV2 replication in the mammary gland.<sup>128</sup> Antibodies in milk protect against clinical disease but not against infection. Shedding of PCV1 and PCV2 was found in whey for the first time.<sup>138</sup>

Vaccination decreases the shedding of virus in colostrum and milk.<sup>132,133</sup>

Pigs shed virus for a prolonged period following viral exposure, and growing pigs were the source of horizontal PCV2

transmission in PCV2-infected herds.<sup>134</sup> There is a high level of PCV2 DNA in colostrum, sow sera, and piglet sera.<sup>135</sup>

The intermingling of affected and healthy pigs<sup>136</sup> showed transmission by direct nose-to-nose contact, and two were infected without being in direct contact with infected animals. On-site control animals in a separate compartment did not develop clinical disease.

When pigs from affected herds were mingled with healthy pigs from unaffected herds,<sup>137</sup> it led to horizontal transmission, as did pigs being in adjacent pens but not directly in contact.

In a study of infectiousness and transmission, it was suggested that the probability of horizontal transmission was negligible after 55 days postinfection, even though there was still significant viremia.<sup>102</sup>

Transmission can occur from diseased pigs to healthy in-contacts after mingling, especially if there is very close contact.<sup>139</sup> It can be transmitted in uncooked tissue from viremic animals.<sup>140</sup> A lower infectious dose in some of these tissues (bone marrow and skeletal muscle compared with lymphoid tissue) may result in a delayed onset of infection.

Experimentally produced spray-dried plasma spiked with PCV2 was transmissible.<sup>141</sup>

Airborne transmission has also been shown in an experimental setup.<sup>142</sup> In a study of Canadian swine confinement buildings, up to 10<sup>7</sup> genomes per cubic meter of air were found. Airborne dust concentrations were correlated with airborne PCV2 and total bacterial counts.<sup>143</sup>

The verification of natural infection of peridomestic rodents by PCV2 on commercial swine farms was confirmed,<sup>144</sup> with PCV2 being found in the spleen, lung, and kidney, although transmission from rodents to pigs has not been confirmed.

PCV2b has been transmitted by house flies.<sup>145</sup> The flies in the nursery and weaner areas were most likely to be positive.

In practice, there is often a pattern of elevated antibody levels in the herd because it is a mixture of passive and active immunity<sup>130</sup> and, as a result, may maintain consistent infection dynamics in the farm.

Under field conditions, PCV2 can be recovered from mice and rats at quite high prevalence levels, and therefore there is the possibility of indirect transmission and persistence on a farm site.<sup>146</sup>

There is also the possibility that vaccines may introduce the virus. In Canada, the appearance of the PCV1/PCV2 chimera may have been associated with the use of inactivated PCV2 vaccines.<sup>147</sup>

Pigs from PMWS-affected herds had at least 10<sup>3</sup> higher mean serum titer of PCV2 compared with pigs from PMWS-free herds. Pigs that were able to control the infection (as measured by PCV2 titer in serum)

recovered clinically (from PMWS-affected herds) or stayed healthy (from unaffected herds). Pigs with titers below 5 × 10<sup>8</sup> copies/mL serum during the study period had a chance of recovery, but those above this generally died.<sup>136</sup>

### Vertical Transmission

Transplacental infection was demonstrated following the intranasal infection of sows 3 weeks before farrowing, and the virus was recovered from both aborted and live-born piglets.<sup>148</sup>

PMWS was reproduced in pigs fed colostrum and milk from PCV2-infected sows and infected postnatally with PPV or immunostimulated.<sup>149</sup> PCV2 was detected in mammary and other tissues in experimentally infected sows.<sup>128</sup>

The virus has also been demonstrated in myocarditis in aborted fetuses and still-born piglets.<sup>150</sup> In earlier experiments, the cardiomyocytes of the fetus were found to be the main target of PCV2.

In a study in Poland, the heart of the fetus contained the highest amounts of virus and the highest number of antigen positive cells. The myocardium was full of hypertrophic cells and showed multiple and irregular pale areas that corresponded to histologic lesions of necrosis.<sup>151</sup>

Boars show excretion of PCV2 virus in semen (with no differences between 2a and 2b) continuously until at least 50 days after inoculation of the boars.<sup>152</sup> The virus has been shown to be excreted in the semen of boars with serum antibodies.<sup>153</sup>

Naïve sows inseminated with PCV2 spiked semen exhibited reproductive failure, and their fetuses were infected.<sup>154</sup> The mummified fetuses died between 42 and 105 days of gestation.

PCV2-seropositive gilts can be infected with PCV2 after intrauterine exposure, and low maternal antibody may increase the probability of a fetal infection.<sup>155</sup>

PCV2 viremic sows had a higher number of exposed fetuses compared with nonviremic sows, which means that PCV2 can cross the placenta and cause fetal damage. Sows with low antibody titers had greater mortality in their piglets than those with higher levels.<sup>119</sup>

In a study of porcine circovirus viremia in newborn piglets in five clinically normal swine breeding units in North America, it was found that all sow colostrum samples (125/125) and 96.8% (121/125) of the sow serum samples were positive for anti-PCV2 antibodies. The overall PCV2 DNA prevalence was 47.2% (59/125) in the sow serum and 40.8% (51/125) for sows' colostrum and 39.9% in presuckle piglet serum. PCV2b was detected more frequently than PCV2a. Concurrent 2a and 2b was detected in 11.9% of the sow sera, 5.9% of the colostrum, and 15.6% of the piglet sera.<sup>135</sup> Natural exposure to PCV2 results in long-term infection, and

PCV2 is shed in similar amounts by nasal, oral, and fecal routes.<sup>130</sup> When the PCV2 viremic pigs were segregated from their dams, PCV2 DNA was detected for extended periods (81-day observation period).

Experimental PCV2 exposure results in long-term infection. PCV2 is shed in similar amounts by nasal, oral, and fecal routes and is infectious to naïve pigs.<sup>156</sup>

PCV2 has also been detected in the semen of naturally and experimentally infected boars, including seropositive animals.<sup>127,153,157</sup> The PCV2 material in semen is infectious.<sup>158</sup> The younger the boar, the more likely it is to be shedding virus in the semen.

Maternal antibodies have an effect on PCV2 shedding in vertically infected pigs.<sup>159</sup>

### Risk Factors

A cross-sectional study of 147 pig farms in the United Kingdom was undertaken from 2008 to 2009 and risk factors identified. Increased PMWS was associated with rearing growers indoors, more veterinary visits, poorly isolated hospital pens, buying replacements, and seropositivity to *M. hyopneumoniae*. Factors associated with a decreased risk were low stocking density for growers, adjusting diets at least three times between weaning and 14 weeks of age, and requiring visitors to be “pig-free” for at least 2 days.<sup>160</sup>

The spatio-temporal patterns and risks of herd breakdowns in pigs with PMWS<sup>161</sup> and closeness to another infected pig farm, large herds, and no prevention of visitors who had not been through a pig-free period were identified as being risks for infection. The affected farms were also more likely to have other infections.

There is a “litter effect,” which is mainly explained through the sow PCV2 status (viremia), in that fewer piglets died when born to nonviremic sows.<sup>119</sup>

In the individual pig, low levels of antibody at 7 weeks of age is considered a risk factor, as is being born to a seronegative sow.

Pigs with PMWS have greater amounts of PCV2 in their serum and shed larger amounts of the virus than do nonaffected pigs.<sup>136</sup>

In many ways, the risk factors are the same as for many other diseases and are listed as follows:

- Infection in the herd or vaccination
- The occurrence of type 2 strains in a country only normally having type 1 (e.g., Denmark, which used the U.S. vaccine based on ATC-2332)
- Other affected herds in the area, especially if they are close
- Purchasing large numbers of replacement gilts (>500 a year)
- A herd size of over 400 sows
- Purchase of replacement gilts
- A high prevalence of PCV2 antibodies
- PPV antibodies in the finishers
- Active PPV infection in the gilts

- On-farm semen collection and artificial insemination (AI)

Other factors include the following:

- The presence of visitors to the farm without a 3-day pig-free period before their visit is regarded as a hazard
- Large pens in the nursery and grower stages
- A high level of cross-fostering
- Early weaning less than 21 days
- Mixed ages and weights in the same airspace
- Lack of proper cleaning, disinfection, drying, and rest periods between batches—continuous flow through the nursery is a source of environmental contamination.
- Vaccination for PRRSV, *E. coli*, and separate use of PPV and *Erysipelas* vaccines may be disadvantageous.

The risk to a herd is reduced when there is a high level of biosecurity, including reducing the numbers of visitors; proper isolation and quarantine for new arrivals; use of semen from an AI station; group housing of sows during pregnancy; protective clothing on entry to the unit and showering in and out; separate sites for removal and arrival of pigs; long empty periods of rest for the buildings before restocking; proper vaccination protocols for other diseases, which also help to control concurrent infections<sup>162</sup>; sorting pigs by sex in the nursery; greater minimum weights at weaning; regular vaccinations for endemic disease and following the recommendations for use; routine anthelmintic treatments and for ectoparasites; and oxytocin during parturition, which may also help reduction of PMWS. The use of spray-dried plasma in initial rations also is helpful, and it was shown<sup>163</sup> that commercial spray-dried porcine plasma does not transmit PCV2 in weaned pigs challenged with PRRSV. On the other hand, it was shown that PCV2b in an experimental spray-dried product was not effectively inactivated by the process used.<sup>141</sup> The efficiency of the process therefore determines the likelihood of PCV2b resisting the spray drying.

Studies have found that the earlier the infection occurs, the higher the risk of PMWS, and also if the offspring are weaned early<sup>117</sup>; however, other studies<sup>118</sup> have stated there is no effect of the timing of infection on subsequent PMWS development. Colostrum-deprived piglets are more sensitive to PMWS development.<sup>164</sup> Healthy pigs had higher titers at an earlier age than piglets that subsequently developed PMWS.<sup>118</sup>

More piglets die of viremic sows and from sows with low antibody levels.<sup>119</sup>

### Occurrence

It has also been found in wild boar.<sup>86</sup> An antigen shift was shown in the wild boar from PCV2a to PCV2b. It was originally described in western Canada and has

subsequently spread to Europe,<sup>165</sup> North and South America, Australia,<sup>95</sup> and Asia, including Japan.<sup>103</sup> It was first described in Slovakia in 2009,<sup>166</sup> and this was similar to the Austrian PCV2 isolate. It was described in Israel in 2008.<sup>167</sup> In Poland, 50% of the farms in a study had PMWS, and PMWS was confirmed in all herds with over 1000 sows in the study, but the small herds with less than 100 breeding sows were free.<sup>168,172</sup>

A Romanian isolate was closely related to viruses from France and Hungary.<sup>169</sup> A Romanian isolate from wild boar was recently shown to be closely related to PCV2a and PCV2b types and to possess a high degree of sequence heterogeneity.<sup>170</sup> In Korean wild boar, the prevalence was 4.98%,<sup>171</sup> and all were type PCV2b.

The epizootic onset in Switzerland was observed in late 2003,<sup>68</sup> and before that infection with PCV2 was mainly subclinical. The epizootic was accompanied by a switch to PCV2b, but this was present in the Swiss population as far back as 1979.

Retrospective studies on the occurrence of PCV2 in Germany showed that it was first detected in a pig in 1962, with a low incidence between 1962 and 1984 and with a subsequent increase between 1985 and 1998. Associated lesions such as PMWS and PDNS were not observed before 1985, and it appears that there were no major changes in the sequence analyses over the period from 1962 to 1998, suggesting that other factors were involved in the altered virulence.<sup>173</sup>

It was found to be ubiquitous (106/108 farms had at least one positive pig) in Mexican backyard pigs.<sup>174</sup>

### Breeding

The clinical expression of PMWS under field conditions is modulated by the pig's genetic background.<sup>175</sup> Certain breeds have been shown to be more susceptible. Landrace were more susceptible than Duroc or Large Whites<sup>176</sup>; in an earlier study, Large White and Duroc were more susceptible than purebred Pietrain pigs. Sometimes, field studies suggest that the boar lines used may have an influence on the occurrence of PMWS, but other studies do not support this.

Two regions of the porcine genome may have genes that are linked to increased susceptibility.<sup>177</sup> In a study of over 16,000 piglets from 2034 sows inseminated by 13 Hungarian Landrace boars, it was found that there was a considerable difference in the proportion of the piglets with signs of PMWS, still-born piglets, and mummified piglets sired by the different boars. Rates varied from 3.06% to 15.6% for PMWS, 1.76% to 8.52% for still-borns, and 0% to 3.22% for mummies.<sup>178</sup>

### Concurrent Infections

As yet, no novel agents have been found to be associated with the triggering of PCVAD.<sup>12</sup>

Pigs infected with PCV2 and immunized with a modified live-virus CSFV vaccine

developed mild to moderate PMWS, whereas none of the pigs infected with PCV2 alone or immunized with modified live-virus CSF alone developed PMWS.<sup>179</sup>

Concurrent viral or bacterial infections often enhance the effects of PCV2 infection in terms of occurrence, severity, and duration. The effect of PCV2 on the immune system also predisposes to viral, bacterial, fungal, and metazoal infections in turn.

One of the first agents to be associated with PCV2 was PPV. It is not normally the cause of disease in piglets, but in early Canadian studies coinfection was found frequently, and the association of both had been confirmed in studies of microscopic lesions.<sup>148</sup> In cell culture, concurrent PCV2/PPV infection has been shown to decrease the ability of pulmonary macrophages to phagocytose.<sup>180</sup> Another contributor may be TNF- $\alpha$ ,<sup>181</sup> which may be produced by PPV and could promote the high levels of PCV2 typically seen in conjunction with PPV. High levels of TNF- $\alpha$  are induced by this coinfection, and the high level of proinflammatory cytokines may lead to PMWS.<sup>181</sup>

Random amplification methodologies have been used to discover new viruses, and in one study using random multiple displacement amplification (MDA) and large-scale sequencing, a unique novel porcine boca-like virus was isolated from two Swedish pigs with systemic PCVAD<sup>182</sup> (the genus *Bocavirus* of the subfamily Parvovirinae). The occurrence of this virus was confirmed in a further study,<sup>183</sup> and a PPV4 virus was also found.<sup>184</sup>

PRRSV has long been associated with PCV2 in Spain<sup>119,185,186</sup> and in Japan,<sup>103,187</sup> the United States,<sup>188</sup> the Netherlands and Canada,<sup>64</sup> and Italy.<sup>189</sup> The immunosuppression and immune-response modifications have been shown to play a part in respiratory infections, with a possible increased apoptosis.<sup>190</sup>

Swine alveolar macrophages infected with PCV2 first and then with PRRSV later or simultaneously displayed marked reductions in PRRSV antigen-containing rate, cytopathic effect, and TNF- $\alpha$  expression level. In this study,<sup>191</sup> PCV2 was easily internalized in the cytoplasm of alveolar macrophages (AMs) but caused no noticeable cell death, and PRRSV displayed a low infection rate but severe cytopathic effect and strong TNF- $\alpha$  induction in AMs. PCV2-induced IFN- $\alpha$  likely caused a reduction in the PRRSV infection rate and PRRSV-related AMs dysfunction when AMs were coinoculated with PCV2 and PRRSV simultaneously. Similar PCV2-induced IFN- $\alpha$  effects were seen in the PCV2/PRRSV group but not in the PRRSV/PCV2 group where there was also a significant induction of IFN- $\alpha$ . If pre-existing damage has been caused by PRRSV infection, it is unlikely that IFN- $\alpha$  production induced by the PCV2 will be able to stop the adverse effects of the PRRSV.

PRRSV can cause enhanced PCV2 replication, as evidenced by higher serum and tissue PCV2 loads, increased severity of the pathologic changes and clinical manifestations, and higher incidence of PCVAD.

PCV2 that was inoculated first or simultaneously with PRRSV not only hinders PRRSV replication but also reduces the PRRSV-induced adverse effects on the phagocytosis of AMs. The impaired microbicidal capability in PCV2- and/or PRRSV-inoculated groups may be attributable to the reduction in reactive oxygen groups produced. PCV2a and PCV2b would also appear to have the same effects on the reduction of killing capability of AMs.<sup>191</sup> Fas (CD95) and FasL play a major role in the induction of apoptosis. In this same study, it was shown that PCV2 could induce swine AMs to produce FasL but PRRSV could not, except when they were both present, when there was an additive effect. The increased expression of IFN- $\alpha$ , TNF- $\alpha$ , IL-8, and FasL mRNA in AMs from pigs with various infections with PCV2 and PRRSV observed<sup>191</sup> in this study may contribute to some extent to the pneumonia and bronchiolar epithelial cell damage in the lungs of PCV2- and/or PRRSV-infected pigs.

The risk of PRRSV and PCV2 coinfection was 1.85 times greater in piglets from a sow with low titers of PCV2 antibodies than in piglets from sows with medium to high titers. It was also greater in piglets from primiparous sows, PCV2-infected sows, and farms in an area of high pig density than in piglets from sows of higher parity, noninfected sows, and farms in a low-pig-density area.<sup>192</sup>

Compared with infections with PRRSV alone, combined infections with PCV2 resulted in significantly more severe macroscopic and microscopic lung lesions and a stronger anti-PRRS IgG response.<sup>193</sup> In the origin of the replication of the genome of PCV2, an interferon-stimulated response element (ISRE) was identified. During the early stages of infection, at 14 days postinoculation (PI), the mutant reduced viral replication and elicited low antibody responses. However, at 28 days PI, viremia in the infected pigs showed an upward trend, and lesion scores were more severe than with the wild-type virus. With the mutant and PRRSV the lesions were more severe than with wild-type PCV2 and PRRSV. These results suggest that the ISRE element may play a part in viral pathogenesis.<sup>194</sup>

The severity of microscopic lesions and the PCV2 antigen load associated with these lesions were higher in the PRRSV-vaccinated piglets compared with those detected in the PCV2-only infected animals.<sup>195</sup>

Torque teno sus virus (TTSuV) has two main species: TTSuV1 and TTSuV2.<sup>196</sup> It is not known whether they cause disease or not,<sup>197</sup> and they were found in a higher prevalence in PCVAD-affected animals than in controls.<sup>198</sup>

A Spanish study found that TTSuV2 viral loads were related to PCVAD but not TTSuV1,<sup>198,199</sup> and a similar finding was found in Japan.<sup>200</sup> It may not exacerbate PCVAD in all instances,<sup>182,201</sup> and this was also noted in Canada<sup>64</sup> and in the United States.<sup>202</sup>

PCV2 also has a complex relationship with hepatitis E virus<sup>203,204</sup> and was found more commonly where there were lesions of hepatitis. In an experiment with gnotobiotic pigs, it was found that TTSuV1 had to be given 7 days before PCV2 challenge to produce any effects.<sup>205</sup> Tissues from systemically infected PCV2 showed widespread loads, but the higher TTSuV2 loads were in the affected animals' tissues compared with the healthy group.<sup>206</sup> A similar trio of agents has been associated with PMWS in the United Kingdom.<sup>207</sup>

There was no evidence of a relationship between hepatitis E (HEV) and PCV2 in a study in Italy from necropsied pigs.<sup>208</sup> There was an association demonstrated in Spain in sick pigs,<sup>209</sup> especially in pigs evidencing hepatitis lesions. The detection of PCV2 and HEV in the liver of aborted fetuses and from sera and feces of the dams suggests the possibility of transplacental infection and associated reproductive disorders in cases of coinfection.<sup>210</sup>

PCV2, a porcine boca-like virus, and a torque teno virus were isolated from PMWS cases. In 71% of the PMWS cases, the three viruses were found, but in 33% of the pigs, PMWS was not found.<sup>183</sup> It is possible that TTV may contribute to the development of PMWS.<sup>211</sup>

There is probably an influence of transplacental PCV2 infection on neonatal diarrhea associated with an epidemic diarrhea virus.<sup>212,213</sup> In a study of transplacental PCV2 infection on porcine epidemic diarrhea virus-induced enteritis in preweaning piglets,<sup>213</sup> it was found that the mean villous height and crypt depth ratio in PEDV-infected piglets from PCV2-infected sows were significantly different from those of PEDV-infected piglets from PCV2-negative sows. It is concluded that the clinical course of PEDV disease was markedly affected by transplacental infection with PCV2.

It has also been associated with Aujeszky's virus (before 2006), but a study recently showed that subclinical PCV2 does not modulate the immune response to an Aujeszky's disease virus vaccine<sup>214</sup> or porcine Teschovirus in Japan.<sup>200</sup>

Swine influenza can frequently be identified with PCV2 in the field,<sup>188</sup> but experimentally, SIV did not increase the severity of clinical disease or gross or microscopic lesions.<sup>215</sup>

Experimental coinfection with bovine viral diarrhea virus (BVD) type 1 and PCV2 suggested that ruminant pestivirus and/or vaccination with BVD might have a role in the development of PCVAD.<sup>216</sup>

In a study in the United Kingdom, one of the identified factors associated with increased PCVAD was *M. hyopneumoniae* (MH) infection,<sup>160</sup> which also occurs in the United States.<sup>188</sup> The mycoplasma probably potentiates the severity of PCV2-associated lung and lymphoid lesions by increasing the amount and the duration of the PCV2 antigen. Recently, experiments with MH have shown that the MH potentiated PCV2 infection by increasing IFN- $\gamma$  and IL-10 mRNA expression levels,<sup>217-219</sup> which suggests that the severity of the lesions in dual-infected pigs is associated with PCV2 antigen and alterations of cytokine expression. Overall, MH potentiated PCV2 infection by increasing IFN- $\gamma$  and IL-10 mRNA expression levels. *Mycoplasma* infection or vaccination does increase the incidence of PMWS.<sup>220</sup> Simultaneous PCV2 and *M. hyorhinis* coinoculation does not potentiate disease in conventional pigs.<sup>221</sup>

There is often an association between PCV2 and *M. hyorhinis* in healthy pigs and pigs with pneumonia, with *M. hyorhinis* being detected more frequently than MH.<sup>222,223</sup> Pigs with the dual infection naturally show respiratory disease and microscopic lesions and clinical signs suggestive of PCV2 infection,<sup>224</sup> and PCV2 vaccination reduces considerably the number of coinfections with *M. hyorhinis*.<sup>225</sup>

In a study of the presence of endemic pig diseases in England, it was found that there was a significant association of *A. pleuropneumoniae* antibodies with the presence of a positive PCR for PCV2 in weaners.<sup>226</sup>

An association between *M. hyorhinis* and PCV2 was also noticed in Canada<sup>64</sup> and in Japan<sup>103</sup> and between *M. suis* and PCV2 in Argentina.<sup>227</sup>

In a study of PMWS in Korea, it was found that the most common lesions were multifocal, granulomatous inflammation in the lymph nodes, liver, and spleen characterized by infiltration of epithelioid macrophages and multinucleated giant cells. In 85% of pigs there was a dual infection, and a combination with *H. parasuis* was the most common combination.

With *Salmonella* it is likely that prior exposure to PCV2 may increase the clinical effects of salmonellosis in the field.<sup>463</sup> In a study in Japan, it was found that prior PCV2 infection potentiated the severity of clinical signs, lung lesions, and fecal shedding and tissue dissemination of *S. Choleraesuis* in infected pigs. *Salmonella* *Choleraesuis* was implicated in PMWS in Japan.<sup>228</sup>

Bacterial lipopolysaccharide has been shown to induce PCV2 replication in swine alveolar macrophages.<sup>229</sup>

Experimental reproduction of PCV2-associated enteritis in pigs infected with PCV2 alone or concurrently with *Lawsonia intracellularis* (LI) or *Salmonella* Typhimurium<sup>230</sup> showed that PCV2 could

induce enteritis independently from other enteric pathogens. A study of low growth rate in grower-finishing pigs was examined for associations between *Lawsonia* and PCV2. Gross lesions in the small intestine and an LI load were significant risk factors for low growth, but no association with PCV2 was found.<sup>231</sup>

*Aspergillus* and *Cryptosporidium* had been found before 2003. *Pneumocystis carinii* is commonly found with PCV2 in Brazilian pigs<sup>232</sup> and in wild boar.<sup>233,234</sup>

*Candida albicans* in Brazil and *Zygomycetes* spp. were found in Hungary.<sup>235</sup> Toxoplasmosis was diagnosed in a fattening pig with PCV2 infection<sup>236</sup> using immunohistochemistry. Either PCV2 may have triggered systemic toxoplasmosis, or *T. gondii* may have caused extensive replication of PCV2.

Recently, a case of fatal bronchopneumonia was found with *Metastrongylus elongatus* in a PCV2-infected pig,<sup>237</sup> and it is suggested that a concurrent PCVAD condition may trigger metastrongylosis.

A pie chart<sup>92</sup> from earlier data on the existence of coinfections suggested that PCV2 was found in 1% of cases. A joint infection with SIV was found in 4% of cases, bacterial pneumonia in 6%, bacterial septicemia in 10%, PPV in 11%, *M. hyopneumoniae* in 27%, and PRRSV in 41%.

## PATHOGENESIS

Pathogenicity was reported to be a function of the individual properties of an isolate and not related to genotype.<sup>238</sup> In one study, tissues from diseased pigs showed infection with both PCV2a and PCV2b, but those with subclinical infection had either PCV2a or PCV2b.<sup>239</sup>

In all cases of PMWS, the common factor is PCV2, but the discussion on the other factors continues. Although PCV2 alone is not sufficient to produce the full spectrum of disease, none of the other currently recognized "trigger factors" is considered essential on its own.<sup>164</sup> These include changes in husbandry on the farm, immuno-stimulation by vaccination strategies, and the occurrence of other primary and secondary agents or new agents.<sup>6</sup>

The most pivotal step in the pathogenesis of PMWS associated with PCV2 is activation of the immune system. This may lead to increased lymphoid depletion in swine cells in both PCV2- and PRRSV/PCV2-infected swine cells.<sup>190</sup>

In a study of inguinal lymph nodes, PCV2, PRRSV, and PPV had their own contributions to the development of lymphoid lesions in PMWS, with PCV2 as the main causative agent. B-lymphocyte depletion and macrophage proliferation/infiltration are two hallmarks of PCV2-associated lymphoid lesions. Apart from blood recruitment, local T-cell and macrophage proliferation may play a part in the granulomatous inflammation. Apoptosis is an apparent feature in

association with lymphoid depletion. The higher apoptotic rate and the PCV2 load in the germinal center and a higher apoptotic rate but lower PCV2 load in the interfollicular region suggest that there may be a direct cell injury to B cells by PCV2 infection; associated lymphoid lesions may develop through the combination of several different mechanisms with the help of coinfecting viruses.<sup>240</sup> It is possible that lymphoid depletion in PMWS is attributable to a combination of apoptosis, viral induced lysis, destruction of lymphoid architecture, and other unknown mechanisms.

PCV2 is most frequently associated with monocytes, macrophages, and dendritic cells (DCs). These cells may accumulate viral antigen for long periods and therefore may play a role in persistence.<sup>241</sup> It appears not to affect the DCs or interfere with their relationships with lymphocytes and is not transmitted to the lymphocytes, which do carry antigen or viral nucleic acid for a short period.<sup>242</sup> It may be that these cells are not sites of replication but have phagocytosed or endocytosed PCV2 antigen.<sup>47,243</sup> The asymptomatic piglet does produce antibodies and cytotoxic responses, so lymphocyte communication is not affected.<sup>244</sup>

The most characteristic pathologic features of PMWS are lymphocyte depletion and granulomatous infiltration of lymphoid tissues. PCV2 alone induces cell proliferation, cell fusion, and chemokine expression in swine monocytic cells in vitro<sup>245</sup> and therefore may be capable of causing granulomatous inflammation unaided by other pathogens. There is a subcellular immunolocalization of PCV2 in lymph nodes from pigs with PMWS. PCV2 has been detected exclusively in histiocytes. The endoplasmic reticulum was dilated, and the mitochondria were swollen, associated with PCV2-labeled intracytoplasmic inclusions with recognizable virions.<sup>246</sup> There is a close relationship between the PCV2 and the mitochondria, which may suggest that the mitochondria may be involved in replication. It is likely that lymphocyte cell populations support the initial PCV2 replication.<sup>247</sup>

PCV2 induces apoptosis both in vitro and in vivo.<sup>248-251</sup> PCV2-induced apoptosis involves activating both the caspase-8 and caspase-3 pathways and a variety of other pathways and factors.<sup>252-255</sup> The regulatory role of ASK 1 in PCV2-induced apoptosis has been described.<sup>256</sup>

Apoptosis is increased following PCV2 infection under certain stimulation conditions, and the rate of replication increases with the cell stimulation. This same study suggests that there may be a specific stimulation or trigger for increased viral replication that is independent of cell proliferation.<sup>257</sup>

PCV2a and PCV2b coinfection administered 35 days apart is not sufficient to induce clinical disease. Experimental infection of conventional SPF pigs with PCV2 results in

persistent viral infection despite the presence of high levels of PCV2 antibodies without the presence of clinical disease.<sup>258</sup>

PCV2 induces a procoagulant state in naturally infected swine and in cultured epithelial cells.<sup>259</sup>

In some studies, vascular disorders have been highlighted. Animals in Brazil were found to have blood hypercoagulation, petechiae, and vasculitis associated with lymph node atrophy and organ failure. Widespread petechiae have also been reported in kidneys.<sup>249</sup> The presence of PCV2 antigen has been revealed in lymphatics and blood vessels with severe degeneration of the endothelial cells of the blood vessel thrombi and vasculitis associated with organ necrosis and ischemia.<sup>260</sup> In another study, the activation of the hemostatic system was highlighted, with PCV2 being shown to modulate the swine hemostasis.<sup>259</sup> Plasma coagulation times were diminished, which points to the activation of coagulation systems in PCV2-affected animals. Fibrinogen was lower in the PCV2 group, and fibrinogen was found in the brain vasculature.<sup>261</sup> PCV2-affected animals had lower platelet counts. The platelet function was 40% higher in the PCV2-affected animals, and this implies a likely prothrombotic state. Thrombin plasma activity was also increased. The occurrence of PCV2 antigen in the vascular endothelium and the precoagulant state suggests an activation of the endothelium.<sup>262</sup> In one study,<sup>259</sup> PCV2-infected cells had higher viral loads. How PCV2 causes lymphadenopathy has yet to be elucidated.

### Host-Virus Interactions

Because of its very small size, PCV2 relies entirely on the host for completing its life cycle. Several porcine proteins have been identified.<sup>53,261,263</sup>

### Cytokine Studies

Immune gene expression profiles in swine inguinal lymph nodes with different viral loads of PCV2 support a close interaction between immune activation and suppression of PMWS development.<sup>264</sup>

There are many *in vitro* studies on the immunomodulatory effects of PCV2 on lymphoid cells. It can suppress the release of some cytokines and stimulate the release of other proinflammatory cytokines.

The PCV2 genome as a whole was found to induce IFN- $\alpha$  in culture of monocytes and may help in immune-evasion mechanisms.<sup>265</sup>

Proinflammatory cytokines (IL-8, TNF- $\alpha$ , and IL-1 $\beta$ ) and immune (IFN- $\gamma$ , IL-10) cytokines were evaluated in PCV2-vaccinated and unvaccinated pigs exposed to natural PCV2 infection. PMWS-affected animals were not able to mount an efficient innate proinflammatory response to cope with PCV2 infection because there were low levels of IL-8, TNF- $\alpha$ , IL-1 $\beta$ , and IFN- $\gamma$ . Conversely,

there was a high expression of IL-8, TNF- $\alpha$ , and IL-1 $\beta$  in the vaccinated group. A significant increase of IL-10 occurred in the early phase of infection in the PMWS-infected animals, whereas vaccinated pigs had low viremia and absence of PMWS and had a more stable IFN- $\gamma$  response.<sup>266</sup>

Studies *in vitro* have shown that in PBMCs and macrophages from PMWS pigs, there were reduced antiviral activities and an increase in proinflammatory cytokines (IL-1 $\beta$  and IL-8 expressions). Peripheral blood monocytes from PMWS-affected pigs are less able to produce IL2, IL-4, and IFN- $\gamma$  upon challenge and are able to produce IL-10 after stimulation with recall viral antigens. Different components of PCV2 have been shown to play an important role in the modulation of the *in vitro* responses by PBMCs.<sup>267</sup> IFN- $\gamma$  is up-regulated in the tonsils. PCV2-induced IL-10 may participate in down-regulation of specific responses through the inhibition of IFN- $\gamma$ , IFN- $\alpha$ , and IL-12. PCV2 induced production of IL-10 (immunosuppressive), and when this was neutralized, a clear increase in IL-12 was noted.<sup>268</sup> These effects are independent of viral replication. The PCV2 capsid does not influence dendritic or monocytic responses, although the viral DNA does.<sup>268</sup>

These studies suggest that DNA sequences may be found in the genome that modify DC function. The immunosuppressive component is strongest in the whole genome or the circular replicative form. The full-length genome induced a clear suppression of IFN- $\alpha$  in responses in a dose-dependent manner.<sup>269</sup>

In addition, PCV2 is able to inhibit IL-2 through an IL-10-independent mechanism.<sup>268</sup>

Swine alveolar macrophages show reduced microbicidal activity, with a decrease in the production of O<sub>2</sub> free radicals and H<sub>2</sub>O<sub>2</sub> and an increased production of TNF- $\alpha$ , IL-8, and other factors.<sup>270</sup>

*In vitro* data indicate that PMWS-affected animals also show elevated serum IL-10 levels; subclinically, PCV2-infected pigs develop transient IL-10 PCV2-specific responses during the viremic phase of the infection.<sup>271</sup>

In pigs suffering from PMWS, mRNA expression levels of IL-1 $\alpha$  and IL-10 increase, whereas levels of IL-2, IL-8, TNF- $\alpha$ , and IFN- $\gamma$  decrease.

Increased levels of IL-10 in the thymus were associated with the thymic depletion and atrophy that is observed in PMWS pigs. IL-10 was elevated from 10 to 14 days in experimentally infected pigs that subsequently developed PMWS.<sup>272</sup> IL-10, IL-12p40 in the spleen, IL-4 in the tonsils, and IL-10, IL-12p40 and IL-4 in the lymph nodes were detected in PMWS pigs.<sup>271</sup> Increased levels of IL-10 in PCV2-infected pigs are responsible for the depression of the Th1 responses in the peripheral blood monocytes of the infected

pigs. PCV2-induced IL-10 leads to impaired IFN and antigen-recalled responses to pseudorabies immunized animals.

The IL-10 elevated expression is common in PCV2 infections—in the thymus,<sup>273</sup> lymph nodes, spleen, and tonsil<sup>273</sup>—and is mainly located in T-cell areas. IL-10 was increased in PMWS-affected pigs<sup>274</sup> and was mainly associated with CD163+, CD4+, and CD8+ cell populations in the spleen. IL-1 is expressed at higher levels by bystander cells than by PCV2-infected cells, suggesting that IL-10 production is the result of paracrine action.<sup>273,274</sup> In a pig suffering from interstitial pneumonia, elevated IL-10 and IL-8 mRNA would be expected, and this is what was shown in a pig with PCV2-associated respiratory disease.<sup>100</sup>

A variety of substances that are proinflammatory cytokines are also up-regulated, including TNF- $\alpha$ , macrophage inflammatory protein, and C-reactive proteins.<sup>272</sup>

In pigs, the main acute-phase proteins (APPs) are CRP, SAA, Pig-MAP, haptoglobin, and AGP. In PMWS-affected pigs, the concentrations of Pig-MAP, C-reactive protein, and serum amyloid in infected animals were increased at 14 and 21 days postinfection.<sup>275</sup>

In a study of the spleen in PMWS-affected animals it was found the CD163+, CD4+, and CD8+ cell produced IL-10 in the spleen, and IL-10+ cell numbers were higher in PMWS animals compared with their levels in healthy counterparts. IL-10-producing cells were not infected by PCV2 and were mainly localized in the periarterial lymphoid sheaths.<sup>274</sup>

### Interferons

The immune response produced by many PCV2 components varies with the cell type. Infection of natural IFN-producing cells may prevent the maturation of dendritic cells.<sup>276</sup>

An interferon-stimulated response element (ISRE) sequence was found in the PCV2 genome, which influences the interferon-mediated enhancement of PCV2 replication *in vitro* and may play a role in virus pathogenesis in pigs.<sup>194,277</sup>

In a study of cell-mediated immunity to PCV2 in CD/CD piglets, it was shown that viral clearance might be mediated by the development of PCV2 IFN- $\gamma$ -secreting cells in contribution to the PCV2-specific neutralizing antibodies.<sup>278</sup>

### IMMUNITY

In an infected but nonclinically diseased animal, PCV2 may exist with the host by undergoing minimal replication, inducing a limited but balanced Th1/Th2 response, and a trigger then sets disease in operation.

Clinical PMWS was preceded by low levels of serum antibodies and a high load of PCV2 but did not develop in all such animals.<sup>279</sup>

The interaction with the host immune system is the key to PCV2 infections and the development of PMWS. It was originally thought that it required cofactors to produce PMWS, but now it is known that it can produce PMWS on its own.

In affected piglets there is a lymphoid depletion, leucopenia, and destruction of lymphoid follicles. The absolute numbers of total T cells, Th cells, cytotoxic T cells, and  $\gamma/\delta$  T cells—but not memory/activated T cells—decreased after PCV2 infection.<sup>280</sup> There is a reduction of numbers of interfollicular dendritic cells, interdigitating cells, B cells, natural killer (NK) cells,  $\gamma/\delta$  T cells, CD4+, and CD8+ T-lymphocytes and reduced expression of high endothelial venules, together with an increase in monocytes and granulocytes. The amount of PCV2 antigen in tissues is directly related to the amount of depletion.<sup>281</sup> Coinfection with PRRSV increases the immune cell depletion.<sup>282</sup> CD4+ and CD8+ T cells are important in the response to PCV2 infection.<sup>244</sup>

PCV2 can persist in dendritic cells without affecting their performance, but in cells producing interferons, it reduces IFN- $\alpha$  and TNF- $\alpha$  production, thereby interfering with immune priming. In diseased pigs there is a state of activation with higher level and earlier expression of MHC-II on T and B cells and a higher level of CD25, IL2 receptor expression.<sup>281</sup> Both T and B cells are important targets for PCV2.<sup>242,247</sup>

IgM antibodies were first detected at week 8 PI and reached their highest at week 12. IgG antibody appeared at week 10, and levels were at their highest at week 16, with an average titer of 1:3500. Viral load peaked at week 10 ( $7 \times 10^7$  genomes copy/mL of sera) and persisted to adult age ( $10^5$  genomes copy/mL of sera).<sup>283</sup>

PCV2 capsid specific antibodies appear within 10 to 28 days postinfection,<sup>284</sup> and their appearance coincides with a decrease in serum viral load<sup>284</sup>; however, in clinically diseased pigs the level of neutralizing antibody is greatly reduced.<sup>284</sup> It is not clear why some pigs can remove the infection, whereas others succumb to disease. Pigs infected with PCV2 appear to mount strong PCV2-specific antibody responses.

In the field, there is a decrease in maternal antibodies from 3 to 11 weeks, and then there is an active response around 15 weeks that persists for life. Experimental infections produce antibodies within 14 days PI and neutralizing Abs at about 21 days PI.

Antibodies particularly IgM Abs, may be lower in pigs with PMWS. The IgM is not neutralizing but indicates an infection.<sup>284</sup> Increased levels of IL-10 lead to a high ratio of IgG to IgM.<sup>271</sup>

There is a strong correlation between antibody titers and protection.<sup>285,286</sup>

High PCV2 antibody levels in sows at parturition did not prevent early PCV2

infection and viremia in piglets from the first day of life or peripartum maternal viremia and virus shedding into the lacteal secretions. Vertical transmission of PCV2 could generate PCV2 seropositivity in viable piglets even on farms with no signs of reproductive failure.<sup>287</sup>

Lack of antibody protection against PCV2 and PPV in naturally infected dams and their offspring has been shown.<sup>288</sup> After ingesting colostrum, piglets from vaccinated sows had significantly higher numbers of PCV2-specific gamma-interferon-producing cells, an increased PCV2-specific delayed-type hypersensitivity response, and a stronger proliferative response of peripheral blood mononuclear cells compared with piglets from nonvaccinated sows.<sup>289</sup> This is the first report of a transfer of a maternally derived adaptive cellular immune responses from vaccinated dams to their offspring.

The PCV2 Cap and Rep proteins are involved in the development of cell-mediated immunity upon PCV2 infection. In the course of subclinical infection, the development of and the strength of these responses may be related to the level of PCV2 replication.<sup>290</sup>

The T-helper type 2 response primarily stimulates B-cell proliferation and specific antibody formation. This humoral response is largely regulated by the secretion of IL-4, IL-5, IL-10, and IL-13 by T-helper type 2 cells. The interleukins were up-regulated differently in different lymph nodes and peripheral blood mononuclear cells.<sup>291</sup>

Pigs with high neutralizing antibody levels and high IFN- $\gamma$  responses showed the lowest levels of viral replication, whereas pigs with weak or nil responses had the highest levels of replication. The levels of NA could be correlated with the clinical status of the pig and the viral load.<sup>284</sup>

## NECROPSY FINDINGS

Not all pigs with PCV2 infection develop PMWS. PMWS incidence is highest where there is coinfection. Lymph nodes in affected pigs had the highest levels of viral load, but there was no significant difference between lesion severity and the viral load in these structures. There was no difference in the viral load in inguinal lymph nodes with or without PMWS, but in the former, the lesions were more severe.<sup>292</sup>

## Gross Pathology

### Fetal Pathology

PCV1 can, when used to experimentally, infect midgestational porcine fetuses, replicate, and produce pathology (severe hemorrhages in the lung) in the fetuses inoculated at 55 days of gestation.<sup>293</sup>

There are increased numbers of mummified and stillborn fetuses. The mummified can be as small as 6 to 7 cm.<sup>154</sup> Frequently, gross lesions are not seen at all. If lesions are seen, they are generally associated with myocardial failure.

Generally, in a fetus the lesions are found in the cardiovascular system, particularly the heart. Myocardocytes may be degenerate, necrotic, or lost and replaced by fibrous connective tissue. There is often abundant PCV2 antigen in these lesions.

Dilated cardiomyopathy, pulmonary edema, hepatomegaly with congestion in an accentuated lobular pattern, hydrothorax, ascites, and subcutaneous edema are also seen.<sup>154</sup> Sometimes there is lymphadenopathy,<sup>18</sup> thymic atrophy, perirenal edema,<sup>18,154</sup> mesocolic edema,<sup>154,294</sup> and cerebral and splenic petechiation.<sup>18,154</sup>

Microscopically, there are often lesions in the myocardium in mummified, stillborn, and weak live-born piglets.<sup>154</sup> The myocardocytes are often necrotic, degenerate, or lost, and are replaced by fibrous tissue and mineralization with inflammatory cells, including macrophages, plasma cells, and multinucleated giant cells. Occasionally, there are inclusion bodies.<sup>54,294</sup> Sometimes, lesions may include interstitial pneumonia, bronchopneumonia, and hepatic congestion with hepatocellular loss; nonsuppurative hepatitis with periportal necrosis; and lymph node and splenic lymphocyte depletion with occasional multinucleated cells or lymph node follicular hyperplasia.

Myocarditis with high viral load of PCV2 in several tissues in cases of fetal death and high mortality in piglets has been described.<sup>150</sup> A high load of PCV2 DNA was observed in the myocardium, liver, and spleen from mummified or stillborn piglets.

## Pathology in Piglets and Pigs

In some cases all lymph nodes are affected, but in others only a few; thus, a range of nodes is essential in any postmortem examination.

Necrotizing lymphadenitis associated with PCV2 infection has been characterized.<sup>251</sup> The pathogenesis of the lesion has been linked to apoptosis induced by PCV2. Lymphoid necrosis in PMWS-affected pigs may be related to hypertrophy and hyperplasia of high endothelial venules. Necrotizing lymphadenitis may develop following vascular damage, with thrombosis and subsequent follicular necrosis.

A reactive hyperplastic lymphadenopathy was shown in submaxillary lymph nodes with granulomatous lymphadenitis and necrotic foci.<sup>295</sup>

Based on the necropsy of three unthrifty pigs from all herds in a case-control study, approximately 78% had PMWS in the case herds and 26% in the control herd.<sup>296</sup>

Postmortem examination may reveal the following:

- Lesions in the liver, which are often yellowish-orange, indicating jaundice, with mild to moderate mottling; wasting is often seen.
- Noncollapsed lungs that are rubbery, with pronounced grayish nodules;

in some cases, there may be pulmonary edema, pleurisy, and pneumonia.

- Swollen, pale, homogeneous lymph nodes, particularly the inguinal, mesenteric, and tracheobronchial
- Thymic atrophy
- In the kidneys, there may be either no lesions or scattered white foci visible on the subcapsular surface and edema of the peripelvic connective tissue. Interstitial nephritis lesions were classified into three groups: lymphoplasmacytic, tubulointerstitial, or lymphohistiocytic to granulomatous and mixed patterns.<sup>295</sup>
- There may be limb edema and hemorrhagic joint fluid, and the spleen may be enlarged, meaty, and noncongested.
- The classical blue/purple skin lesions of PDNS may be a feature.
- There may be gastric ulcers and enteritis, with fluid-filled, thin-walled sections of the lower intestine, particularly the ileum and the spiral colon, with occasional edema of the cecal wall.

Mid- to late-term abortions may be seen, with affected fetuses showing necrotizing myocarditis and the presence of PCV2 antigen in cardiac tissues. Pathologic and virologic findings have been described in midgestational fetuses after experimental inoculation with PCV2a or PCV2b.<sup>293</sup> At 21 days PI 11/12, were edematous and had distended abdomens, and 1/12 looked normal. All PCV2-inoculated fetuses had internal hemorrhages and congestion and an enlarged liver. High PCV2 titers were found in all tissues, especially the heart, spleen, and liver. High numbers of infected cells were seen in the heart. The 2a and 2b types produced similar lesions and replicated to similar titers in the organs of 55-day-old immunocompetent pig fetuses.

Acute enteritis may be seen in otherwise normal pigs. In the early cases, particularly in the United Kingdom and Spain, porcine dermatitis and nephropathy syndrome was a feature and closely resembled African or classical swine fever cases. It was not common but was associated with a high mortality. There were coalescing red to purple skin lesions, particularly over the perineal region; glomerular and interstitial nephritis; vasculitis; and deposition of immune complexes in the kidneys. In the cases with brain and cord lesions described,<sup>297</sup> there was hemorrhage on the cut surface, as multifocal to coalescent areas of hemorrhage extending from the cervical to the lumbar region. Brain lesions in pigs affected with PMWS have been described.<sup>298</sup> They included cerebellar multiple hemorrhages and edema, which were microscopically associated with mononuclear vasculitis in the molecular zone of the cerebellum; hypertrophied endothelium;

and perivascular lymphohistiocytic infiltrate with deposits of fibrin.

An acute pulmonary edema was described in the Midwest of the United States. The pigs were found dead without previous signs and had clear fluid in the thoracic cavity and diffusely heavy and wet lungs with moderate to severe expansion of interlobular septae. Histopathology revealed the edema and also a diffuse interstitial pneumonia. There was often a fibrinoid necrosis of the blood vessel walls.<sup>299</sup>

### Histopathology

PCV2 has been associated with primarily PMWS and PDNS, proliferative and necrotizing pneumonia, cerebellar vasculitis,<sup>249</sup> granulomatous enteritis, reproductive failure with abortion and premature farrowing, neonatal losses with tremor, and myocarditis.

The major histopathologic lesions in PCV2 diseases are lymphoid, with a depletion of T and B-lymphocytes. There should be PCV2 antigen in moderate to large amounts in the lymphoid tissues. This lymphocyte depletion is the result of a combination of factors, including destruction of lymphoid architecture, apoptosis, and cell lysis induced by PCV2 infection.<sup>300</sup> The main cellular changes are a decrease in follicular DCs, interdigitating cells, interfollicular lymphocytes, and B cells. Typical microscopic findings in lymph nodes include lymphocyte depletion, histiocytic infiltrations, and occurrence of multinucleated giant cells. There are losses of both B cells and T cells. There is a loss of lymph node architecture. These may be atrophic or necrotizing. Occasionally basophilic intracytoplasmic inclusions are found in the B-cell-dependent areas. Necrotizing lymphadenitis, interstitial nephritis, and interstitial pneumonia may also be found.

Lesions in the liver may include those such as infectious hepatitis and apoptosis.<sup>248</sup> There is often lymphohistiocytic infiltration of the portal areas, with occasional atrophy of the bile duct epithelium. Single-cell necrosis may be seen. In late stages there may be hepatocyte swelling and karyomegaly.

PCV2 inclusion bodies have been found in pulmonary (bronchial and bronchial glandular) and renal epithelial cells,<sup>301</sup> but pathologist experience suggests that these are now much less frequent than when the disease first occurred.

CNS lesions in PCV2 infections are rare but if found are usually in the brain and are usually found in the cerebellum.<sup>249,302</sup> In the Zlotowski cases, there was a moderate lymphohistiocytic vasculitis with thrombosis and marked mural fibrinoid degeneration with perivascular edema in meninges and parenchyma. Marked Wallerian degeneration and occasional Gitter cells were seen in the white matter of the cord. In animals experimentally inoculated with PCV2b, vasculitis was a hallmark of the lesions.<sup>303</sup> Two

cases of nonsuppurative encephalitis were attributed to PCV2 infection by virtue of ISH when viral nucleic acid was found in the mesencephalon, cerebellum, and medulla oblongata, mainly in the cytoplasm of macrophages, endothelial cells, and some glial cells, and real-time PCR detected PCV2 in the brain samples from seven other pigs.<sup>304</sup> In natural cases of PCV2 infection there may be interstitial nephritis, tubulointerstitial nephritis, and granulomatous or lymphoplasmacytic nephritis. Lesions are often associated with PCV2 antigen. The renal lesions tend to occur later on in PCV2 infections. Renal tubular necrosis and interstitial hemorrhage ("turkey-egg kidney") have been seen in a PCV2-infected Yorkshire cross pig.<sup>305</sup> There was edema and petechiation of both kidneys, with renal tubular epithelial necrosis with extensive interstitial edema, and hemorrhage and inclusions in renal tubular epithelium. PCV2 was readily identified within these lesions. In the lungs, there may be interstitial pneumonia, lymphohistiocytic infiltration in the interstitium, granulomatous inflammation with syncytia, epithelial airway destruction, and bronchiolitis obliterans. There may be peribronchiolar fibrous hyperplasia, often with PCV2 antigen. Association of PCV2 with vascular lesions in porcine pneumonia has been seen in PCV2-infected lungs in Hungarian swine, particularly type 2b infections.<sup>306</sup> Vascular lesions are often reported in PCV2-affected pigs in the form of distension of interlobular septae with edema and fibrinoid necrosis. In the heart, the PCV2 antigen is associated with the myocyte swelling or necrosis.

Lesions in the sow's reproductive tract or the boar's reproductive tract are rarely reported.

Granulomatous enteritis may be seen with inclusion bodies in the Peyer's patches. There may be lymphohistiocytic infiltration of the gastric, cecal, and colonic mucosa. There may also be sloughing of crypt or glandular epithelium. There may be dilation of lymphatics. The pancreas may show areas of acinar epithelial atrophy and lymphoid aggregates in the interstitial regions.

The liver may show inflammatory and apoptotic changes with mononuclear cell infiltration in the parenchyma. Hepatitis may be seen. Singular 2a and 2b infection results in apoptosis of hepatocytes in clinically affected gnotobiotic pigs.<sup>250</sup> There were higher amounts of PCV2 antigen in clinically affected pigs.

### Porcine Dermatitis and Nephropathy Syndrome

Porcine dermatitis and nephropathy syndrome (PDNS) is characterized by systemic vasculitis and glomerulonephritis affecting pigs of 20 to 65 kg. It is often solely associated with the occurrence of *Pasteurella* as a specific condition known in the United Kingdom as sporadic PDNS before the onset

of the condition associated with PCV2. It has been seen in pigs, from 5-week-old nursery pigs to 9-month-old gilts. The affected animals are usually afebrile, anorectic, and depressed and show ventrocaudal subcutaneous edema. The course of the disease is rapid, and most pigs die within 3 days of the onset of clinical signs. This condition is now regarded as being part of the PCVAD complex.

Except in the condition of PDNS, PCV2 is rarely found in the skin of the pig, except in ear necrosis, as mentioned earlier.

### Ultrastructural Changes

The ultrastructural changes in lymph nodes suffering from PMWS showed swelling of histiocytes, proliferation of mitochondria, and proliferation and swelling of endoplasmic reticulum and Golgi complex. Infected histiocytes contained large numbers of intracytoplasmic inclusions.<sup>307</sup> Lymphocyte depletion was a striking feature. Viral replication is probably a frequent event in macrophages.

### CLINICAL SIGNS

PCV2 infection is widespread worldwide,<sup>105</sup> but clinical PCVAD is only seen in a minority of pigs. Subclinical infection is the normal occurrence in PCV2 infection, but it may be associated with decreased vaccine efficacy.<sup>162</sup> Clinical signs of PMWS were only visible in pigs 1 to 2 weeks before death, when they wasted rapidly. There were no other characteristic clinical signs and no obvious gross lesions at postmortem. PCV2 antigen level was higher from 4 to 6 weeks of age in pigs that died from other causes.<sup>308</sup> When it first occurred, it was seen a classical PMWS in weaners with a high mortality but now seems to be a more chronic disease associated with finishers with nonspecific signs (unthrifty, increase in mortality, decreased productivity, and increased disease from concurrent infections) in both the United States and Europe.

The first 41 cases in Denmark showed an average postweaning mortality of 11% in the nursery (7–30 kg), with comparable figures in other countries.

PCV2 is suspected to be associated with other diseases, such as PRDC, reproductive disorders, PDNS, and congenital tremor.

During their lives, most pigs will get PCV2, will seroconvert, and will never show any signs of the disease. It can also be recovered from healthy units that have never had any disease incidents.

PMWS most commonly affects pigs from 60 to 120 days of age at the end of the nursery phase or the beginning of the finishing phase.

The age at which the disease occurs is similar in Spain, but no pigs under 4 weeks have been affected, and the maximum age was 6 months.<sup>309</sup> A study of fattening pigs in the Netherlands with respiratory disease but no signs of PMWS looked at the contribution

of PCV2. Eight herds had a high percentage of pneumonia at slaughter, and eight had a low percentage of pneumonia at slaughter. High PCV2 viral loads were found in 58% of the high group but only in 29% of the low group. High loads were found more frequently with other pathogens in the high group.<sup>310</sup> The study confirmed that PCV2 plays a role in pneumonia in pleurisy in pigs from 10 to 24 weeks in herds with PMWS and in herds with no clinical signs of PMWS.

The PCV2 genome plasticity is a major contributing factor to the PMWS disease manifestation.<sup>68</sup> Piglets of 5 to 12 weeks are most commonly affected, but occurrence of signs 5 to 16 weeks is not unknown. In the initial cases the condition affected the nursery pigs, but now more finishing pigs are reported with the signs. Pigs under 5 weeks are probably protected by maternal antibody, and the lowest levels of antibody are usually around 7 weeks under natural conditions. Infection levels peak at around the same age as the peak of PMWS outbreaks (12–13 weeks of age) and then decrease progressively following seroconversion.<sup>118</sup> The incubation period is thought to be 7 to 28 days.

The clinical signs are highly variable and are said to be multisystemic, which is their main characteristic. Some farms had high morbidity, mainly in weaners and others in the finishing pigs.<sup>311</sup> Mortality may be high.<sup>67</sup> Morbidity may be high or low, and only a small proportion may actually develop clinical signs (5% to 30%).<sup>2</sup>

There is a blurred border between PCV2 systemic disease and PRDC, and it is probable that PCV2 lung disease is a negligible condition and that PCV2 mainly contributes to PRDC in relation to PCV2 systemic disease occurrence.<sup>312</sup> There may be fever. Other signs may include weight loss; wasting is the extreme effect, but reduced weight gain is now typical. This is a frequent occurrence. In a case-control study in Denmark, affected weaners had a lower weight gain of 36 g/day and finishers of 52 g/day.<sup>296</sup> Feed utilization is also reduced, with an increased daily gain-to-feed value (396 g/kg of feed in vaccinated pigs) compared with 390 g/kg of feed in unvaccinated animals.<sup>313</sup> Respiratory dysfunction, including dyspnea, is also a frequent occurrence. Enlargement of superficial lymph nodes, particularly the superficial inguinal, which is not palpable in normal healthy animals, is a frequent occurrence. Antibiotic usage is increased with PMWS when comparing usage before an outbreak to that until a year after the outbreak.<sup>314,315</sup> Anemia or pallor is often present. Diarrhea is often present. Jaundice may occur but is not frequent. Generalized depletion of lymphocytes and secondary infections with opportunist and secondary infections are a feature. Necrotizing dermatitis and renal failure<sup>316</sup> may also occur.

Reproductive failure is a feature in breeding units.<sup>317</sup> The authors think there

is a distinction between PCV2-associated reproductive failure and subclinical PCV2 in utero infection. For the diagnosis of PCV2-associated reproductive failure the following must be confirmed:

1. Clinical signs, which include early termination of pregnancy and increased numbers of mummified fetuses, stillborn, or weak-born pigs
2. Microscopic lesions within fetal tissues
3. PCV2 antigen or DNA within fetal tissues

Subclinical infection in utero is identified by the detection of PCV2 DNA or antibodies in fetal tissues, presuckle serum, or fetal thoracic fluid. Some piglets were found to be infected with both PCV2a and PCV2b.<sup>135</sup> A high level of reproductive losses was seen in a herd in Japan,<sup>318</sup> where there were 48.8% stillborn piglets and 14.5% preweaning mortality rate; the problem was rapidly solved after vaccination.

PCV2 infection in pregnant sows was reproduced using isolates from reproductive failure<sup>319</sup> and in naïve sows inseminated with semen contaminated with a PCV2b virus.<sup>154</sup> Any PCV2 isolate is capable of causing PCV2-associated reproductive failure. PPV has been recognized in fetal tissues,<sup>294,320,321</sup> as have PRRSV,<sup>294</sup> PCV1,<sup>294</sup> porcine TTV viruses,<sup>322</sup> and *E. coli*.<sup>294</sup>

Reproductive failure often occurs in gilts and start-up herds and is probably a reflection of seronegative populations.<sup>150,323–325</sup>

Homologous anti-PCV2 antibodies are at least partially protective for in utero PCV2 infection and the development of reproductive failure.<sup>133,159</sup> Abortion is not a major feature. The PCV2 virus is capable of infecting and damaging embryos in early pregnancy, leading to failure or reduction in litter size. In later gestation, damage to the fetus may result in stillbirth, mummification, embryonic death and infertility (SMEDI), mainly in primiparous sows,<sup>326</sup> and a potential return to estrus.<sup>44</sup> The most consistent feature of PCV2 infection in sows is stillbirth or mummified fetuses. Pyrexia and anorexia are often features of aborting sows. Delayed farrowing may also be seen. In a recent outbreak of PCV2-associated reproductive failure, gilt displayed pneumonia, diarrhea, and wasting.<sup>324</sup>

Paralysis in pigs with a spinal cord injury has been described<sup>327</sup> in Brazil.

Clinical signs are not usually seen in boars. In Poland, a reduction in ear necrosis was noted after a vaccination program for PCV2 was started.<sup>328</sup>

A clinical syndrome that affected healthy nursery and younger finisher pigs in the Midwest of the United States has been described in PCV2-vaccinated herds. Mortality reached 20% in some affected groups. Clinical signs included the rapid onset of respiratory distress followed almost immediately by death.<sup>329</sup>

One of the most important aspects of PCV2 infection is that vaccination using the Lapinized Philippines Coronel (LPC) vaccine was shown to have an effect in decreasing the efficacy of the vaccine. The level of neutralizing antibodies produced and the presence of lymphocyte subsets were reduced by the PCV2.<sup>330</sup>

### CLINICAL PATHOLOGY

Acute-phase proteins are synthesized mainly by the liver and are used as biomarkers of diseases for diagnosis and prognosis.<sup>331-333</sup> They are under the control of cytokines that are released during the inflammatory process. IL-6 and IL-1 type cytokines that are produced mainly by macrophages and monocytes (IL-1 $\alpha$ , IL-1 $\beta$ , IL-6, TNF- $\alpha$ , and IFN- $\gamma$ ) appear to be the major regulators.<sup>334</sup> It is controlled largely at the level of transcription. The regulators include NF- $\kappa$ B and the STAT proteins.

In the blood there is a reduction of both B cells and all T-cell subpopulations (naïve Th, activated Th, Tc, and gammadelta cells and also NK cells). In the 14 days postinfection with PCV2, there is a decrease of leukocytes, followed by an increase in neutrophils 7 to 14 days later. No changes in circulating monocytes, basophils, and eosinophils were detected.<sup>335</sup>

The major acute-phase protein (MAP) and haptoglobin serum concentrations correlate with PCV2 viremia and the clinical course of PMWS.<sup>336</sup> There was a significant correlation between PCV2 loads and both MAP and haptoglobin concentrations in serum of PMWS-affected pigs.

### Diagnosis

Diagnosis of systemic PCVAD requires the presence of microscopic lesions and detection of PCV2 antigen or nucleic acids associated with the microscopic lesions. This is achieved using IHC or ISH. The ISH stain may be easier to read with more stained cells.<sup>337</sup>

Diagnosis of fetal infection on clinical signs is impossible to differentiate from other infections and effects of management changes. Sows with PCV2 infection frequently have no signs, are usually seropositive, and can be viremic or nonviremic.<sup>157</sup> Sampling of four to six fetuses per litter is recommended. Immunohistochemistry (IHC) and in-situ hybridization (ISH) are the gold standard for detection of antigen in the myocardium. DNA can be detected by PCR in the heart, liver, kidney, spleen, lymph node, and brain. Liver and myocardium have the highest amounts of DNA. Myocardium, liver, and splenic tissues were positive for PCV2 DNA in all live-born piglets.<sup>279</sup> The DNA extraction method has an important role in the usefulness of PCV2 quantification in swine lymph nodes,<sup>338</sup> and it casts doubt on comparable results unless the extraction methods are comparable. Laboratories in

North America have been compared, and it has been shown that there are considerable differences in their detection limits and quantification.<sup>339</sup>

In utero infection can also be diagnosed by demonstrating ABs in fetal or live-born presuckle piglets using an ELISA.<sup>135,340</sup> Fluorescent antibody and IPMA have also been used.

Virus isolation is more difficult, but PCV2 can be isolated from most fetal tissues, particularly the myocardium.

Piglets from dams with low PCV2 antibody titers or with viremia had more morbidity and mortality associated with PMWS.<sup>119</sup> A protocol for the diagnosis of PMWS was developed in Italy.<sup>341</sup> Samples were examined histologically first and then by IHC for PCV2 when histologic lesions were first recognized. The lymphoid tissues were more reliable for diagnosis of PMWS than lungs.

### Serology

An immunochromatographic strip for the detection of antibodies against PCV2 has been described,<sup>342</sup> and it agreed with the ELISA in 94% of cases.

Neither viral load nor antibodies can be used for diagnosing herds as PMWS-affected pigs or free herds (serology and qPCR are used<sup>118,308,343</sup>) because the diagnostic sensitivity and specificity are low.<sup>118</sup>

An indirect ELISA using a recombinant truncated capsid protein of PCV2 has been described as a serodiagnostic assay for detection of PCV2 antibodies.<sup>344</sup> Histopathology plus detection of PCV2 in tissues is necessary for diagnosis in the individual animal.

The pathogen is ubiquitous, which hinders the diagnosis because many pigs are infected without clinical signs or have subclinical infections. To make a diagnosis, the following must be present:

1. Recognizable clinical signs
2. Moderate to severe histopathologic lesions
3. Moderate amounts of PCV2 antigen in the lesions

During the PCVAD outbreak in Ontario from 2004 to 2006, the probability of a positive PCR for PRRSV decreased. It was concluded that when a decrease in test positivity occurred for a known disease, it may suggest that a new disease agent is emerging in the population.<sup>345</sup>

The diagnosis of PCV2 infection, mostly PMWS, is based on the clinical signs of the condition in individuals and groups of animals and by laboratory detection of PCV2.

In the individual animal, histopathologic examination together with viral detection in the lymphoid tissue is the definitive diagnosis.<sup>118,346</sup>

For herd diagnosis, there is a problem, because individuals may have the disease although the herd may have good production

figures.<sup>347</sup> In some herds, 32% may not fulfill the diagnostic criteria,<sup>348</sup> or even 55%.<sup>118</sup> In these cases there must be (1) a significant increase in postweaning mortality and wasting and (2) the use of individual diagnoses in at least 1/5 of every group of animals subjected to postmortem examination

### Diagnosis in Boars

PCV2 is found 5 days after experimental infection of boars. Shedding in semen has been reported in the absence of viremia. Antibodies develop within about 2 weeks of infection. Intermittent shedding was continued over an 8-week observation period,<sup>157,349</sup> with continuous shedding of the virus for 90 days.

Naturally infected boars shed for 27.3 weeks in a positive boar stud.<sup>127</sup> Peak shedding occurs at around 9 to 20 days.<sup>157,349</sup>

Experimentally infected boars can be viremic for at least 90 days, and blood swabs can be positive for DNA at least 47 days after cell-free viremia was last detected.<sup>157</sup>

The virus DNA can be detected in the bulbourethral glands, testes, epididymis, prostate, and seminal vesicles.<sup>350-353</sup> Detection of PCV2 DNA in boar semen is variable and depends on age.<sup>127,153,354</sup> Infectivity of PCV2 is possible, but because of the low amount semen in each dose after extension, the virus in each ampule is very low, so the risk of infection is low. PCV2 DNA can be detected using a quantitative real-time PCR.<sup>355</sup>

Postmortem examination of one and preferably up to five piglets is necessary to ascertain the spectrum of gross lesions.<sup>2</sup>

### Virus Detection

Samples should be taken and examined histologically for the presence of characteristic PCV2 cytoplasmic inclusion bodies; second, IHC should be applied to confirm the PMWS cases with positive histochemistry. The lymph nodes were more reliable than the lungs for the diagnosis of PMWS, both in individual pigs and in groups of pigs.<sup>356</sup> PCV2-DNA was subsequently detected in the formalin-fixed lymph nodes by PCR.<sup>357</sup>

### Detection of Viral Antigen by Immunohistochemistry

PCV2 antigen was identified by IHC in the tissues of 61% of Danish finishing pigs examined.<sup>358</sup> Up to 78% of the pigs had mild lymphoid depletion, indistinct follicle development, and/or histiocytic infiltration of the lymph nodes. But these lesions were not associated with PCV2. No association was found between lung and kidney lesions and the detection of PCV2. Three patterns of PCV2 labeling were seen:

1. Labeling of cells with stellate morphology and reticular distribution
2. Labeling of isolated nonepithelial cells
3. Epithelial labeling

PCV2 may interface with FDCs to cause depletion of B-lymphocytes. Follicular dendritic cells may be a reservoir of infective PCV2 in subclinically infected animals or be a simple storage site for PCV2 antigen.

In a study of reproductive failures in Danish pigs, it was found that IHC was only useful in the diagnosis of reproductive failure in the early stages of reproductive failure, whereas quantitative PCR can be used over a wider time span.<sup>325</sup>

It can also be detected in primary lymphoid organs from naturally and experimentally infected pigs by ISH.<sup>359</sup> PCV2 nucleic acids and replication were found in bone marrow and thymus of PMWS-affected pigs, but there was no evidence that primary lymphoid organs were major supporters of PCV2 replication.

Multiplex PCR and multiplex RT-PCR for inclusive detection of major swine DNA and RNA viruses in pigs with multiple infections<sup>360</sup> were described as a useful combination for the rapid and accurate identification of major pathogenic viruses with multiple infections.

An indirect in situ PCR for the detection of PCV2 in formalin-fixed and paraffin-embedded tissue specimens has been described<sup>361</sup> and was shown to be a useful technique.

A quantitative PCR for PCV2 in swine feces in a PCV2-affected commercial herd and a nonaffected commercial herd proved useful for the detection of virus shedding.<sup>362</sup>

Quantification of PCV2 was described.<sup>131</sup> Detection of viral genome by ISH and/or PCR is necessary for diagnosis. There is considerable variance between labs in the qPCR test.<sup>363,364</sup>

A DNA miniarray was devised for the simultaneous detection of PCV1 and PCV2,<sup>365</sup> and a multiplex real-time PCR has also been used to differentiate PCV1 and PCV2.<sup>366</sup>

Many types of real-time in vitro amplification techniques<sup>367</sup> and real-time PCR assays using SYBR Green,<sup>131</sup> TaqMan PCR,<sup>242</sup> and molecular beacon technology<sup>368</sup> have been developed.

A simultaneous detection of PCV2, CSF, PPV, and PRRSV by using multiplex PCR was described.<sup>369</sup> It was found to be a rapid, sensitive, and cost-effective diagnostic tool for the routine surveillance of viral disease in pigs. Also, oligo-microarray has been used.<sup>370</sup>

Multiply primed rolling-circle amplification (MPRCA) of PCV2 genomes has applications for detection, sequencing, and virus isolation.<sup>371</sup> It was concluded that this is a useful tool to amplify PCV2 genomes for sequencing and virus isolation. However, it is less sensitive than PCR for diagnostic purposes.

A LUX real-time PCR assay has been described,<sup>372</sup> which was more specific for the generation of fluorogenic signals than the SYBR Green PCR.

## Oral Fluids

Surveillance methods used in oral fluids have been described.<sup>373,374</sup> PCR methods have been described for use in porcine fluid oral samples.<sup>375</sup> Antibody methods have been described for oral fluid samples.<sup>376</sup>

## CONTROL

Management may influence the appearance of the condition, and the application of the Madec principles<sup>377</sup> will undoubtedly ameliorate the condition. The Madec 20-point plan is in fact no more than the rules of good husbandry and pig practice crystallized to make control easier. Most people follow some of the points, but not the majority or all of the points. However, the more that are implemented, the better the control. Essentially, the 20-point plan recommends the following:

1. Improvements in hygiene
2. Minimization of the mixing of pigs
3. Provision of clean feed, water, and air
4. Minimization of the stress on pigs through overstocking, draughts, poor husbandry conditions, and so forth<sup>103,188,378</sup>

All-in, all-out by age is particularly significant in control of the infection.

Vaccinating pigs against *Mycoplasma* 2 weeks before suspected exposure to PCV2 will also help.<sup>379</sup>

Serum from pigs recovered from PMWS by injection could prevent PMWS in some cases, but in other cases it did not work.<sup>380</sup> It is not to be recommended for health transmission reasons and is no longer necessary now that there is vaccination.

The absence of an external envelope leaves the virus resistant to lipid-dissolving disinfectants, but it can be inactivated by alkaline disinfectants (sodium hydroxide), oxidizing agents (sodium hypochlorite), and quaternary ammonium compounds.<sup>381</sup> Results of a study<sup>120</sup> showed that Virkon S, Clorox bleach, and sodium hydroxide were the most effective agents for disinfection. Disinfection of an airspace could be achieved using formaldehyde vapor, assuming optimal temperature and humidity.

Infected boar semen is a possible source of infection, so AI centers should use boars that are free from infections.<sup>382</sup>

Attention to good nutrition will help, and there is some evidence that a selenomethionine supplement may help by reducing PCV2 replication in PK-15 cells (probably by enhancing glutathione peroxidase).<sup>383</sup>

Dietary aluminium silicate given to experimentally infected pigs produced a significant decrease in the load of viral genome in nasal swabs, serum, and lung tissue of pigs compared with a control group 28 days after PCV2 infection. Pigs in the treated group also had less severe histopathologic lesions.<sup>384</sup>

In theory, plasma-containing products may contain PCV2, but in a recent study, piglets fed spray dried plasma containing PCV2 DNA did not become infected.<sup>163</sup>

A modeling approach was used to estimate the effects of husbandry and control measures on the dynamics of PCV2 infection,<sup>385</sup> and it was found that early infection was significantly reduced when mixing of piglets was reduced by avoiding cross-fostering and mixing of groups. Sow targeted vaccination reduced the infectious process until waning of passive immunity. Piglet vaccination considerably decreased the force of infection. Changing from a low prevalence of PCV2-infected semen to a high one significantly increased the risk of early infections. Reducing replacement rate or changing sow housing from individual crates to sow group housing had little effect.

Increased morbidity occurred for an extended period before the diagnosis of PMWS both in the sow units and the weaner pig units, and there was an increased use of antibiotics in the third (35%) and fourth quarters (43%) before diagnosis was made.<sup>314</sup>

After a herd had an outbreak of PMWS (PCV2) in Danish herds, the use of antibiotics in the weaners was increased for about 1 year, and the use of antibiotics before the outbreak was 37% higher in herds with weaners and 17% higher in herds with finishers in the year compared with herds that did not have PMWS.<sup>315</sup> In the 4-year period when the incidence of PMWS rose from almost zero to 20%, the national use of antibiotics increased by 4% to 5%.

## Vaccination

The relationship between antibody titers and protection is unknown, but PMWS-affected pigs do show an impaired PCV2 humoral response.

The vaccines were developed to control PMWS but are now used for all PCVAD. The vaccines have been successful in reducing mortality in Europe, Canada, and the United States.<sup>6</sup> The vaccines probably work by activating both humoral and cellular immunity.<sup>386,387</sup> Vaccination of sows does not prevent PCV2 infections but reduces the viremia.<sup>287,388</sup> The antibody titers do not appear to influence the occurrence of disease because gilts and sows with high antibody titers against PCV2 and PPV presented viremia, and fetal exposure during gestation occurred in these animals.

It has been shown that IFN- $\gamma$ -secreting cells develop during the adaptive response to PCV2 and probably contribute to viral clearance in infected pigs,<sup>389</sup> and CD4+ and CD8+ cells contribute to this response.<sup>244</sup>

The efficacy of the five commercial PCV2 vaccines has been described experimentally,<sup>135,389-394</sup> and studies have been made in the field.<sup>395-404</sup>

## The Vaccines

The Vaccines Use Different Adjuvants.

Circovac (Merial) is an inactivated oil-adjuvanted vaccine originally designed for

sows (2 ml) and now available in a reduced dosage for piglets (0.5 ml).<sup>404</sup>

Four additional vaccines were licensed for use in piglets; three are based on ORF2 capsid protein (main neutralizing epitope) expressed in the baculovirus system: Circoflex (Boehringer Ingelheim), Circumvent Intrvet (Merck; North America), and Porcilis PCV (Schering Plough/Merck; Europe).

Suvaxyn PCV2 One Dose (Pfizer Animal Health/Fort Dodge Animal Health) is another vaccine but is based on a chimeric PCV1/2 virus using the genome of PCV1 with the ORF2 from PCV2. This was replaced using a natural PCV1/PCV2 chimera from Canada,<sup>405</sup> and this was relaunched as Fostera PCV (Pfizer Animal Health).

All the commercial vaccines are based on PCV2a, which does protect against the more common strain of PCV2b,<sup>390,393</sup> which appears to be essential for triggering PCV2 into PVCAD (16/17).<sup>15,406,407</sup> The four commercial vaccines are all killed or recombinant vaccines based on PCV2a,<sup>387,389,399</sup> even though PCV2b has now become the globally dominant genotype. These vaccines still continue to provide good protection even though PCV2a and PCV2b differ in nucleotides by up to 10%.<sup>54,389</sup> An experimental 2b vaccine has also been shown to provide protection from both 2a and 2b.<sup>389</sup>

### Vaccine Effects

In a study of four vaccines, it has been shown that the average daily gain of vaccinated animals was much higher than that of nonvaccinated animals. There were more IFN- $\gamma$ -secreting cells and CD4+ cells in the vaccinated animals. The histologic lesions and the PCV2-antigen scores in the lymph nodes were significantly lower in vaccinated animals.<sup>408</sup>

As always with pig farmers, one-dose vaccines are preferred to two-dose vaccines. One-dose vaccines improve daily gain in the field by 16 to 69 g/day from 3 to 19 weeks and decrease mortality by 1.9% to 9.3%. PCV2 vaccines reduce the proportion of viremic pigs and the viral load in blood and reduce the length of the viremic period in both experimental and field situations. They also reduce nasal and fecal shedding of the virus. The presence of NA is induced by commercial PCV2 vaccines, and there is a decreased replication of virus correlated with the absence of clinical signs. The induced presence of IFN- $\gamma$ -secreting cells in vaccinated animals is also likely to increase PCV2 clearance. Vaccination of pigs reduces the number of PMWS-associated microscopic lesions and the PCV2 load in lymphoid tissues compared with nonvaccinated animals. The vaccines will control PMWS under field conditions, but their role in protecting against the PCV2 component of PRDC is still unknown.

When the killed vaccines were originally introduced in the United Kingdom, it was noted that it had the following results:

- An improved growth rate (7–10 days faster to slaughter)
- A 1% to 5% reduction in nursery mortality
- A 1% to 6% reduction in finisher mortality
- An improvement in numbers weaned/litter by up to 0.5 piglets (sow vaccine), with improvements in fertility and litter size
- More even growth within a litter
- Improvement in fat measurements, probably as a result of more rapid growth

Most pigs in commercial production are now vaccinated against PCV2 infections. The introduction of the sow vaccine was beneficial for the following reasons:

- Lower cost
- Lower workload and reduced stress on piglets
- Prevention of *in utero* infection and early fetal death
- Control of reproductive losses.

On some farms where disease occurs over 10 weeks, the sow vaccination may not help in prevention, probably because maternal derived antibody has disappeared.

In the United Kingdom the initial use of the piglet vaccines was associated with a reduction in mortality of up to 50% and an improvement in growth rate of 50 gm/day, with most of the increase occurring in the finishing stage.

PCV2 infection may be a factor contributing to weight variation in vaccinated, market pigs.<sup>409</sup> The mean antibody titer, proportion of viremic pigs, and virus load differed between the light and heavy pigs on three different farms.

Mortality rate reduction with the PCV2 vaccination might depend on the genetic types of PCV2 that occur on the farm.<sup>410</sup>

With a vaccination program in operation, there is a large decrease in mortality, a reduced viremia, reduced back-fat depth, reduced number of culls, a reduced time to market, and reduced medication costs when vaccinated pigs are compared with unvaccinated pigs.<sup>411–418</sup>

PCV2-vaccinated pigs also have a better daily gain, a higher percentage of lean meat, a better feed conversion, a higher number of pigs reaching slaughter, and a higher carcass weight.<sup>400,412–416,418,419</sup>

An early antibody boost was sufficient to protect pigs from contracting PVCAD before the fattening period and also enhanced pigs' growth<sup>401</sup> and performance in the fattening period, although new infections were detected as early as 56 days after birth (on the basis of PCV2-specific IgM measurements).

It was shown that sow vaccination, piglet vaccination, or vaccination of sow and piglet produced similar control of PMWS.<sup>400</sup> However, decreased mortality in piglets

before weaning was only observed in the piglets from vaccinated sows.

### Sow Compared with Piglet Vaccination

Under field conditions, piglets born to sows that are vaccinated have a preweaning weight gain. Experimentally vaccinated 8-week-old piglets have lower PCV2 loads than those receiving passive protection from MDA.<sup>393,400</sup> The duration of protection may be 11 to 13 weeks.<sup>135,396</sup> Sow vaccination is to be used if there is a high level of infection before weaning, but piglet protection is best to ensure that there is active immunization.

A comparison was made of the effectiveness of dam (passive) versus piglet (active). Immunization and the impact of passively derived PCV2 vaccination induced immunity on vaccination.<sup>393</sup> Both dam and piglet vaccines had similar efficacy in reducing PCV2 viral loads and antigen levels in the growing pigs. Vaccination of the piglets with the same vaccine as used on their dams did not appear to affect the vaccine efficacy because they had the same levels of AB and genome copies of PCV2 as those receiving the piglet vaccine alone.

### Sow Vaccination

Vaccination of sows appeared to improve reproduction in sows and provided protection for the piglets.<sup>422</sup>

Vaccination of sows before mating is designed to protect sows against PCV2 reproductive disease<sup>423</sup> and also leads to stabilization and homogenization of the PCV2 immune status of the sow population during gestation.<sup>424–427</sup> The effect of vaccinating sows before farrowing is to increase the transfer of PCV2 antibodies to piglets and to protect piglets against systemic disease.<sup>399,425,426</sup>

Vaccination of sows reduces the prevalence of PCV2 viremia in their piglets in the field.<sup>426</sup> Vaccinated sows had less PCV2 in the colostrum than nonvaccinated sows.<sup>424</sup> Vaccinated sows had more PCV2 antibody in their serum and colostrum than unvaccinated sows.<sup>428</sup> A study compared sow vaccination, piglet vaccination, and sow + piglet vaccination<sup>429</sup> and found similar efficacy. Sow vaccination and piglet vaccination were found to be similar in another study.<sup>393</sup>

Vaccination of sows during pregnancy reduces the viral load in the blood and the rate of transplacental infection,<sup>133</sup> but it does not eliminate intrauterine infection completely. It also reduced the numbers of nonviable fetuses.<sup>133,154</sup> It may therefore reduce reproductive failure.<sup>340</sup>

Colostrum from vaccinated sows may also contain PCV2-specific IFN- $\gamma$ -secreting cells.<sup>430</sup>

### Semen Shedding in Boars

Boars can shed PCV2 for a long time without showing clinical signs or changes in semen

quality,<sup>127,157</sup> and thus AI may be a possible source of virus.<sup>152</sup>

Vaccination of boars with an inactivated PCV2 vaccine was followed by challenge with a PCV2b virus.<sup>431</sup> The number of PCV2b genomes in the semen correlated with that in the blood in both vaccinated challenged and nonvaccinated challenged boars. The PCV2b vaccine significantly decreased the amount of PCV2b DNA shedding in semen from vaccinated boars after experimental infection with PCV2b, and also the duration.<sup>432</sup>

### Piglet Vaccination

Piglet vaccination of 5-day-old or 21-day-old piglets using either a chimeric or subunit PCV2 vaccine produced a detectable humoral immune response and provided reduction or complete protection against PCV2 viremia and PCV2-associated lesions after triple challenge with PCV2, PPV, and PRRSV.<sup>434</sup>

A single dose of vaccine to sows produced a higher level of antibody in piglets at 4 weeks and a different level of PCV2 infection dynamics than in nonvaccinated piglets. Piglet vaccination in any case caused an earlier seroconversion and lower percentages of PCV2-infected piglets. There was some interference with piglet vaccination, but this was overcome by the vaccination because the average daily gain was improved in both groups of vaccinated piglets.<sup>435</sup>

Unusual manifestations of PCVAD in vaccinated finishing pigs have been described.<sup>420</sup> Vaccinated pigs also have a much lower prevalence of PRRSV and *M. hyorhinis* in lung tissues than do unvaccinated pigs.<sup>398</sup> There was a larger average daily gain in herds free from PRRSV infection.<sup>421</sup>

In a study of a one-shot, inactivated PCV2 vaccine, it was found that it reduced clinical signs, PCV2 viral load in sera and feces, and overall mortality in nurseries and fattening units.<sup>404</sup> Average daily gain was increased, but maternally derived antibody (MDA) did interfere with the development of an active humoral response.

### Maternally Derived Antibodies

Maternally derived antibodies are found in nearly all piglets because most sows are infected with PCV2 and are therefore producing colostral antibodies. The vaccine efficiency is determined by the level of colostral antibody at the time of vaccination. It appears that the vaccines are not affected in the field because PCV2 associated lesions and viral load are not inhibited.<sup>390,391</sup> The vaccines produce specific antibodies and IFN- $\gamma$ -secreting cells even in the presence of MDA.<sup>389,390,433</sup>

There may or may not be an effect of maternal antibody on piglet vaccination. It was shown that there was an effect of maternal antibody,<sup>390,396</sup> but it has also been said there is no such effect.<sup>395</sup> Vaccination at 3 weeks seems to be a good compromise

between wanting to vaccinate and waiting for maternal antibody to wane. It produces neutralizing antibodies and prevents PCV2 infection during weaning.<sup>390</sup> A comparison of one-shot and two-shot vaccinations has been described.<sup>392</sup> PCV2 vaccination reduced PCV2 in a PCV2/*S. choleraesuis* (SCS) coinfection model and in animals with SCS challenge.<sup>436</sup> Piglets were given the vaccine at 3 weeks of age followed by PCV2 and SCS at 5 and 7 weeks of age.

### Experimental Vaccines

RNA aptamers, which are RNA molecules that bind specifically to a target, have been shown to block the infectivity of PCV2 in vitro in a dose-dependent manner.<sup>437</sup> Short-hairpin RNA has also been shown to result in a reduced PCV2 level in vitro.<sup>438</sup>

A PCV2 vaccine based on genotype PCV2b is more effective than a 2a-based vaccine to protect against PCV2b or a combined 2a/2b viremia in pigs with concurrent PCV2, PRRSV, and PPV infection.<sup>439</sup> The piglets had significantly higher levels of PCV1-2b viremia and shedding but also a much more robust humoral immune response. The PCV1-2b vaccine reduced the amount of viremia compared with the PCV1-2a vaccine. Concurrent PCV2a/PCV2b infection is necessary for optimal PCV2 replication.

A genetically engineered chimeric vaccine against PCV2 improves clinical, pathologic, and virological outcomes in PMWS affected farms.<sup>399</sup> The vaccine reduced clinical signs, viral load in lymphoid organs and/or sera, and overall mortality in nurseries and finishing units. This is the first time that a vaccine has been shown to reduce PMWS mortality. The vaccine also reduced the severity of histologic lesions in the PMWS cases.

The live chimeric PCV12a vaccine is attenuated, immunogenic, and genetically stable, providing similar protection as the commercial inactivated and subunit vaccines.<sup>440,441</sup> It is not uncommon to vaccinate piglets with PRRSV and PCV2 concurrently.<sup>442,443</sup> The chimeric PCV12b live vaccines have the advantage in that they are not likely to revert.

A potential PCV12b vaccine was shown to be effective in preventing infection with 2a and 2b,<sup>444</sup> with decreased lymphoid lesions and viral load. One-dose and two-dose commercial PCV2 vaccines were evaluated in a PRRSV-PCV2-SIV model.<sup>392</sup>

Viremia was reduced by 78.5% in pigs vaccinated by one dose and by 97.1% in pigs vaccinated with two doses. Overall, the microscopic lesions were reduced by 78.7% and 81.8%, respectively.

A triple-coinfection model was used to show that the chimeric PCV12b vaccine was efficacious.<sup>441,445</sup> Vaccines, both commercial and experimental PCV2, used a triple challenge with PCV2, PRRSV, and PPV, and it

was found that both vaccines reduced the PCV viremia at 16 weeks of age and after PCV2 challenge,<sup>441</sup> even though there was PCV2 viremia at the time of vaccination.

PCV2 vaccination usually reduces the prevalence and severity of clinical disease.<sup>445,446</sup> A longitudinal study on the efficacy of Ingelvac CircoFLEX against PRDC showed that there was a significant improvement in the economics of late-occurring PRDC.<sup>447</sup>

A single-dose schedule for *M. hyopneumoniae* bacterin at 1 week of age and PCV2 vaccine at 3 weeks of age improved ADG (122.4%) and slaughter weight (120.5%) and reduced the incidence of clinical signs and lung and lymph node lesions.<sup>72</sup> Mineral oil-adjuvanted bacterins carry with them heightened potential for induction of PMWS, whereas the other adjuvanted bacterins tested have minimal or no potentiating effects on PMWS.<sup>220</sup>

In a study of PCV2 and PRRSV vaccination in a PCV2-PRRSV challenge model,<sup>448</sup> it was found that vaccination against PCV2 reduced PCV2 viremia, PCV2-induced lesions, and PCV2 antigens in the dually infected pigs. Therefore, the PCV2 vaccination reduced the potentiation of PCV2-induced by PRRSV in dually infected pigs. In contrast, the PRRSV vaccine did not decrease the potentiation of PCV2-induced lesions by PRRSV in dually infected pigs.

Some evidence of priming of young piglets in the presence of maternal antibodies was shown<sup>449</sup> using a prototype adjuvanted PCV2 vaccine.

Vaccination against PCV2 can reduce antibody titers when given postinfection and has no dramatic effects on semen characteristics.<sup>432</sup> There was also evidence that vaccination reduced the reoccurring infections in the vaccinated boars.

A comparison of the effectiveness of dam (passive) or piglet (active) immunization was carried out, and both had similar efficacies.<sup>393</sup>

In this study,<sup>450</sup> the PCV2 vaccine response was evaluated in a PCVAD challenge model. Dual challenge with PCV2 and PRRSV resulted in high mortality and the presence of clinical signs. PRRSV increased PCV2 infection. The results of IFA tests showed that PCV2 infection and vaccination resulted in similar levels of total serum antibody. Vaccination produced nearly 4 times as much virus neutralizing activity as infection and disease. The magnitude of the total antibody response cannot be used as the measure of protective immunity.

Only occasionally has vaccine failure been reported, possibly as a result of off-label uses. In some herds vaccinated against PCV2, acute pulmonary edema with a peracute onset has been reported.<sup>451</sup>

In one study of an apparent vaccine failure, it was found that only 50% of the pigs developed a detectable immune response to

vaccination, and this may have been associated with simultaneous 2a and 2b infection.

It may be necessary to produce vaccines based on 2b rather than 2a now that this is much more common, because the efficacy of currently available PCV2 vaccines depends on the genotypes of PCV2 on the farm.<sup>410</sup>

Some experimental vaccines have been suggested, including an ORF2 baculovirus vaccine,<sup>452</sup> an ORF2 DNA vaccine, a recombinant pseudorabies vaccine expressing ORF1, an ORF2 fusion protein,<sup>453</sup> and a recombinant adenovirus vaccine expressing the ORF2 protein,<sup>454</sup> and these have been shown to provide protection under experimental conditions.

Vaccination with inactivated or live-attenuated chimeric PCV1-2 results in decreased viremia in challenge-exposed pigs and may reduce transmission of PCV2.<sup>455</sup> Both of these vaccines did not reach the higher level of antibody of the commercial inactivated vaccine. The results suggested that 140-day closure of a small pig population in a controlled environment may result in stabilization and elimination of PCV2.

A similar study using a reformulated inactivated chimeric PCV12 vaccine induced humoral and cellular immunity after experimental PCV2 challenge.<sup>456</sup>

The induction of mucosal immunity by intranasal immunization with recombinant adenovirus expressing major epitopes of PCV2-capsid protein has been described.<sup>457</sup> It can elicit both humoral and Th1-type cellular protective immunity in mice. A *B. bronchiseptica* mutant has been used as a live vehicle for heterologous PCV2 major capsid protein expression.<sup>458</sup>

Small interfering RNAs have also been suggested as a potential treatment for PCV infection because *Rep* gene expression was inhibited.<sup>459</sup>

### Vectored Vaccines

The preparation of bacteriophage lambda particles displaying PCV2 capsid epitopes, in the absence of an adjuvant, induced PCV2-neutralizing ABs and elicited both cellular and humoral immune responses in pigs, with no reactions.<sup>460</sup>

Subunit vaccines may also play a part in the future, such as capsid protein in yeast,<sup>461</sup> recombinant baculovirus,<sup>462</sup> recombinant pseudorabies expressing PCV2 capsid protein,<sup>454</sup> and an attenuated *Bordetella* vaccine expressing the capsid of PCV2,<sup>459</sup> which have all been shown to be immunogenic.

## TORQUE TENO VIRUS

Torque teno virus is, as far as is known at the moment, a nonpathogenic commensal inhabitant of vertebrates. It is one of a newly created family of Anelloviridae, which has nine genera. It may be one of what are now called "bystander viruses."<sup>1</sup>

## ETIOLOGY

These are emerging circular DNA viruses affecting many species, including pigs. Currently, two genera have been found in pigs: type 1 (TTSuV1), now known as *Iotatorquevirus*, which has 1a and 1b subtypes; and type 2 (TTSuV2), now known as *Kappatorquevirus*, which has 2a and 2b subtypes. In addition, a novel virus was also discovered in

New Zealand in 2012, and this has also been found in China.<sup>23</sup> The virus may have an immunosuppressive effect when found as a natural infection before vaccination with PRRS.<sup>1</sup> The replication site of the virus is unknown.<sup>4</sup> Several strains have been found in one pig.<sup>5</sup> They can also be widely divergent in genotype.<sup>6</sup> In a study measuring TTV quantitatively, there was no difference in viral load between PCV2-negative and PCV2-positive pigs.<sup>7</sup>

## EPIDEMIOLOGY

These viruses have also been found in pig commercial vaccines, enzymes for laboratory use, and human drugs containing components of porcine origin.<sup>8</sup>

They were first linked to PCV2-associated diseases (PCVAD)<sup>9</sup> and PDNS<sup>10</sup> and may be a cofactor in the disease. They were found very commonly in animals with nephropathy. They are widely distributed in tissues in the pig. The virus is found in fetal tissues, blood, semen,<sup>11</sup> and colostrum. In piglets, it can be found in week 1 of life, and the highest detection is at 11 weeks for type 1 and 16 weeks for type 2.<sup>12</sup> A study in the United States showed that it was common and increased with age.<sup>13</sup>

It has a long-lasting viremia, probably because there is a very poor immunologic response. The virus load increases progressively for suckling pigs to finisher pigs and then decreases in mature animals. It can be transmitted vertically and horizontally.

It has been found in wild boar,<sup>14</sup> in Spain,<sup>15,16</sup> Czechoslovakia,<sup>17</sup> Italy,<sup>18</sup> Hungary,<sup>19</sup> China,<sup>20-22</sup> the United States,<sup>13</sup> and Austria.<sup>23</sup>

In Japan, it is widespread in postweaning pigs and may play a part in pig disease. There is a low incidence in young pigs, less than 11% in pigs under 30 days old but 54% to 85% in older pigs.<sup>24</sup> The two species differ in their viral infection dynamics in PMWS-affected herds.<sup>25</sup> In a South Korean study, there was shown to be an early onset of viremia and a chronic viremic state regardless of the PCV2 vaccination status.<sup>7</sup>

In a Spanish retrospective study of pigs from 1985 to 2005, 113/162 pigs were infected with one or another type; 38/162 had both types of virus, 90/162 had type 2, and 54/162 had type 1.<sup>16</sup>

There is evidence for vertical transmission<sup>14</sup> and in utero infection.<sup>26</sup> An increased viral load and prevalence of TTsuV2 in pigs experimentally infected with a highly pathogenic CSFV has been shown.<sup>4</sup>

## CLINICAL SIGNS

There are no clinical signs. Coinfection of TTsuV and PCV2 in a reproductive problem was demonstrated, but no clinical disease was found.<sup>27</sup>

## DIAGNOSIS

There are several PCR assays for TTsuV1<sup>16</sup> and for TTsuV.<sup>28</sup> There is a nonspecific

qPCR for both viruses,<sup>29</sup> and ELISAs are available for the detection of antibodies.

## NIPAH

Nipah is a zoonotic virus encephalitic disease of pigs and humans in Southeast Asia. It probably jumped from a wildlife reservoir to domestic pigs first. Infection with two strains of the virus was responsible for fatal respiratory disease in Malaysia in 1999. The outbreak resulted in numerous deaths of pig farmers (fatal febrile encephalitis) and others in contact with pigs, including abattoir workers. About 90% of outbreaks in humans can be associated with close contact with pigs. Recently, outbreaks in humans have occurred without reference to pigs.<sup>1,2</sup> It can cause huge economic loss in the pig industry. The pig serves as an “amplifying host.”

## ETIOLOGY

Pigs are highly susceptible to Nipah virus.

The virus is a member of the *Henipavirus* genus in the *Paramyxoviridae* family, which includes Hendra virus, which is transmitted from frugivorous bats (*Pteropus* spp.) to pigs, among which it spreads horizontally to other pigs and humans. Horses can be exposed and develop antibodies to the virus, and there is one anecdotal report of dilated meningeal vessels in a horse from which Nipah virus was isolated. It grows readily in cell culture to produce syncytia.

## EPIDEMIOLOGY

There is strong evidence that the reservoir from which the virus originated was pteropod bats.

It is highly contagious in swine, and transmission may be by several routes, including direct contact with large droplets. The oronasal route is the most common method because the virus can be demonstrated in nasal secretions. Cats and dogs can be affected but probably do not transmit to pigs.

## PATHOGENESIS

The virus affects the vascular, nervous, and lymphoreticular systems, leading to a viremia and specific infections of the endothelial cells<sup>3</sup> and immune cells,<sup>4</sup> particularly some T cells and monocytes. Nipah can then cross the blood-brain barrier. The virus infects monocytes and a subset of T-lymphocytes.

## CLINICAL SIGNS

It may be asymptomatic in pigs, but it is usually a severe, fatal disease with respiratory or CNS signs. Affected weaners may have a temperature in excess of 40°C (104°F), with a harsh characteristic (but not pathognomonic) barking cough, mouth breathing, and poor exercise tolerance. There is hindleg weakness, thrashing, and recumbency, with head pressing, titanic spasms, and fits. In adults there may be sudden death, which is quite rare, and sometimes there are neurologic signs, such as pharyngeal muscle paralysis, frothy salivation, and drooping of the tongue. In experimental infections, piglets often only showed a mild temperature rise.<sup>4</sup>

## NECROPSY FINDINGS

There are few gross lesions. There may be lung consolidation and froth in the trachea. The lymph nodes may be enlarged. Histologically, there is a pneumonia and the presence of syncytia and multinucleated alveolar macrophages; if neurologic signs, there may be a nonsuppurative meningitis.

## DIAGNOSIS

Diagnosis is based on exposure to affected pigs or fruit bats; the presence of the harsh barking cough, which is said to be almost pathognomonic; and the nervous signs. Specimen collection and diagnostic assays have been reviewed,<sup>5</sup> but any handling of suspect material should be carried out in category 4 laboratories. It is possible to demonstrate the antigens in formalin-fixed material.

The virus can be demonstrated in the tissues using a tagged monoclonal antibody or RT-PCR. There is high sensitivity of qRT-PCR.<sup>6</sup>

For the presence of antibodies, blocking ELISAs are superior to virus neutralization.<sup>6</sup>

## TREATMENT

No treatment is available.

## CONTROL

Neutralizing antibodies appear 7 to 10 days postinfection<sup>7</sup> and reach a maximum at 14 to 16 days postinoculation.

It is necessary to keep the pigs on farms where there are no fruit bats nesting in trees. Isolation and quarantine are the best control methods, rapid slaughter of infected pigs is absolutely necessary, and other species must be kept away from infected farms.

## PORCINE RETROVIRUSES

All mammals have leftover traces of past viral infections in their genetic makeup.<sup>1</sup> Commercial pigs carry high and variable titers of retroviral RNA in their blood, with differences according to their age and herd health status. These endogenous retroviruses<sup>2</sup> may contribute up to 8% of the genome of all vertebrates.<sup>3</sup> All pigs carry endogenous porcine retroviruses (PRs) in their genome.<sup>4</sup> There may be an association between PRs and mortality in commercial herds.<sup>1,5,6</sup> The discovery that PRs can infect human cells triggered research into how xenotransplantation infection may be prevented.

## MENANGLE

Menangle virus was first identified in a three-farm disease outbreak in New South

Wales in 1997. It causes reproductive problems in pigs and congenital defects and has the fruit bat as an asymptomatic reservoir. It can cause a flulike disease in humans. Only one outbreak has been described. The virus normally lives asymptotically in fruit bats.

## ETIOLOGY

It is a RNA virus in the family Paramyxoviridae, probably in the genus *Rubulovirus*. It is closely related to Tioman virus found in fruit bats on Tioman Island, Malaysia.

## EPIDEMIOLOGY

A variety of fruit bats are seropositive, but the virus has not been isolated from them, including the gray-headed flying fox, black fruit bat, and spectacled fruit bat. These fruit bats have been found in other areas of Australia and the original area around Menangle, New South Wales.

Bat feces and urine are probably the source of infection. Transmission from pig to pig is slow and probably requires close contact. In one building, it took a long time for the sows to become affected. It probably spreads from farm to farm via infected animals. There is no sign of persistent infection and no evidence of long-term virus shedding. Present evidence suggests that virus survival in the environment is short because sentinel pigs placed in an uncleaned area did not seroconvert.

## CLINICAL SIGNS

Currently, there is no knowledge of the incubation period. In the initial outbreak, clinical signs were seen only on the farrow-to-finish farm, but infected pigs were found in all three farms.

The disease was an outbreak of reproductive disease with fetal death; fetal abnormalities, including congenital defects such as skeletal and neurologic defects,<sup>1</sup> mummified fetuses, and stillborn fetuses; smaller litters with fewer live piglets; and a reduced farrowing rate. The farrowing rate fell from 80%+ to a low of approximately 38%, reaching an average of 60%. Many sows returned to estrus 28 days after mating, which suggests that there has been an early death of the litter. Some sows remain in pseudopregnancy for more than 60 days. It probably crosses the placenta and spreads from fetus to fetus. Once the infection became endemic in the farrow-to-finish herd, the reproductive failures ceased.

## NECROPSY FINDINGS

The mummified fetuses vary in size and are of 30 days' gestation or older.

The virus causes degeneration of the brain and spinal cord. In particular, the cerebral hemispheres and cerebellum are smaller. Occasionally there may be effusions and pulmonary hypoplasia. Eosinophilic inclusions are found in the neurons of the cerebrum and spinal cord. Sometimes there is

nonsuppurative meningitis, myocarditis, and hepatitis. Experimental infections show shedding 2 to 3 days after infection in nasal and oral secretions. A tropism for secondary lymphoid tissues and intestinal epithelium has been demonstrated.<sup>2</sup> No lesions have been seen in piglets born alive or other post-natal pigs.

## DIAGNOSIS

The diagnosis is suspected when the reproductive parameters change very suddenly, as previously described.

Diagnosis is confirmed by virus culture, and electron microscopy (EM) and virus neutralization (VN) tests confirm the identity of the virus. Serologic tests include ELISAs, and the best way to test the herd is to use this for the sows for antibody.

## DIFFERENTIAL DIAGNOSIS

The differential diagnosis includes porcine parvovirus (PPV), classical swine fever (CSF), porcine reproductive and respiratory syndrome (PRRS), encephalomyocarditis virus (EMCV), pseudorabies virus (PRV), Japanese encephalitis, swine influenza virus (SIV), and blue eye. Noninfectious causes such as toxins or nutritional deficiencies should also be considered.

## TREATMENT

It seems likely that young pigs are infected by the virus when the maternal antibody falls at 14 to 16 weeks of age. By the time they enter the breeding herd, their immunity is quite strong.

## CONTROL

Avoiding contact with all fruit bats is the best advice.

## JAPANESE B ENCEPHALITIS (JAPANESE ENCEPHALITIS)

This is the most important of the encephalogenic flaviviruses. It causes in excess of 50,000 human cases a year, with a case-mortality rate of 25%. It causes reproductive failure in pigs.

## ETIOLOGY

It is a *Flavivirus* and is found in at least five genotypes.

## EPIDEMIOLOGY

The natural distribution range of the virus is Southeast Asia and Australasia. The vectors are *Culex* spp., in particular, *C. tritaeniorhynchus*. The virus activity is naturally maintained through bird-mosquito

cycles, with the Heron family in particular. The night herons, little egrets, and plumed egrets are particularly active as a reservoir. Pigs are important “amplifying hosts.” Pigs and these birds may allow the overwintering of the virus when mosquitoes are absent.

### **PATHOGENESIS**

Viremia results from the mosquito bite, and usually nothing is seen; occasionally there may be a mild fever, but quite often the virus goes straight to the testicles and causes orchitis.

### **CLINICAL SIGNS**

Fetal death is common, with mummified fetuses, stillborns, and weak pigs. Boars undergo reproductive failure.

### **NECROPSY FINDINGS**

Pathology is largely related to the abnormal fetuses.

### **DIAGNOSIS**

RT-PCR and nested RT-PCR can be used to detect the virus when virus isolation is negative. Antibody can be detected by hemagglutination inhibition (HI), ELISAs (IgM-capture ELISA), and latex agglutination tests.

### **CONTROL**

Live attenuated vaccines should be given to breeding stock 2 to 3 weeks before the start of the mosquito season. Killed and adjuvanted vaccines are also available.

### **FURTHER READING**

Mackenzie JS, Williams DT. The zoonotic flaviviruses of southern, south-eastern and eastern Asia and Australasia; the potential for emergent viruses. *Zoon Pub Hlth*. 2009;56:338.

### **RESTON VIRUS**

Reston virus, an *Ebolavirus*, was recently detected in pigs in the Philippines. Specific antibodies were found in the pig farmers, indicating exposure to the virus. In an experimental situation, pigs were infected with Zaire Ebola virus (ZEBOV), and it was found to replicate to high titers, mainly in the respiratory tract, and developed severe lung pathology.<sup>1</sup> Shedding from the oronasal mucosa was detected for up to 14 days after infection, and transmission was confirmed in all naïve pigs cohabiting with inoculated animals. These results confirm an unexpected site of virus amplification and shedding linked to transmission of infectious virus

### **REFERENCE**

1. Kobinger GP, et al. *J Infect Dis*. 2011;204:200.

### **BUNGOWANNAH VIRUS**

Bungowannah virus is possibly a new species of pestivirus that was found on a pig farm in

New South Wales, Australia. Sudden death was experienced by 3- to 4-week-old pigs, and at the same time, there was an increase in the number of stillborn piglets with multifocal nonsuppurative myocarditis and myonecrosis leading to a secondary congestive heart failure.

### **PORCINE PARVOVIRUS**

Usually parvoviruses are described with the acronym SMEDI, are associated with reproductive failure in pregnant sows, and are characterized by embryonic and fetal death, mummification, stillbirths, and delayed return to estrus. In other groups of postnatal nonpregnant pigs, the acute infection is usually subclinical, but it has been linked to skin lesions in piglets, interstitial nephritis in slaughter pigs, and nonsuppurative myocarditis in piglets. Tonsils are the main site of replication of the virus, but it also occurs in the heart, lungs, spleen, kidney, and endometrium. In the fetus, the replication is mainly in the heart, spleen, lung, and testis.

### **NOVEL PORCINE PARVOVIRUSES**

Several new members of the subfamily Parvoviridae have been discovered in animals, particularly pigs.<sup>1</sup>

The subfamily Parvoviridae infects birds and mammals. Two of the five genera in this group contain pig viruses. These are *Bocavirus* and *Parvovirus* genera, and recently the newly proposed genus *Hokovirus* may contain newly identified pig viruses.

The viruses are called porcine parvoviruses (PPVs). These new viruses are important because they have been associated with PCVAD,<sup>2-4</sup> or “high-fever” disease.<sup>5</sup>

PPV1 is ubiquitous in swine and is associated with reproductive disease.<sup>6</sup>

In 2001, a new parvovirus was discovered in Myanmar and called porcine parvovirus 2;<sup>5</sup> it is of a novel and distinct lineage. It was also recently isolated in Hungary,<sup>7</sup> and two strains were isolated in the United States.<sup>8</sup> This virus, like other parvoviruses and RNA viruses, has a high substitution rate in the capsid gene. These new viruses may not have the same protection following use of the old vaccines. PPV2 does not belong to any of the known clusters, has been found in swine serum, and has not been associated with any known disease. It was the second of the new viruses discovered and is now found worldwide.<sup>5,8</sup> Not much is known about porcine parvovirus 2 and disease, but on one Chinese farm the virus was detected 3 weeks before a severe respiratory disease outbreak. In one study, DNA was detected in the lung tissues from nursery pigs and grow-finish pigs. Porcine parvovirus 3 was found in Hong Kong and originally called *Hokovirus*.<sup>9</sup> PPV3 of the proposed *Hokovirus* genus has been found in both sick and healthy pigs<sup>10</sup> and was also

called partetravirus.<sup>11</sup> Coinfection with both PPV3 and PCV2 was shown in China and Hong Kong.<sup>3</sup> PPV4<sup>12</sup> and the porcine bocavirus<sup>13</sup> belong to the group. PPV4<sup>9</sup> was identified in association with PCV2. It is not clear whether it can cause disease on its own or whether it exacerbates PCV2 infections. It has been reported since in Asia, Europe, and Africa.<sup>1,7,14-16</sup>

A novel porcine parvovirus was identified in the lung lavage of a diseased pig coinfecting with PCV2.

In a recent study in Germany, it was shown that PPV1 through PPV4 strains were found in the tonsils of piglets,<sup>17,18</sup> and PPV1 and PPV4 were found in the hearts. A real-time PCR has been developed to detect and analyze virulent PPV loads in artificially challenged sows and piglets,<sup>19</sup> using a conserved region of the genome. Previous RT-PCR methods have used the VP2 gene.<sup>20,21</sup> Diagnosis is through use of PCRs, virus isolation, hemagglutination inhibition tests, and immunofluorescence. Anti-PPV antibodies occur in the fetus at about 56 to 70 days.

## **Multi-Organ Diseases Due to Protozoal Infection**

### **SARCOCYSTOSIS (SARCOSPORIDIOSIS)**

#### **SYNOPSIS**

**Etiology** *Sarcocystis* species. There are numerous species, with various carnivore species as their final host, but usually a specific intermediate host species.

**Epidemiology** High prevalence of infection in most areas. Source of infection is feces from carnivores. Primary definitive hosts include farm dogs and cats fed raw meat,

*Continued*

or other carnivores if they have access to ruminant carcasses.

**Clinical findings** Severity of disease is dose dependent. Most infections are subclinical. Abortion and depressed growth rate. Neurologic disease and ataxia in sheep. Severe infection in some species results in carcass condemnation.

**Clinical pathology** Anemia and elevated concentrations of enzymes in blood associated with tissue damage during acute disease.

**Lesions** Nonsuppurative encephalitis in sheep with neurologic signs. Nonsuppurative encephalitis, myocarditis, and hepatitis in aborted fetus. Cysts in carcasses in chronic cases.

**Diagnostic confirmation** Identification of parasite microscopically in biopsy or postmortem material.

**Treatment and control** No effective treatment. Amprolium or salinomycin may aid in control. Proper disposal of carcasses. Raw meat not to be fed to farm dogs or cats. Control of carnivores.

## ETIOLOGY

*Sarcocystis* species are cyst-forming coccidial parasites with indirect life cycles.<sup>1-3</sup> They are obligate two-host apicomplexan parasites. There are numerous species, each with omnivorous or carnivorous definitive hosts. One system of naming the species identifies the intermediate and definitive host in the name (e.g., *S. bovifelis*) and has been commonly used in the literature. However, currently the organisms are known by their original names. Table 21-5 shows the currently accepted name of *Sarcocystis* species of importance in agricultural animals and their definitive hosts.

## EPIDEMIOLOGY

### Occurrence

In all countries where there have been surveys, the prevalence of infection in cattle, sheep, and horses approaches 100%, with a lower, but significant, infection rate in swine.<sup>1</sup> Clinical disease is relatively rare.

### Source of Infection

*Sarcocystis* spp. have an obligatory prey-predator life cycle in which the definitive host is a predator or scavenger.<sup>1,2</sup> The **carnivorous definitive host** becomes infected by ingesting tissue from a suitable intermediate host that contains mature sarcocysts. Following ingestion, bradyzoites are released from the sarcocyst in the stomach and intestine, and they transform into micro- and macrogamonts. The microgamonts (male) mature to release microgametes, which fertilize the macrogamont to form a zygote and then an oocyst. Within the intestine, the oocyst sporulates to produce two **sporocysts**. The sporulated oocyst ruptures in the

**Table 21-5** Definitive and intermediate hosts for *Sarcocystis* spp.—associated infections in agricultural animals

Intermediate host	<i>Sarcocystis</i> spp.	Synonyms	Definitive host
Cattle	<i>S. cruzi</i>	<i>S. bovicanis</i>	Dog, wolf, fox, raccoon, coyote
	<i>S. hirsuta</i>	<i>S. bovifelis</i>	Cat
	<i>S. hominis</i>	<i>S. bovi hominis</i>	Humans
Sheep	<i>S. tenella</i>	<i>S. ovicanis</i>	Dog, coyote, fox
	<i>S. arieticanis</i>	—	Dog
	<i>S. gigantea</i>	<i>S. ovifelis</i>	Cat
	<i>S. medusiformis</i>	—	Cat
Goats	<i>S. capracanis</i>	—	Dog, coyote, fox
	<i>S. hericanis</i>	—	Dog
	<i>S. moulei</i>	—	Cat
Pigs	<i>S. miescheriana</i>	<i>S. suicanis</i>	Dog, raccoon, wolf
	<i>S. sui hominis</i>	—	Human
	<i>S. porcifelis</i>	—	Cat
Horses	<i>S. bertrami</i>	<i>S. equicanis</i>	Dog
	—	<i>S. fayeri</i>	
	<i>S. neurona</i>	—	New World opossums

intestine. Sporocysts (each containing four sporozoites) are passed in the feces and are directly infective to the intermediate host.

The prepatent period is variable, approximately 14 days, and there is no illness in the carnivore host in association with this cycle. However, the replicative cycle of the parasite in the intestine results in the production of large numbers of sporocysts in the feces, and the infection can be **patent for a relatively long period**. Intermediate hosts become infected by **ingesting sporulated sporocysts** in the food or water.<sup>1,2</sup>

### Risk Factors

#### Climate

Sporocysts develop and mature before excretion in feces, and they are quite resistant to environmental factors. Under experimental conditions, they can survive freezing, but they are susceptible to desiccation. Consequently, they might overwinter in the environment. Some studies have shown a lower herd prevalence of sarcocystosis in cattle in arid and semiarid environments compared with cattle from temperate and tropical areas, which might be a consequence of relative aridity and a lower density of definitive and intermediate hosts for *Sarcocystis* spp. in arid climatic zones.<sup>1</sup>

### Species of *Sarcocystis*

Individual species vary in their **pathogenicity** and in their ability to produce clinical disease in intermediate hosts. In cattle, for example, *S. cruzi* is considerably more pathogenic than *S. hominis*.<sup>1,2</sup>

*S. tenella* is the most pathogenic species of sheep, and *S. capricanis* for goats; naturally occurring clinical disease in sheep is not observed with *S. gigantea* or *S. medusiformis*.<sup>5</sup> There is a strong correlation between the number of sporocysts ingested and the

severity of disease. The size of the sarcocyst that occurs in the tissues of the intermediate host also varies with the infecting species. Those from cats and occurring in sheep (*S. gigantea*, *S. medusiformis*) or cattle (*S. hirsuta*) are of particular economic importance because they produce macroscopically visible sarcocysts that can result in meat condemnation. *S. cruzi* is pathogenic but produces microscopic sarcocysts in muscle and will escape gross detection at meat inspection.

### Farm Dogs

There is a positive association between herds infected with *Sarcocystis* and the presence of working dogs on a farm, the practice of leaving carcasses in the field, and the feeding of dogs with raw meat.<sup>1,2</sup> Virtually all reported clinical cases of sarcocystosis in cattle in the literature record that the dogs on a farm were fed offal or uncooked beef. Housing of dogs and cattle in the same shed or area can be linked to an increased risk for infection and clinical disease, and cattle pastured close to farm buildings where there are dogs are at greater risk. The presence of foxes on farms is also strongly associated with *Sarcocystis* infection in those herds that leave carcasses on the field.

### Cats

The main risk for cat-associated sarcocystosis is the farm cat that is fed raw meat. Farm cats use hay barns as dens and can contaminate hay and other feedstuffs.<sup>1,2</sup> Feral cats have the potential to distribute sporocysts widely in the grazing environment; however, the presence of feral cats on a farm may not increase the risk for *Sarcocystis* infection of cattle because scavenged sheep or cattle carcasses are a relatively unimportant part of the diet of feral cats.

### Stocking Density

The risk for infection with *Sarcocystis* is higher with higher stocking densities,<sup>4</sup> which might reflect a more intense contamination of pastures by working dogs. Cattle on farms that graze sheep and cattle on the same pastures are less likely to be infected.

### Economic Importance

The major economic loss occurs with those sarcocysts that produce macroscopic cysts and meat condemnation, although acute outbreaks of sarcosporidiosis have been reported. More severe infection can depress growth rates, and there is a greater risk for abortion in infected herds.

### PATHOGENESIS

In the intermediate host, sporozoites are released from ingested sporocysts in the small intestine, where they penetrate the mucosa and enter the endothelial cells of blood vessels. The schizogony stages and the distribution of merozoites vary according to *Sarcocystis* species, but in cattle endothelial infection is followed by **parasitemia**, with merozoites subsequently localizing in striated muscles (usually) or nervous tissue, where they develop into sarcocysts. Immature sarcocysts can be found in muscle 45 to 60 days following ingestion of sporocysts and are infective at approximately 70 days.<sup>2</sup>

Schizogony in the endothelial cells of the arterioles and capillaries results in **wide-spread hemorrhage** and anemia. Fever is associated with the parasitemia, and in the experimental disease it coincides with the time of maturation and rupture of schizonts.<sup>2</sup> The **vascular lesion** appears to be an essential part of the disease's pathogenesis. It has been proposed that the parasite produces growth retardation as a result of changes in plasma concentrations of somatostatin and growth hormone and changes in cytokine interactions with the endocrine system.<sup>1</sup>

The severity of the illness and the degree of infection of tissues at postmortem appear to relate to **infective dose**. The number of asymptomatic infections probably reflects the early ingestion of a few sporocysts that provoke a strong immunity to subsequent challenge. When groups of animals that have not been exposed to infection previously are suddenly exposed to large numbers of sporocysts, originating from dogs and cats, outbreaks of disease are likely to occur.

### CLINICAL FINDINGS

Infection and disease can occur at all ages. Clinical disease may be more severe in situations where there is **intercurrent nutritional stress**, and copper deficiency may be an exacerbating factor. Monensin is suspected of being able to potentiate recent infections to cause a severe myositis.<sup>1,2</sup>

### Cattle

**Acute illness** is recorded with experimental infections, but it is rarely seen or recognized in the field. Illness commences with a rise in temperature and heart rate, followed by anorexia, anemia, weight loss, a fall in milk production, nervousness, muscle twitching, hypersalivation, lameness, abortion, and, in heavy infections, death. The agent is an occasional cause of nonsuppurative encephalomyelitis in cattle and manifests with ataxia and recumbency.

**Chronic disease** in cattle is manifest by poor weight gains; loss of hair of the neck, rump, and the switch of the tail ("rat-tail"); anemia; and/or abortion.

### Sheep

In sheep, naturally occurring sarcocystosis has been associated with *S. tenella* and *S. arieticanis* and presents primarily as a **neurologic disorder**, with muscle weakness, trembling, ataxia of varying severity, followed by hindlimb paresis or flaccid paralysis and lateral recumbency. All ages of sheep can be affected, although lambs under 6 months of age are most susceptible.

Infection may also be manifest with depressed growth, reduced wool growth, and anemia. Less common manifestations include signs of congestive heart failure associated with endocardial and myocardial infection. Infestation of the muscle of the esophagus in sheep is thought to be a cause of **esophageal dysfunction** and regurgitation in sheep.<sup>1,2</sup>

### Swine

Disease does not seem to be associated with natural infections. Sarcocystosis produced experimentally in pigs is manifested by cutaneous purpura on the snout, ears, and buttocks, and dyspnea, tremor, and weakness or recumbency.<sup>1</sup> There is evidence that the breed of pig affects the severity of disease with experimental infections and also the subsequent severity of the parasite burden.

### Abortion and Perinatal Fatality

Fetal infection, with abortion or neonatal mortality, is recorded in both cattle and sheep when pregnant animals are infected experimentally or naturally with pathogenic species or strains.

### CLINICAL PATHOLOGY

Characteristic laboratory findings for systemic disease include a responsive anemia, a prolonged prothrombin time, and high titers of antibody to *Sarcocystis*. Blood creatine phosphokinase, lactic dehydrogenase, and aspartate aminotransferase are significantly elevated. Indirect hemagglutination (IHA) and ELISA tests can be used for serologic surveys, although there are limitations with the specificity immunologic assays. Many animals have been exposed to *Sarcocystis* spp., and serologic examination cannot

differentiate reliably current infection from past infection or exposure, and there are problems with serologic cross-reactivity.

### NECROPSY FINDINGS

Emaciation, lymphadenopathy, laminitis, anemia, and ascites can be present, but an obvious feature is the presence of petechial and ecchymotic hemorrhages throughout the body.<sup>2</sup> There are also erosions and ulcerations in the oral cavity and esophagus, likely as a result of microvascular damage. Cysts of *S. gigantea* on the esophagus of sheep are usually visible with the naked eye. Microscopically, schizonts are found in endothelial cells throughout the body, and hemorrhages, lymphocytic infiltration, and edema are observed in heart, brain, liver, lung, kidney, and striated muscle. Death is probably a result of the severe necrotizing myocarditis that occurs. There is an association between **eosinophilic myositis** and sarcosporidiosis, but this relationship is not proven in all cases.

In sheep presenting with **neurologic disease**, there may be no findings at gross postmortem examination, but a nonsuppurative encephalomyelitis is evident upon histologic examination.<sup>1,2</sup> Aborted bovine fetuses show nonsuppurative encephalitis, myocarditis, and/or hepatitis.

Different options are available to achieve a definitive diagnosis of the *Sarcocystis* species involved, including animal transmission studies, immunohistochemistry, electron microscopy, and/or PCR. Although such techniques are seldom used for routine diagnosis, there have been some efforts toward developing specific and sensitive molecular diagnostic tools.<sup>3-5</sup>

### Samples for Confirmation of Diagnosis

- **Histology**—formalin-fixed heart, skeletal muscle (several sites, and tongue, diaphragm, and masseter muscle) (light microscopy)

### DIFFERENTIAL DIAGNOSIS

Clinical diagnosis of disease can be difficult because of the nonspecific signs observed and the widespread prevalence of infection. Sarcosporidiosis is a consideration in the examination of problems of fever and anemia of undetermined origin in cattle and of ill-thrift in cattle or sheep.

The examination of muscle biopsies can aid in the determination of the presence of infection, but still begs the question of its relationship with disease.

The differential diagnoses for abortion are covered under brucellosis of cattle and sheep. Causes of encephalitis and ataxia in sheep are listed under those headings.

### TREATMENT

No approved treatment is available, but **amp-rolium** or **salinomycin** may relieve clinical

signs.<sup>1</sup> Amprolium 100 mg/kg BW, given daily, can reduce the severity of infection in experimentally infected calves and sheep and might be used to control outbreaks in sheep. Treatment of experimentally infected calves with salinomycin (4 mg/kg BW daily; in divided doses for 30 days) can reduce the severity of disease. Monensin may have a similar ameliorating effect, but is also suspected to exacerbate muscle lesions. Oxytetracycline, at very high dose rates, and halofuginone might be effective in acute infections.<sup>1</sup>

## CONTROL

Control is challenging because it involves the **separation of carnivores from stock**, which is not possible on most farms. However, infection in farm dogs and cats can be reduced if all meat fed to them is thoroughly cooked. Feral canids and felids should be controlled, and livestock carcasses should not be left on paddocks. Prior exposure to small numbers of pathogenic sarcocysts produces a strong immunity, but no vaccine is readily or commercially available.

## TOXOPLASMOSIS

### SYNOPSIS

**Etiology** *Toxoplasma gondii*.

**Epidemiology** Infection from the ingestion of oocytes excreted in the feces of cats. Any vertebrate can acquire infection from ingestion of different stages of *T. gondii*.

**Clinical findings** Abortion and stillbirths in ewes is the major veterinary manifestation; other manifestations can be neonatal mortality, encephalitis and/or pneumonia. Major importance as a zoonosis.

### Pathologic findings:

- Lesions**—granulomatous lesions in organs of all species, with abortions, placentitis, and focal necrotic lesions in brain, liver, and kidney of aborted fetus.

**Diagnosis** Detection of the parasite in tissues or tissue fluids. Serologic and DNA-based tests, which vary in diagnostic sensitivity and specificity.

**Treatment** Not usually indicated in livestock. Sulfamethazine and pyrimethamine in abortion outbreak.

**Control** Reduce exposure to infective stages, including oocysts. In pregnant sheep, prophylactic feeding of monensin or decoquinate; vaccination.

## ETIOLOGY

The causative agent *Toxoplasma gondii* is cyst-forming coccidian parasite (*Apicomplexa*). Felids (cat family) are **definitive hosts**, and vertebrates are intermediate hosts. Different strains can differ in their virulence and epidemiology.<sup>1,2</sup>

*T. gondii* has three infective stages:

1. Tachyzoites—rapidly replicating stage of the parasite during the acute phase of infection (endodyogeny) in the intermediate or accidental host
2. Bradyzoites—slowly replicating or dormant stage of the parasite (usually within a cyst or pseudocyst) during the chronic phase of infection in the intermediate or accidental host
3. Oocysts (containing sporocysts and sporozoites)—present in cat feces

Oocysts are the **infective stage** of importance in farm animals, and they are the only environmental infective stage for herbivores. Oocysts excreted in the feces of cats can survive in soil for months or years and are ingested by the intermediate (livestock) host. The parasite (sporozoite stage) invades any host cell, with the exception of nonnucleated erythrocytes, and undergoes tachyzoite replication (acute phase of infection). Any tissue (including nervous system, myocardium, lung tissue, and placenta) of the host or fetus can be infected and affected. An inoculum of as few as 10 oocysts can be infective to goats. Following the acute phase of infection, as host immunity develops, the replication rate decreases. The bradyzoites replicate slowly within cells and then stop replicating to become dormant within cysts ("tissue cysts" containing many bradyzoites). These cysts, containing live bradyzoites, are a source of infection to carnivorous or omnivorous animals (including pigs and humans).

## EPIDEMIOLOGY

### Occurrence

Toxoplasmosis occurs in domesticated and wild animals and birds in most parts of the world, although surveys indicate considerable variation in prevalence.<sup>2-4</sup> Although some studies indicate a relatively high seroprevalence in some farm animals, infection is often subclinical. With the exception of abortion and neonatal disease in sheep, *T. gondii* has limited importance as a cause of

disease in farm animals. *T. gondii* has major importance as a **zoonotic parasite**.

## Source of Infection

### Cat Feces

The source of infection in sheep, pigs, and other livestock is **oocysts** excreted in the feces from felids. In almost all agricultural areas, the feces originate from domestic or feral cats.

Cats become infected as a result of ingesting tissues from intermediate hosts infected with tachyzoites or bradyzoites (within cysts) and then shed oocysts in the feces. All vertebrates can act as intermediate hosts; rodents and small birds are common intermediate hosts for infection to cats. For instance, rodents pass the parasite from generation to generation through congenital infection and thus can provide a reservoir of infection in an area for a long time. Cats ingest infected rodents and develop an intestinal infection, leading to oocyst excretion into the environment. The prevalence of infection is highest in young cats hunting for the first time. Following infection of the cat, the period of excretion of oocysts is short, usually ~2 weeks, but it can be high, with several million oocysts being excreted during patency. In a given environment, the number of cats excreting oocysts in their feces at any point in time is likely to be quite small, but the contamination of the environment over time can be significant.

**Domestic and barn cats** in farm environments tend to nest and to defecate in hay and straw mows, grain stores, or loose piles of commodity feeds, thus providing the potential for direct contamination of livestock feeds with *T. gondii* oocysts.<sup>5</sup> Fields fertilized with manure and bedding contaminated with cat feces can also be a source of infection. **Feral cats** bury feces superficially in the soil, but contamination can spread, for example, via the elements or invertebrates, to pasture and be ingested by livestock. Feral cats can have territories of up to 250 acres and are capable of widely distributing oocysts of *T. gondii*.<sup>1</sup> Oocysts may be found in feed, water, and soil in the vicinity of livestock units.

### Other Sources

Oocysts are also an important source of infection to swine, although it is possible for swine to be infected by the ingestion of tachyzoites or bradyzoites present in meat (**dead rodents**, cannibalized piglets, etc.) or through the ingestion of blood while **tail- or ear-biting**. *T. gondii* infection has been shown in all wildlife mammalian species tested in the environment of swine units. Direct sheep-to-sheep transmission by close contact with grossly infected placenta and transmission via the semen of infected rams could occur but is not thought to be of significance. There is some evidence that *T. gondii* can be present in the placental tissue from sheep following

successful pregnancies, suggesting that congenital infection perpetuates infection in sheep flocks in the absence of cats.<sup>3</sup>

### Risk Factors

#### Pathogen Risk Factors

Oocysts are very resistant to external influences and can often survive in the environment for at least 1 year. They can **overwinter** in cold climates but are more susceptible to desiccation. Fifty grams of infected cat feces can contain as many as 10 million oocysts, and infection in farm animals can be established by the ingestion of fewer than 40 oocysts.<sup>1</sup> Oocysts are destroyed by exposure to high temperatures and freezing.

#### Environmental and Management Risk Factors

In sheep, a high rate of infection can relate to areas of **high rainfall**, allowing increased survival of oocysts on pasture. The prevalence of infection in small ruminants is much lower in hot, arid countries than in regions with wet climates.

Sheep raised in **cat-free areas** have almost no toxoplasmosis, whereas sheep raised in similar environments with cats can have a high level of exposure or infection.<sup>1</sup> In many recorded toxoplasmosis outbreaks with high prevalence rates in sheep and goats, there was a link to stored feed contaminated with cat feces. Cat access to sows is also a risk factor for toxoplasmosis in swine.<sup>4</sup>

Other management risk factors include **housing**. Swine housed outdoors can be at a greater risk for infection in some areas. Prevalence is low in sows that are kept indoors. Infected pork is a significant source of infection to humans, and the trend to outdoor rearing on free-range farms may increase the risk for human infection.

### Experimental Studies

#### Sheep

Experimental disease can be achieved by challenge with oocysts, tissue cysts, or tachyzoites.<sup>1</sup> Ewes may show a febrile response during the parasitemic phase 5 to 12 days following inoculation. Abortion and fetal mortality occur in sheep that suffer a primary infection during pregnancy. The parasite invades the placenta and can be detected in the fetus between 5 and 10 days following the onset of parasitemia. Infection may result in resorption, abortion, or the birth of stillborn or congenitally infected live lambs. Infection in early pregnancy (less than 60 days), before the fetus acquires immunologic competence, usually results in embryonic death and resorption and a barren ewe. Infection in mid-pregnancy usually results in abortion and the birth of stillborn lambs, whereas ewes infected in late pregnancy (more than 110 days) may give birth to live but congenitally infected lambs.

#### Cattle

Cattle are **relatively resistant** to infection.<sup>2</sup> Diarrhea, anorexia, poor weight gain, depression, weakness, fever, and/or dyspnea follow challenge infection of calves with pathogenic strains. Using strains of low virulence, there is a mild fever and lymphadenopathy, and the parasite is detectable only in the lymph nodes for only a few weeks. Adult cows are usually not susceptible to infection, and it is apparent that cattle do not readily acquire persistent *T. gondii* infection. *T. gondii* is not important in causing abortion or clinical disease in cattle. It is probable that many cases previously diagnosed as bovine toxoplasmosis were actually cases of neosporosis or sarcosporidiosis.

#### Other Ruminants

High numbers of oocysts fed to (susceptible) goats cause a febrile, anorectic, fatal illness and pregnant goats abort. The pathogenesis of the abortion is as for sheep. Disease in buffalo calves is described as peracute, with pulmonary consolidation, necrotic foci in all organs, and fluid accumulations in body cavities.

#### Pigs

Infection is relatively readily established in pigs,<sup>4</sup> but it is usually not associated with disease or only with a short period of fever and growth suppression. Congenital toxoplasmosis is not readily induced experimentally. Young pigs (less than 12 weeks of age) are considerably more susceptible than older pigs. Infections induced by tissue cysts are usually less severe than those induced by the ingestion of oocysts.

#### Horses

Horses appear to be **relatively nonsusceptible** to *T. gondii* and toxoplasmosis.

### Economic Importance

Abortion and neonatal mortality in sheep and goats are the major clinical manifestations of toxoplasmosis in livestock and result when primary infection occurs during pregnancy. Ovine abortion and neonatal mortality as a result of toxoplasmosis are important problems in New Zealand, Australia, Canada, the United States, and the United Kingdom; in most countries, they are second in importance only to chlamydial abortion. Perinatal mortality rates (including abortions and neonatal death) in affected flocks may be as high as 50%. Toxoplasmosis can be a primary cause of economic losses in flocks with an abortion problem. Toxoplasmosis of goats is also associated with mummification of fetuses and perinatal death.

### Zoonotic Implications

Humans are accidental intermediate hosts for *T. gondii*, and approximately one-half of the population in the United States is infected.<sup>1</sup> Infection can result from the

ingestion of oocysts from cat feces that contaminate waterways or food, that contaminate the hair of domestic dogs and cats, or that are inadvertently ingested because of poor hygiene practices. However, the major risk for human infection relates to the ingestion of bradyzoites and/or tachyzoites in **meat** or tissues that are eaten or handled. The risk is with raw or undercooked meats. Adequate freezing and/or cooking will kill the parasite. Beef is a minor source of infection, with pork and, to a lesser degree, sheep meat posing a greater risk. Tachyzoites can be passed in the milk of goats challenged with oocysts; **raw goat milk** has some public health risk for toxoplasmosis, although the risk is low.

Usually, *T. gondii* infection in immunocompetent humans is asymptomatic. However, disease can occur in people suffering from **AIDS** or malignancy, in those treated with cytotoxic or immunosuppressive drugs, and in children and the elderly. There is also the risk in **pregnant women** for abortion or congenital infection of the fetus with resultant hydrocephalus, intracranial calcification, and retinochoroiditis. Maternal infection in the first and second trimesters may result in severe congenital toxoplasmosis and death of the fetus in utero and subsequent abortion. Infection late during pregnancy may result in the birth of an apparently normal child who is at risk of developing chorioretinitis later in life.

Toxoplasmosis poses an **occupational risk** for veterinarians, farmers, and slaughterhouse workers who handle infected tissues, such as placenta, brain, or muscle. For instance, the risk can be high during contact with lambing ewes in infected flocks; veterinarians and farm workers, particularly if pregnant or immunocompromised, should take precautions to avoid infection when handling infected material.

### PATHOGENESIS

*T. gondii* is an **intracellular parasite** that attacks most tissues and organs, with predilection for the **reticuloendothelial and central nervous systems**.<sup>2-4</sup> Sporozoites from oocysts or bradyzoites from tissue cysts invade and penetrate cells of the intermediate host by an active process and then replicate as tachyzoites, initially in intestinal epithelial cells. After invasion of various cell types, the tachyzoites multiply (rapidly during endodyogeny) and eventually fill and destroy cells. Following their release from ruptured cells, liberated tachyzoites reach other organs via the bloodstream. **Parasitemia** commences ~5 days following infection and declines with the development of immunity 2 to 3 weeks after infection. At this stage, the parasite undergoes bradyzoite replication within cells/tissues to produce tissue cysts.

The presentation of disease varies depending on the organ(s) affected and on

whether the disease is congenital or acquired. The principal manifestations are encephalitis when infection is **congenital** and febrile exanthema with pneumonitis and enterocolitis when heavy infections occur **postnatally**. However, most infections are asymptomatic; tissue cysts can be found in many animals and appear to cause no harm. When the immunity of the animal declines, because of stress, disease, immunosuppressive therapy or an immunocompromised state, tissue cysts can rupture, and granulomatous lesions can develop. Immunodeficient or immunocompromised animals can develop severe disease.

### Pregnant Sheep and Goats

Abortion and fetal mortality occur in sheep or goats that contract a primary infection during pregnancy. In the dam, the infection is limited by a developing immune response, but it is not limited in the placenta or in the immuno-incompetent fetus. The fetus, and the ability of the fetus and its associated placenta, to mount a protective response depend on the age of the fetus at the time of infection.

**Immunocompetence against *T. gondii*** does not usually develop before 60 days of gestation. Infection in early or midpregnancy results in fetal death, with resorption or mummification. Some lambs infected in midpregnancy may survive to near term and be stillborn, or they may survive to parturition but are weak and die shortly after birth. Parasite replication in the placenta results in multiple foci of necrosis, and these lesions likely contribute to abortion or to the birth of weak lambs. In addition, congenital infection of the central nervous system may result in locomotory and sucking dysfunction. Only sheep that become infected during pregnancy abort. With infection in late pregnancy, the fetus can mount an immune response and is usually born live, infected, and immune. Infection of pregnant and nonpregnant sheep usually provokes sufficient protective immunity to prevent abortion in future pregnancies.

### CLINICAL FINDINGS

The clinical syndrome and the course of toxoplasmosis vary a great deal among species and among age groups.<sup>3-5</sup> The only clinical syndrome recognized with any regularity in the field is abortion and neonatal mortality in sheep. The other, less common, syndromes are described in the following subsections.

#### Sheep

In sheep, although a syndrome of fever, dyspnea, generalized tremor, abortions, and stillbirths can occur,<sup>3</sup> the clinical manifestation of the systemic disease in the ewe is rare. The principal manifestations of toxoplasmosis in sheep are fetal resorption, abortion, the birth of mummified or stillborn lambs,

neonatal death, and the birth of full-term lambs that show locomotor and sucking disorders.

Abortion commonly occurs during the last 4 weeks of pregnancy, and the rate may be as high as 50%. Full-term lambs from infected ewes may be born dead, or alive but weak, with death occurring within 3 to 4 days of birth. Lambs affected after birth show fever and dyspnea, but a fatal outcome is uncommon. Fetal resorption can occur in ewes infected in early pregnancy.

#### Goats

Toxoplasmosis of sheep and goats is similar. Caprine toxoplasmosis is manifested by perinatal deaths, including abortion and stillbirth. Systemic disease, with a high case-fatality rate, can occur, particularly in young goats.

#### Pigs

Pigs are **susceptible**. If an outbreak occurs, pigs of all ages can be affected.<sup>4</sup> Clinical signs include debility, weakness, incoordination, cough, tremor and/or diarrhea, but no fever. Young pigs can be acutely ill, with a high fever of 40° to 42°C (104–107°F); they develop diarrhea and can die after several weeks. Pigs of 2 to 4 weeks of age have additional signs, including wasting, dyspnea, coughing, and nervous signs, particularly ataxia. Pregnant sows commonly **abort**; piglets are premature or **stillborn**, or they survive and can develop disease at 1 to 3 weeks of age. Toxoplasmosis should be considered in the case of a resident problem of abortion and stillbirth in a pig herd.

#### Cattle

Rare bovine toxoplasmosis may be manifested in fever, dyspnea, and nervous signs, including ataxia and hyperexcitability, in the early stages, followed by extreme lethargy. Stillborn or weak calves that die soon after birth may also occur. However, usually, toxoplasmosis does not play a significant role in bovine abortion. Congenitally affected calves can show fever, dyspnea, coughing, sneezing, nasal discharge, clonic convulsions, grinding of the teeth, and/or tremor of the head and neck. Death can occur after 2 to 6 days.

#### Horses

Toxoplasmosis is **rare** in horses.

### CLINICAL PATHOLOGY

**Serologic tests** available for the detection of humoral antibodies to *T. gondii* include the Sabin–Feldman dye test, the indirect hemagglutination assay, the indirect fluorescent antibody test (IFAT), the modified agglutination test (MAT), the latex agglutination test (LAT), the enzyme-linked immunosorbent assay (ELISA), and the immunosorbent agglutination assay test (IAAT).<sup>2-4</sup> Serologic tests are commonly used to estimate the seroprevalence of *T. gondii* exposure or

infection in animal populations, but their **sensitivity and specificity can vary** considerably depending many factors, including the actual assay used and the species of animal being tested.

### Abortion

**Serologic testing** to establish toxoplasmosis as the cause of abortion is of limited value. A test-negative titer will likely rule out toxoplasmosis, but because serum antibody can persist for some years, a test-positive titer will only indicate that an animal has been exposed to or infected with *T. gondii* at some stage of its life. Seroprevalence can be high in sheep and swine. **Rising titers** in paired samples are more informative but are likely of limited value for the diagnosis of *T. gondii*-related abortion in sheep, where infection and serum antibody responses may precede the abortion storm. It is informative to test **pleural or peritoneal fluid** of aborted fetuses for the presence of antibody or nucleic acids of *T. gondii*. PCR assays can be used to specifically detect or quantitate *T. gondii* DNA or RNA in infected fetal and any other tissues from suspected cases.

### NECROPSY FINDINGS

Macroscopic lesions consist of **multiple foci of necrosis in various organs**, including the lungs, brain, spinal cord, liver, spleen, kidneys, and heart. Interstitial pneumonia hydrothorax, ascites, lymphadenitis, and intestinal ulceration may be observed. Microscopically, foci of **coagulative necrosis** are present, with little evidence of inflammation, except in the lungs, where there is interstitial pneumonia, and in the nervous system, where there is usually nonsuppurative meningoencephalitis. Stages (tachyzoites, bradyzoites, and/or cysts) of *T. gondii* can be found in the viscera and/or brain.<sup>11,12</sup>

### Abortion

In **sheep**, there may be involvement of the uterine wall, the **placenta**, and the fetus. The lesions in the fetal lambs are usually limited to focal necrosis in brain, liver, kidney, and lungs; characteristic lesions are common and severe in the **placenta**.<sup>1</sup> The lesions are confined to the cotyledons and consist of **multiple white foci of necrosis in the villi**. On histologic examination, there is multifocal necrosis and desquamation of trophoblastic epithelium, sometimes with calcification. *T. gondii* stages can be found in the placenta and other organs.

In **swine**, the prominent lesions are necrotic placentitis, nonsuppurative encephalomyelitis, and/or myocardial degeneration. In contrast to sheep, grossly visible areas of necrosis are not present in the placenta, but numerous organisms may be visible on microscopic examination of the placenta.

Immunohistochemical staining can be used to identify the parasite in formalin-fixed material. Serologic testing of fetal

thoracic fluid can be useful in those fetuses that are immunocompetent at the time of abortion. PCR can be used for the specific detection of *T. gondii* DNA in tissues and can be used on autolyzed tissue.<sup>2-4</sup> On rare occasions, a diagnostic bioassay can be performed to induce infection and propagate the parasite in specific-pathogen-free (SPF) rodents, which is a very sensitive but time-consuming method. Aseptically collected brain, lung, and diaphragm is homogenized and administered orally, or by intraperitoneal or intracerebral injection to mice, or orally to SPF cats. A positive diagnosis depends on the presence of *T. gondii* cysts in the brains of the mice ~8 weeks after the inoculation or the excretion of oocysts in the feces of infected cats. Cats are a more sensitive assay because of the volume of tissue that can be tested. The mouse bioassay is useful to propagate *T. gondii* for subsequent molecular or genetic analyses or in vitro experiments.

### Samples for Diagnostic Testing

- **Parasitology**—fresh or chilled brain, lung, placenta
- **Serology**—fetal thoracic fluid
- **Histology**—placental cotyledons, lung, liver, brain, spinal cord, kidney, heart

### DIFFERENTIAL DIAGNOSIS

Toxoplasmosis is rarely considered in a primary diagnostic list other than with problems of abortion and associated neonatal mortality. The differential diagnosis of abortion in cattle is dealt with under brucellosis, in sheep under brucellosis, and in pigs under leptospirosis. The causes of encephalitis and pneumonitis in animals are listed under respective headings.

### TREATMENT

Treatment with a combination of sulfamethazine and pyrimethamine (administered over 3 days for three periods with an interval of 5 days between the start of each treatment period) has proved effective in mitigating the effects of experimentally induced toxoplasmosis in pregnant ewes. This therapy should be considered in the face of an outbreak of abortion associated with toxoplasmosis.<sup>1</sup> These drugs appear to be effective against proliferating tachyzoites in the acute stage of toxoplasmosis, but they will not eliminate infection and will have limited activity on bradyzoites within tissue cysts.

### CONTROL

There are two key issues in the control of toxoplasmosis in agricultural animals. The first is to reduce the economic impact of disease; the second is to reduce the risk for human disease associated with consumption of infected meat.

### Cat Control

The elimination of cats from the farm environment will preclude feed contamination

and contamination of pasture areas. Although it is possible to **ban domestic cats** from the farm, this will not usually eliminate the risk of toxoplasmosis because of the range of activities of cats from adjacent areas, the presence of feral cats, and the possibility of spread of oocysts.<sup>5</sup> Nevertheless, risk of infection/disease will be reduced by eliminating cats from the farm environment or restricting them to **neutered** animals. Where **possible, feeds should be stored in cat-proof areas**. In swine units, rodent control and preventing the access of pigs to any **carcass** are key measures. On farms, any animal carcass or material (e.g., placenta and fetus) linked to suspected or confirmed cases of toxoplasmosis should be eliminated immediately.

### Serologic Monitoring

Serologic testing can be used to estimate seroprevalence and seroconversion in sows housed indoors and outdoors, and it may assist in assessing whether changes need to be made to farm management practices. Such testing can also be employed to assess seroprevalence and monitor specific antibody titers in sheep to support a risk management strategy against toxoplasmosis and to assess whether antitoxoplasmal drugs or vaccination should be implemented for prevention/protection.

There is an effective and long-lasting immunity following primary *T. gondii* infection, and ewes that have aborted should be kept in the flock. Exposure of ewes to natural infection in a contaminated environment before breeding would be possible means of preventing toxoplasmosis but is difficult to control.

### Prophylaxis

Feeding **monensin** at a dose of 15 mg/animal per day during the first 100 days of pregnancy has been shown to reduce lamb loss following experimental infection with *T. gondii*, as has decoquinate fed at 2 mg/kg daily.<sup>1</sup> **Decoquinate** is more palatable and has less risk of toxicity. Preventative medication offers an option for ewes that are test-negative for anti-*T. gondii* serum antibodies and likely to be exposed in pregnancy to feed, water, or an environment contaminated with oocysts. Both drugs are best fed to ewes before they encounter infection and are not effective as therapeutic agents.

### Vaccination

Tachyzoites from an attenuated strain of *T. gondii* are used in a vaccine to protect sheep, which is available commercially in some countries.<sup>3,6-8</sup> Such tachyzoites readily infect seronegative sheep but do not initiate chronic infection or tissue cysts, and the parasite cannot be detected in muscle or brain 6 weeks after vaccination. Ewes should be vaccinated at least 3 weeks before mating, and a single injection will protect for the life of the

sheep. In flocks where toxoplasmosis is a cause of lamb loss, initial vaccination of the whole flock, followed by vaccination of replacement ewes, is a better economic option than only vaccinating replacement ewes.<sup>3</sup> Vaccination does not completely protect pregnant ewes against parasitemia or the infection of the fetus following challenge with virulent *T. gondii* oocysts, but there is a significant reduction in the birth rates of dead lambs. It has been postulated that vaccination results in reduced numbers of tachyzoites invading the gravid uterus or fetus, with a consequent reduced potential for inducing significant pathologic changes in the placenta and the fetus. Immunity appears to be cell mediated. Experiments with an adjuvanted vaccine in pigs show protection from clinical challenge and a reduction in recoverable *Toxoplasma* from tissues of vaccinated challenged pigs.<sup>1</sup>

### Reduction of Zoonotic Risk From Food and Water

Oocysts from cat feces are an important source of human infection, as is meat from sheep, swine, and sometimes from other livestock animals that are infected with tachyzoites or bradyzoite cysts.<sup>2</sup> The implementation of control procedures on farms will reduce infection risk, and the major aspect will be to reduce the numbers of cats on farms or eliminate them. The infectivity of meat can be destroyed by freezing, proper cooking, or irradiation. Reviews of other strategies for the control of food-borne toxoplasmosis are readily available.<sup>9,10</sup>

## THEILERIOSES

Theilerioses are those tick-borne protozoan diseases associated with *Theileria* spp. in cattle, sheep, goats, and horses and in wild and captive ungulates. The genus *Theileria* belongs to the Apicomplexa group, which includes *Babesia*, *Toxoplasma*, *Neospora*, and *Plasmodium*, among others. The life cycle of *Theileria* spp. involves cyclical development in ticks to form sporozoites; on being injected with tick saliva into the mammalian host, sporozoites develop into schizonts in leukocytes and then piroplasms (merozoites) in erythrocytes. The diseases in ruminants are characterized by fever and lymphoproliferative disorders and are associated with varying degrees of leucopenia and/or anemia.

*Theileria* spp. are found throughout the world, and their nomenclature and classification, although still controversial, are being gradually elucidated through molecular characterization. The important pathogens of cattle are restricted to certain geographic regions after which the diseases are named (Table 21-6). **East Coast fever** (ECF), caused by *Theileria parva*, and **tropical theileriosis (or Mediterranean Coast fever)**, caused by *T. annulata*, are the two most important theilerioses and are dealt with separately in the following discussion.

**Oriental theileriosis (or Japanese theileriosis)** caused by *T. orientalis* is increasingly being associated with disease outbreaks

in Asia and Australia. Molecular analysis has revealed four genotypes of *T. orientalis* (ikedai, chitose, buffeli, and type 5), with the ikeda genotype being the most pathogenic.<sup>1</sup> The disease is transmitted by *Haemaphysalis* ticks, which occur in Europe, the Mediterranean basin, Asia, and Australia. In addition, transplacental (vertical) transmission from pregnant cows to calves has been reported in some countries.

Oriental theileriosis is characterized by moderate to severe anemia in heavily parasitized cattle and moderate enlargement of lymph nodes. Outbreaks of more severe clinical signs and economic losses have been reported occasionally from India, Australia, and New Zealand.<sup>2-4</sup> Such outbreaks are characterized by severe anemia and heavy parasitemia, especially in European breeds of cattle, in their crossbreds, or in naïve animals moved to endemic areas. Affected animals show high fever, lacrimation, nasal discharge, swollen lymph nodes, and hemoglobinuria.<sup>2</sup> Abortion, significant loss in milk production, and deaths were reported in the Australian outbreaks.<sup>3-6</sup> Postmortem lesions include punched-out ulcers in the abomasum, enlargement of the spleen, and massive pulmonary edema, as in East Coast fever and Mediterranean Coast fever (see following discussion).

The pathogenesis of the anemia and hemoglobinuria in oriental theileriosis is not clear but may be related to a hemolytic factor in the serum of acutely affected cattle or to an oxidative damage of the red blood cell membrane leading to hemolysis, as in ovine malignant theileriosis (see following discussion).<sup>7</sup> European breeds are more susceptible than zebu breeds.

Methods of diagnosis include parasitologic, serologic, and PCR assays.<sup>8</sup> In one study involving beef cattle in Australia, prevalence of infection was 28.1% by parasitologic method and 70.8% by PCR assay employing a region within the major piroplasm surface protein (MPSP) gene as marker.<sup>5</sup> With such high infection rates in clinically normal animals, it is important that calves used for the production of live vaccines against babesiosis and anaplasmosis should be free of oriental theileriosis. In Australia, concurrent treatment with primaquine phosphate and halofuginone lactate is effective for this purpose.

*T. mutans*, confined to Africa and the Caribbean islands, causes a usually innocuous disease (**benign theileriosis**), but it may be manifested by fever, anorexia, and anemia. Some genotypes of *T. orientalis* are also associated with subclinical infections in Asia and Australia. Another species, *T. velifera*, is associated with very mild theileriosis in tropical Africa. *Amblyomma* ticks transmit both species. *T. taurotragi* of the eland antelope is generally nonpathogenic to cattle, but it is one of the causes of **cerebral theileriosis (turning sickness)** in southern Africa (cerebral theileriosis can also be associated with *T. parva*). Parasitized lymphoblasts accumulate in cerebral, spinal, and meningeal arteries, with resultant thrombosis and infarction of affected organs. *T. taurotragi* is transmitted by *Rhipicephalus* spp.

The important pathogen of sheep and goats is *T. hirci* (synonym *T. lestoquardi*), the cause of **malignant ovine theileriosis**. The disease is enzootic from North Africa throughout the Middle East to India and China, approximately the same geographic

**Table 21-6** Summary of the theilerioses of domestic ruminants

Disease	Distribution	<i>Theileria</i> spp.	Main vector
<b>Cattle</b>			
East coast fever	East and central Africa	<i>T. parva</i>	<i>Rhipicephalus appendiculatus</i>
Turning sickness (cerebral theileriosis)	Southern Africa	<i>T. parva</i> , <i>T. taurotragi</i>	<i>Rhipicephalus</i> spp.
Tropical theileriosis (Mediterranean coast fever)	Mediterranean countries Indo-China	<i>T. annulata</i>	<i>Hyalomma anatolicum</i>
Oriental theileriosis (Japanese theileriosis)	Asia, Australia	<i>T. orientalis</i> (genotype ikeda)	<i>Haemaphysalis</i> spp.
Benign theileriosis	Africa/Caribbean Africa Asia	<i>T. mutans</i> <i>T. velifera</i> <i>T. buffeli</i> <i>T. sergenti</i>	<i>Amblyomma</i> spp. <i>Amblyomma</i> spp. <i>Haemaphysalis longicornis</i> / <i>H. punctata</i>
Sheep and goats			
Malignant ovine theileriosis	North Africa, Middle East, India	<i>T. hirci</i> ( <i>T. lestoquardi</i> )	<i>Hyalomma</i> spp./ <i>Haemaphysalis</i> spp.?
Benign theileriosis	Worldwide	<i>T. ovis</i>	<i>Rhipicephalus</i> spp.?
<b>Horses, other equidae</b>			
Equine theileriosis	East and South Africa Worldwide	<i>T. separata</i> <i>T. equi</i>	<i>Rhipicephalus</i> spp. <i>Boophilus microplus</i> , <i>Rhipicephalus</i> spp., <i>Hyalomma</i> spp.

region as bovine tropical theileriosis. Malignant theileriosis in sheep and goats is similar to bovine tropical theileriosis as a result of *T. annulata*. Like the latter, it is also transmitted by *Hyalomma* spp., but in China, the main vector is *Haemaphysalis* spp. The disease can be acute, subacute, or chronic, depending on the resistance of the sheep or goats, and is seasonal, depending on availability of ticks. The acute disease is characterized by fever and very high mortality in 3 to 6 days. Anemia, jaundice, and enlargement of lymph nodes are characteristic, and both piroplasms and schizonts can be demonstrated in smears of blood and tissues, respectively. The anemia is severe, progressive, and hemolytic and is associated with oxidative damage.<sup>7</sup> In subacute and chronic cases, signs are generally less marked except for anemia and emaciation. An indirect fluorescent antibody test is available and parasites can be identified by PCR methods. Parvaquone and buparvaquone may be used to treat early cases. **Benign ovine theileriosis** is caused either by *T. ovis* or by *T. separata*, *T. luwenshuni*, or *T. uilenbergi*.<sup>9</sup> Piroplasms are found in blood, but there are no overt clinical signs.

Equine theileriosis is caused by *Theileria equi* (formerly *Babesia equi*) and has been reported from all continents, including North America, where it has reemerged as a persistent subclinical infection of horses in the United States.<sup>10</sup> The term *equine piroplasmosis* is used to refer to *T. equi* infection alone or concurrently with *Babesia cabali*. Horses, donkeys, camels, and zebras are affected. Transmission is by *Boophilus microplus*, *Rhipicephalus* spp., and *Hyalomma* spp. In addition, transplacental transmission from mare to foals is quite common. The disease is generally a benign form of theileriosis detected during routine blood examination or through serology and molecular techniques (PCR). Treatment with imidocarb dipropionate is largely successful in eliminating carrier state and transmission risk in nonendemic countries.<sup>10</sup>

In summary, the pathogenesis of various forms of theileriosis is dependent on the production of schizonts in lymphocytes and piroplasms in erythrocytes. Thus *T. parva*, *T. annulata*, and *T. hirci* produce numerous schizonts and piroplasms and are very pathogenic; *T. orientalis*, *T. mutans*, and *T. ovis* rarely produce schizonts but may cause varying degrees of anemia when piroplasms are many in red blood cells; and with *T. velifera* and *T. separata*, no schizonts have been described, the parasitemia is usually scanty, and the infection is mild or subclinical. Transmission is from tick saliva to the mammalian host, but cases of transplacental infection have been reported rarely for *T. orientalis* and more frequently for *T. equi*.

## EAST COAST FEVER (ECF)

### SYNOPSIS

**Etiology** *Theileria parva*, an Apicomplexa protozoon. Vector is *Rhipicephalus appendiculatus* and, rarely, *R. zambeziensis*.

**Epidemiology** Endemic disease of cattle in East and Central Africa; high mortality and great economic importance.

**Clinical signs** Fever, enlarged superficial lymph nodes, dyspnea, wasting, and terminal diarrhea.

**Clinical pathology** Schizonts in lymphoblasts, piroplasms in erythrocytes, serology.

**Lesions** Massive pulmonary edema, hydrothorax, hydropericardium, emaciation, hemorrhages, lymphadenopathy, and widespread proliferation of lymphoblastoid cells.

### Differential diagnosis list

- Trypanosomosis/babesiosis/anaplasmosis
- Heartwater
- Malignant catarrhal fever/bovine virus diarrhea/rinderpest

**Treatment** Limited success with halofuginone, parvaquone, and tetracyclines.

**Control** Integrated approach involving resistant animal breeds, strategic application of acaricides, and vaccination by infection-and-treatment methods.

## ETIOLOGY

East Coast fever is caused by *Theileria parva* transmitted by ticks. The genus *Theileria* belongs to the apicomplex group (see “*Theilerioses*”). There has been considerable naming and renaming of *T. parva* and the associated diseases in Africa. “Classic” East Coast fever (ECF) occurs in East Africa and is associated with *T. parva* transmitted from cattle to cattle by the brown ear tick, *Rhipicephalus appendiculatus*. ECF also occurs either as **corridor disease** in eastern and southern Africa or as **January disease** in central Africa. Corridor disease is transmitted from buffalo to cattle by either *R. appendiculatus* or *R. zambeziensis*, and the agent responsible used to be called *T. parva lawrencei*. Close contact between buffalo, cattle, and ticks is essential. The disease is more acute than classical ECF, but after serial passage in cattle, it is indistinguishable from classical ECF. January disease occurs mainly between January and March, and the agent was named

*T. parva bovis*. The disease is also more acute than classical ECF, with death sometimes occurring within 4 days. These three clinical diseases are otherwise indistinguishable from one another, and hence the causative agents are currently referred to simply as *T. parva*.

## EPIDEMIOLOGY

### Occurrence

ECF affects mainly cattle but also buffalo, and occurs in 13 countries in eastern, central, and southern Africa. Its occurrence is related to the distribution of the vector tick, which has been recorded from large areas extending from southern Sudan in the north to western Zambia and eastern Zaire in the west, and to Mozambique and Zimbabwe in the south. The disease is prevalent throughout the wetter areas favoring the development of the tick, but is absent from the wet highlands in the horn of Africa. An outbreak was reported in the Comoros following importation of immunized cattle from Tanzania.<sup>1</sup> The disease has been eradicated from southern Africa up to the Zambezi River. The endemic scenarios range from a stable situation with high prevalence of herd infection but low fatality rates (endemic stability) to a low-prevalence/high-fatality scenario (endemic instability). Endemic stability develops in indigenous zebu cattle exposed to constant tick challenge, such as those in wetter areas, whereas endemic instability is seen with commercial production systems utilizing imported breeds or crossbreeds and in areas with a unimodal rainfall pattern that restricts tick activity. Epidemics occur when there is a breakdown in tick control, especially during the rainy season or when susceptible animals are introduced into an endemic area.

### Morbidity and Case Fatality

All susceptible cattle in endemic areas are at the risk of contracting ECF unless they are vaccinated or the tick population is under stringent control. The morbidity and case-fatality rates are very high, approaching 90% to 100% in recently introduced exotic (*Bos taurus*) breeds and in previously unexposed or naive indigenous cattle. However, indigenous zebu cattle (*Bos indicus*) and African buffalo in endemic areas have a strong resistance to the disease, and calfhood mortality is around 5%.

### Methods of Transmission

The vector of ECF is *Rhipicephalus appendiculatus*; in the field, the disease occurs only where this tick is found, except for corridor disease, which may be transmitted by *R. zambeziensis*. Other species of *Rhipicephalus* and *Hyalomma* spp. can transmit ECF experimentally, but they are not significant. Developmental stages of the parasite occur in the tick, and they pass transstadially through the stages of larva, nymph, and adult, but there

is no transovarian transmission. Consequently, larvae or nymphs become infected and transmit infection as nymphs or adults, respectively. Adults are more efficient vectors than nymphs but each developmental stage results in amplification of the vector's competence in parasite transmission and the ability to infect more than one host during the life cycle of the tick.<sup>2</sup> Infected ticks start transmission of the parasite from 72 hours postattachment,<sup>3</sup> and mechanical transmission is of no significance. The epidemiology of the disease is thus largely dependent on the distribution and habitat of the tick and its ability to complete development to the adult stage, usually during the rainy season. Ticks may live for 1 to 2 years, but they lose their infection within 11 months.

### Risk Factors

The most important risk factors relate to the presence of the brown ear tick in a given area and the level of tick burden per animal, even though it takes only one tick to establish an infection that could be fatal. At low infestation rates, an average of five ticks per head (two to three per ear) will sustain endemicity; one to four per head will invite epidemicity, whereas an average of less than one can allow sporadic outbreaks. In addition, there is evidence that *R. appendiculatus* populations that originate from eastern Africa tend to become more highly infected with *T. parva* than those that originate from southern Africa, and consequently the disease they transmit is more virulent.

The infection rate in ticks in endemic areas is usually low (1% to 2%), even though the immunity conferred on recovered or vaccinated animals is no longer thought to be sterile. However, soon after ECF becomes established in susceptible herds, infection rates in ticks become much higher.

Young animals are less susceptible, and indigenous breeds and buffaloes are less clinically affected than exotic breeds, but buffaloes are the carriers of corridor disease. Other wild *Bovidae* may help to sustain the population of the tick vector but are not carriers of *T. parva*. Asiatic or water buffalo are fully susceptible.

### Environmental Factors

In eastern Africa, *R. appendiculatus* normally occurs in grass-covered savannah and savannah woodlands, but it is usually absent from extensive heavily wooded forest habitats. Areas that are too high, too cold, or too dry will not allow the tick to undergo more than one life cycle in a year, thereby reducing the period of transmission of theilerial parasites by the nymphs or adults. For example, the disease is most prevalent in eastern Africa, where adult and immature stages of the tick occur simultaneously on cattle, leading to rapid and continuous transmission. In southern Africa, by contrast, there is a seasonal life cycle for the tick, and thus

there is little overlap between the activity periods of adults (January to March) and immature stages, thereby reducing the frequency of disease transmission.

### Immune Mechanisms

Cattle recovering from ECF have a solid immunity to homologous challenge, but the immunity is not sterile. In endemic areas, premunity is established early, and this provides lifelong protection if reinfection continues and the cattle are not moved to a different location where they may be exposed to a different strain of the parasite. Indigenous cattle are able to limit explosive multiplication of schizonts during the acute phase. Nutritional or climatic stress may seriously reduce the animal's premunity, even among resistant breeds. Although antibody responses to the sporozoite may play some part in protection, immunity is mediated mainly by cellular mechanisms involving cell-mediated cytotoxic T-cell (CTL) responses against surface antigens of macroschizont-infected cells. The CTL response is parasite specific and genetically restricted (major histocompatibility complex [MHC] antigens), and the protection can be transferred between immune and naïve calves in the CD8+ T-cell fraction emanating from a responding lymph node.

### Experimental Reproduction

ECF can easily be reproduced by feeding infected ticks on susceptible cattle or by inoculating cattle with infected tick material, sporozoites, or macroschizont-infected tissue culture cells. This is used as a method of immunization. When working with ticks or tick materials, care should be taken to avoid the risk of contracting other tick-borne diseases.

### Economic Importance

ECF has a major impact on cattle production in eastern, central, and southern Africa. It is estimated that in 1989, ECF killed 1.1 million head of cattle and caused US\$168 million in losses. Serious losses occur in exotic and indigenous cattle, mainly from reduced production of milk and meat as a result of morbidity and mortality, and from the heavy costs incurred in implementing effective tick control. *T. parva* does not infect human beings.

### Biosecurity Concerns

The vector of ECF has strict requirements that limit the spread and establishment of the disease beyond the geographic areas where it normally occurs. Where the vector occurs but there is no disease, as in the Comoros, precautions should be taken to avoid importation of carrier cattle from endemic areas. ECF is not contagious.

### PATHOGENESIS

Sporozoites of *T. parva* are injected into the bovine host by the tick in its saliva. Ticks

must feed for 2 to 4 days before sporozoites in their salivary glands will mature and become infective to cattle. One tick can transmit sufficient sporozoites to cause a fatal infection in a susceptible animal. The sporozoites then enter lymphocytes and develop into schizonts in the lymph node draining the area of attachment of the tick, usually the parotid node. Infected lymphocytes are transformed to immortalized lymphoblasts and continue to divide synchronously with the schizonts, and thus each daughter cell is also infected. Eventually, infected lymphoblasts are disseminated throughout the lymphoid system and in non-lymphoid organs, where they continue to proliferate. The strategy used by the parasite to transform the infected cell is via reprogramming the cell's glucose metabolism and redox signaling.<sup>4,5</sup> It has been suggested that only a proportion of infected lymphocytes will actually proliferate and disseminate.<sup>6</sup> Furthermore, the survival of infected lymphoblasts is promoted by cytoplasmic sequestration of p53, the central effector molecule of the p53 apoptotic pathway.<sup>7</sup> Later, some schizonts differentiate into merozoites and are released from the lymphoblasts. Without the schizonts, proliferation of such lymphoblasts is arrested.<sup>5</sup> Meanwhile, the released merozoites invade erythrocytes, where they are referred to as piroplasms. The latter are the form infective to ticks. Piroplasms ingested by ticks undergo several developmental stages and eventually form sporozoites in salivary glands, thus completing the cycle.

The dominating pathologic lesion is generalized lymphoid proliferation resulting from uncontrolled proliferation of T-lymphocytes containing schizonts. This is followed later by necrosis of infected lymphoblasts induced by cytotoxic T-lymphocytes. In one study involving 3-month old calves, massive necrosis of lymphocytes without initial proliferation was reported.<sup>8</sup> The severe lymphocytolysis often leads to immunosuppression. Terminally, the animal develops severe pulmonary edema, probably as a result of release of vasoactive substances from lymphocytes disintegrating in the lungs. Erythrocytic indices are usually unchanged, but there may be terminal anemia in January disease.

### CLINICAL FINDINGS

The basic syndrome caused by *T. parva* infection lasts for a few weeks. The incubation period is 1 to 3 weeks, depending on the virulence of the strain and the size of the infecting dose. Experimentally, the first clinical sign is enlargement of lymph nodes in the area draining the site of tick attachment (i.e., 8 to 16 days after attachment). One or 2 days later, there is fever, depression, anorexia, and a drop in milk in dairy animals. In later stages, there may be nasal and ocular discharges, dyspnea, generalized lymph node

enlargement, and splenomegaly. In severe cases, diarrhea occurs, sometimes with dysentery, but usually only late in the course of the disease. Emaciation, weakness, and recumbency lead to death from asphyxia in 7 to 10 days. Terminally, there is often a frothy nasal discharge. Occasional cases of brain involvement occur and are characterized by circling, hence “turning sickness,” or cerebral theileriosis.

In southern Africa, cerebral theileriosis is associated with an aberrant form of *T. taurotragi* originating from the eland (see “Theileriosis”). There are localized nervous signs and convulsions, tremor, profuse salivation, and head pressing. Infection with the strain of *T. parva* (formerly *T. parva lawrencei*) responsible for corridor disease causes a similar acute syndrome, with the additional lesion of keratitis and accompanying blepharospasm. ECF in Zimbabwe (formerly attributed to *T. parva bovis*) is generally slightly less virulent but is still frequently fatal.

### CLINICAL PATHOLOGY

The parasites are evident as schizonts, sometimes in circulating lymphocytes, but mainly in biopsy smears of enlarged lymph nodes stained with Giemsa. Piroplasms are also easily visible in erythrocytes from day 16 after tick attachment, and they increase in number until death. Over 30% of the red cells may be infected, but the level of intraerythrocytic piroplasms is not correlated with the severity of the disease. *T. parva* piroplasms are difficult to differentiate from other piroplasms—hence the necessity to find schizonts. Blood counts will reveal a panleukopenia and thrombocytopenia with little or no anemia. The protozoa can be grown on a tissue culture of lymphoblastoid cells.

A range of serologic tests is available, including indirect immunofluorescent antibody test (IFAT), complement fixation test, indirect hemagglutination test, and enzyme-linked immunosorbent assay (ELISA). The ELISA test is increasingly being used for seroepidemiologic studies, and the polymerase chain reaction (PCR) technology can be used as with other theilerioses. However, the IFAT is the most widely used test.<sup>9</sup>

### NECROPSY FINDINGS

The most striking lesion is massive pulmonary edema, hyperemia, and emphysema, along with hydrothorax and hydropericardium. Copious froth is present in the airways. The carcass is emaciated, and hemorrhages are evident in a variety of tissues and organs. There is enlargement of the liver, lymph nodes, and spleen and ulceration of abomasum and intestines. Small lymphoid nodules (the so-called pseudoinfarcts) are present in liver, kidney, and alimentary tract. In protracted cases, animals may have small, exhausted lymphoid organs.

Microscopic lesions are characterized by proliferating lymphoblastoid cells and

varying amounts of necrosis in lymphoid organs, lungs, liver, kidneys, the gastrointestinal tract, and other tissues, somewhat similar to a multicentric lymphoid tumor. Some lymphoblasts contain schizonts, which are better seen in impression smears stained with Giemsa stain. In cerebral theileriosis, infected lymphoblasts sequester in cerebral blood vessels and cause infarction.

Specimens to submit for pathology should include lymph nodes, lungs, kidneys, liver, and any other organ with gross lesions.

### DIFFERENTIAL DIAGNOSTIC

The fever, depression, and lymphadenopathy of ECF can be confused with such diseases as theileriosis attributable to

- *T. annulata*
- trypanosomosis
- heartwater
- malignant catarrhal fever
- bovine virus diarrhea and rinderpest

The lymphoid hyperplasia may also simulate lymphoma. Knowledge of the disease history, coupled with hematologic and lymph node smear examinations, is usually adequate to make a definitive diagnosis.

### TREATMENT

#### TREATMENT AND CONTROL

##### Treatment

Buparvaquone (2.5 mg/kg IM, 2 doses 48 hours apart) (R-1)

Parvaquone (10 mg/kg IM 2 doses 48 hours apart) (R-1)

Halofuginone lactate (1.2 mg/kg PO) (R-1)

Oxytetracycline (20 mg/kg IM) (R-2)

##### Control

Vaccination by infection and treatment method using tetracycline or parvaquone (R-1)

Vaccination by infection with low-pathogenicity isolate (R-2)

Once an animal is manifesting clinical signs of ECF, treatment is generally considered to be either unsatisfactory or too expensive. Tetracyclines were the recommended treatment for many years, but they have only moderate efficacy, especially if the disease has been present for a few days. Two recently introduced drugs, halofuginone lactate and parvaquone, have had a much higher success rate, but recovered animals may become carriers unless the correct dose is used. Halofuginone lactate is an effective oral treatment for the acute syndrome at two doses, 1.2 mg/kg BW. Parvaquone (10 mg/kg BW, two doses 48 hours apart) or the related buparvaquone (2.5 mg/kg BW, two doses 48 hours apart) given IM is effective in most cases. In field trials, buparvaquone gives

results comparable to those of parvaquone, and cure rates are maximized by accurate diagnosis and prompt treatment of both ECF and intercurrent infections. Cure rates are even higher if the animals are also treated for pulmonary edema with dexamethasone or the diuretic furosemide. A recovery rate of 95.2% was reported in field cases in Tanzania treated with buparvaquone alone.<sup>10</sup>

### CONTROL

Until recently, the main method of control of ECF was to break the transmission cycle between cattle and ticks. This was achieved through widespread and strict application of acaricides at 3-, 5-, or 7-day intervals throughout the year (intensive dipping), adherence to legislation on cattle movements and quarantine, and good livestock and pasture management. With the ever-rising costs of acaricides, their effect on the environment, the development of acaricide resistance, and frequent political problems in the affected regions, this strategy to control ECF and other tick-borne diseases in Africa has been revised. Furthermore, it has been observed that indigenous cattle, constituting the majority of the herds in some of the affected countries, may lose their endemic stability with intensive dipping, and the process is not cost-effective. An integrated approach is now advocated involving the use of genetically resistant breeds, a judicious and selective application of acaricides at 3-week intervals (strategic dipping) or when there are at least 100 ticks per animal (tactical dipping), and the use of vaccines. It has been reported that monthly applications of deltamethrin-based pour-on insecticide significantly reduce the incidence of ECF and other hemoparasitic diseases in smallholder dairy farms in Kenya.

The technique used for vaccination is immunotherapy or “infection-and-treatment method.” Initially, cryopreserved suspensions of *T. parva* sporozoites from ground-up infected ticks were injected into the patient. Now, sporozoites from cell culture are used. The infection they cause is controlled with long-acting oxytetracycline (20 mg/kg BW IM), or preferably parvaquone given at the same time, and thus pre-munity is established. It is preferably to use a cocktail of different stocks of parasites. Vaccination, coupled with strategic dipping only when ticks are abundant, is usually successful and economically attractive, provided local stocks of *Theileria* are included. The Muguga cocktail vaccine is being used throughout eastern, central, and southern Africa and has been recommended for use in southern Sudan.<sup>11</sup> Reports indicate that calves in high-risk areas should be vaccinated at 1 to 2 months of age, that immunization campaigns are more efficient when concentrated in the period of low adult tick activity, and that immunization is of no benefit in herds under intensive tick control

but is of high value when combined with strategic tick control. Strategic control plus immunization can markedly reduce the risk of clinical ECF, but immunized animals are carriers, and all stages of *R. appendiculatus* can transmit infection from them to naïve animals.

Studies have indicated that cattle could be successfully immunized without current tetracycline therapy by using low-pathogenicity isolates as vaccines, for example, *T. parva* (Boleni) in Zimbabwe, or low-infectivity sporozoite stabilates stored at  $-196^{\circ}\text{C}$  ( $-321^{\circ}\text{F}$ ) for over 6 months. Because of the high cost of tetracyclines, this procedure would reduce the cost of vaccination by more than threefold in the first year of field application. Furthermore, the *T. parva* (Boleni) isolate was reported to induce protection against a wide spectrum of *Theileria* stocks in Zimbabwe.<sup>12</sup> Economic analyses in Kenya have demonstrated that integrated control in which ECF immunization is always an important component can play an important role in the overall control of the disease.<sup>2</sup> In Tanzania, annual theileriosis costs were US\$205.40 per head, whereas the introduction of immunization reduced this by 40% to 68% depending on the postimmunization dipping strategy adopted.<sup>13</sup>

It needs to be stated that immunity is engendered so far only with live parasites that can establish an infection but can also produce carriers, from which the parasites can be transmitted to unvaccinated cattle that share grazing.<sup>14</sup> Hence, there is inherent risk in the widespread use of such vaccines across national boundaries. On the other hand, this process may be accelerating progress to endemicity.

The possibility of immunizing cattle with recombinant surface molecules from either the sporozoite (the p67 antigen) or the schizont, or a mixture of several antigens derived from both stages, has been investigated but without much success. Such a recombinant vaccine would probably avoid the breakdowns that occur with any immunotherapeutic technique, and if the right antigens are found for the vaccine, it is hoped that the immunity engendered is likely to be broad, robust, and not parasite stock specific.

## TROPICAL THEILERIOSIS (MEDITERRANEAN COAST FEVER)

### SYNOPSIS

**Etiology** *Theileria annulata*, an Apicomplexa protozoon. Vectors are *Hyalomma* ticks.

**Epidemiology** Endemic disease of cattle in Mediterranean basin and parts of Asia.

**Clinical signs** Inapparent in local stock; fever, lymphadenopathy, wasting, anemia, and jaundice in exotics.

**Clinical pathology** Schizonts in macrophages and lymphocytes especially in liver smears; piroplasms in erythrocytes.

**Lesions** As in East Coast fever (ECF); also anemia and jaundice.

### Differential diagnosis list:

- Other theilerioses
- Babesiosis
- Anaplasmosis
- Trypanosomosis
- Malignant catarrhal fever

**Treatment** Buparvaquone is effective.

**Control** None required for indigenous cattle; vaccination and strategic tick control for exotics.

## ETIOLOGY

*Theileria annulata* is a member of the Apicomplexa group, like *T. parva*, the cause of East Coast fever. It is highly virulent for European dairy cattle, whereas infection in local zebu cattle is often subclinical.

## EPIDEMIOLOGY

### Occurrence and Methods of Transmission

The disease occurs from Morocco and Portugal in the west through the Mediterranean basin and the Middle East to India and China in the east. An outbreak in a Scottish dairy farm over a decade ago was thought to have been attributable to mechanical transmission from experimentally infected calves on a research institute associated with the

farm. In the absence of natural vectors, that outbreak was quickly controlled.

*T. annulata* affects cattle and is transmitted transstadially by the three-host tick *Hyalomma anatolicum* in central-western Asia and northeastern Africa, and by the two-host tick *H. detritum* in the Mediterranean basin. The extent of its distribution may overlap with that of *T. parva* in Sudan and Eritrea and with *T. orientalis* in the Far East.

In endemic areas, virtually all adult cattle are infected, but infection rates vary with the method of examination. For example, surveys carried out in different parts of Turkey showed the prevalence to be between 0% and 60.5% by microscopic examination of blood and lymph node smears, 1.8% and 91.4% by serology (IFAT), and between 15.4% and 61.2% by molecular techniques.<sup>1</sup>

Case fatality is approximately 10% to 20% and is confined mainly to calves. Exotic animals recently introduced may have 20% to 90% mortality. The disease occurs when there is much tick activity, mainly in summer and the rainy seasons, and in crossbred animals. A single tick can cause fatal infection because its salivary glands usually contain numerous sporozoites.

## Risk Factors and Immune Mechanisms

The normal state is that of endemic stability. This balance is disturbed when exotic animals are introduced, and heavier losses occur. Recovered animals show a solid, long-lasting immunity, but they remain as carriers. Buffaloes are thought to be the natural hosts, and they may also act as carriers, whereas yaks are highly susceptible. In one study in Egypt, water buffaloes were more severely affected than cattle.<sup>2</sup> As with *T. parva*, immunity is mainly cell mediated but is poor in calves. Experimental reproduction is by feeding infected ticks on cattle or by needle inoculation of sporozoites in macerated ticks, schizonts in lymphocytes, or of merozoites in erythrocytes. Humans are not affected.

## Economic Importance

The disease is a major constraint to livestock improvement programs in many parts of the Middle East and Asia. Around one-sixth of the world cattle population is at risk. Economic losses arising from the disease in Turkey were estimated to vary from US\$130,000 to US\$598,000 per annum in the endemic stable zones.<sup>1</sup> In carrier animals in Tunisia, the greatest loss is from reduced milk production.<sup>3</sup>

## Biosecurity Concerns

There are no biosecurity concerns.

## PATHOGENESIS

The life cycle of *T. annulata* is cattle-tick-cattle, as for *T. parva*, but unlike *T. parva*, the sporozoites of *T. annulata* invade and form

schizonts, mostly in macrophages/monocytes that express major histocompatibility (MHC) class II antigens. The macrophages then stimulate uninfected lymphocytes to undergo lymphoblastic transformation and proliferate.<sup>4</sup> Schizont-infected cells multiply in the draining lymph nodes and disseminate rapidly along with lymphoblasts throughout the lymphoid tissues and in nonlymphoid organs, including the liver, kidney, lung, abomasum, and brain. Virulence of the disease is associated with the capacity of infected cells to disseminate inside the host.<sup>5</sup> Later, schizonts differentiate into merozoites and invade erythrocytes (as piroplasms). The pathogenesis therefore involves proliferation of macrophages induced by schizonts, and anemia with icterus induced mostly by the piroplasms. Macrophages/monocytes are the main producers of inflammatory cytokines that can induce an acute-phase protein response. The response is greater in *Bos taurus* Holstein breed than the *Bos indicus* Sahiwal breed,<sup>6</sup> and this would explain the more severe disease in the Holstein. Infected macrophages from taurine breeds are also more capable of aggressive invasiveness than zebu breeds.<sup>7</sup>

Over 90% of erythrocytes may be parasitized, each by one or more merozoites. Merozoites induce hemolysis most likely by lipid peroxidation of the red cell membrane. The level of hemolysis is dependent on the parasitic burden.<sup>8</sup> Immunosuppression may occur in the acute stages of the disease but is generally less marked than in ECF, probably because leukocyte numbers return to normal soon after the acute phase.

## CLINICAL FINDINGS

In a stable endemic situation, there may be only mild or no clinical disease in local zebu cattle. Clinical signs are acute and severe in exotic cattle and less severe in crossbreeds and are similar to those in ECF. However, the course is longer in tropical theileriosis and may last for weeks before death. Clinical signs include marked fever, swelling of superficial lymph nodes, inappetence, tachycardia, dyspnea, pale mucous membranes, and icterus. Others are diarrhea, weight loss, convulsions, torticollis, and other nervous signs. In chronic cases, there may be small subcutaneous nodules, from which schizonts can be demonstrated in smears. In Egypt, affected cattle and buffaloes also showed ocular signs, including severe lacrimation, bilateral conjunctivitis, photophobia, and corneal opacity,<sup>2</sup> whereas in Spain, there were coalescing skin nodules similar to multicentric malignant lymphoma.<sup>4</sup>

## CLINICAL PATHOLOGY

As with ECF, examination of smears of blood and lymph node biopsy will reveal piroplasms in erythrocytes and schizonts in lymphocytes. Schizonts of *T. annulata* tend to be more common in the liver than in lymph

node smears, but they are otherwise indistinguishable from those of *T. parva*. Furthermore, the piroplasms are predominantly round and oval, as opposed to *T. parva*, which has comma- and rod-shaped piroplasms. Anemia is a significant feature of tropical theileriosis, unlike in ECF, and is associated with bilirubinemia, hemoglobinuria, and bilirubinuria. The anemia results from destruction of erythrocytes containing piroplasms, but other factors may include autoimmune hemolysis and poor bone-marrow response. Reduction in white cell and platelet counts is less severe than in ECF, but animals dying from the disease show persistent and severe lymphocytopenia involving mainly T-lymphocytes.

The most commonly used serologic diagnostic technique is the indirect fluorescent antibody test.<sup>9</sup> For surveys, an indirect enzyme-linked immunosorbent assay (ELISA) test using a recombinant *T. annulata* surface protein has been described. The ELISA tests provide higher sensitivity and specificity than the IFAT. The polymerase chain reaction (PCR) test is more sensitive and more specific<sup>10</sup> and can detect carriers; it can also be used to detect infected ticks. A multiplex PCR method can simultaneously detect single and coinfections with *T. annulata*, *Babesia bigemina*, and *Anaplasma marginale* in cattle.<sup>11</sup> The test is simple, specific, and sensitive and can be applied to epidemiologic studies aimed at assessing the burden of multiple infection with tick-borne pathogens.

## NECROPSY FINDINGS

Apart from pallor of mucous membranes and yellowish discoloration of tissues, the postmortem lesions in animals dying from tropical theileriosis are similar to those of ECF. Lymphoid proliferation can resemble multicentric malignant lymphoma.<sup>4</sup> Liver, spleen, and lymph nodes should be submitted for laboratory examination to detect schizonts, whereas merozoites are detected in blood smears.

## DIFFERENTIAL DIAGNOSIS

Tropical theileriosis may be confused with the other theilerioses that may occur in the region, and with babesiosis, anaplasmosis, trypanosomosis, and malignant catarrhal fever. Liver biopsy and blood examination will help to confirm a clinical diagnosis.

## TREATMENT

### TREATMENT AND CONTROL

#### Treatment

Buparvaquone 2.5 mg/kg IM, 2 doses 48 hours apart) (R-1)  
Halofuginone lactate (1.2 mg/kg PO) (R-1)  
Oxytetracycline (20 mg/kg IM) (R-2)

#### Control

Vaccination by infection and treatment method using tetracycline (R-1 for exotic animals)

Vaccination with attenuated schizont vaccine (R-2)

Buparvaquone is the most effective agent available, and the recommended dose is 2.5 mg/kg BW. In calves, supportive treatment for anemia is indicated. Halofuginone at 1.2 mg/kg is also effective, but tetracycline at 20 mg/kg is less so.

## CONTROL

Indigenous cattle live with the disease and do not require any intensive tick control or treatment. For valuable exotic stock or their crossbreeds, vaccination and strategic tick control are recommended. Vaccines can be made from either the sporozoite or the schizont. The sporozoite vaccine is based on the infection-and-treatment method using schizont-infected cell lines and simultaneous tetracycline treatment, as for *T. parva*. It has been suggested that the most economical way to control theileriosis in India is to vaccinate calves and to reserve buparvaquone for treating clinical cases. The schizont vaccine was formerly blood containing a mild strain of the parasite. The newer vaccines are prepared from live schizonts grown in lymphoid cell culture and attenuated by prolonged passage. They cause virtually no adverse reactions, and vaccinated cattle show good resistance to the disease for at least 3.5 years. Therefore it is necessary to revaccinate, preferably with a different cell-line vaccine, if tick population is too low to establish endemic stability. The risk for spread of the vaccine strains in the field is very low. The disease has been successfully controlled in China by vaccination.<sup>12</sup>

## Multi-Organ Diseases Due to Trypanosome Infection

Trypanosomes are flagellated protozoan parasites belonging to the genus *Trypanosoma*, family Trypanosomatidae. They live in the blood and other body fluids of vertebrate hosts, where some of them cause disease. With the help of the flagellum, trypanosomes swim within the vertebrate bloodstream and prosper despite being constantly attacked by the host immune system. The parasites generally possess a kinetoplast and undergo cyclical development in an arthropod vector but can be transmitted mechanically. Their biological adaptations, morphology, and pathogenicity are fascinating and have been extensively studied. The parasites cause several diseases, each of which was referred to as trypanosomiasis. The currently preferred term is *trypanosomosis*, plural *trypanosomoses*. The diseases are summarized in Table 21-7.

*Trypanosoma evansi* is the first known pathogenic trypanosome. It was first described in India as the cause of surra in animals, but the disease is widespread in the tropics and is transmitted mechanically rather than by a biological vector. In Africa, three species (*Trypanosoma congolense*, *T. vivax*, and *T. brucei*) are the main pathogens for animals and humans. The parasites are

transmitted by the tsetse fly (*Glossina* spp.), and the resulting animal disease is referred to as African trypanosomosis or nagana. Two subspecies of *T. brucei* are responsible for African sleeping sickness in human beings, *T. brucei gambiense* in West and Central Africa, and *T. brucei rhodesiense* in East Africa. Another disease, dourine, specifically affects equines and camels and is caused by *T. equiperdum* transmitted sexually during coitus. *T. evansi* and *T. equiperdum* are regarded as subspecies of *T. brucei*, which have lost their ability to infect tsetse and are therefore able to spread outside Africa. In South and Central America, a different trypanosome, *T. cruzi*, transmitted by reduviid bugs (*Rodnius* spp. and *Triatoma* spp.), is the cause of Chagas's disease or American trypanosomosis, mostly in humans, but it also affects dogs, cats, and pigs. Trypanosomoses of veterinary importance are discussed here.

## NAGANA (SAMORE, AFRICAN TRYPANOSOMIASIS, TSETSE FLY DISEASE)

### SYNOPSIS

**Etiology** *Trypanosoma congolense*, *T. vivax*, *T. brucei brucei*, and *T. simiae*, all salivarian trypanosomes. Tsetse flies (*Glossina* spp.) serve as biological vector, other biting flies as mechanical vectors.

**Epidemiology** Endemic disease of all mammals in tropical Africa, also Central and South America; of greatest economic importance in cattle. Two subspecies of *T. brucei* cause African sleeping sickness, an

important human disease (zoonosis) in tropical Africa.

**Clinical signs** Fever, apathy, pale mucous membranes, swollen lymph nodes, progressive emaciation, cachexia, and death, sometimes preceded by nervous signs. May be acute, subacute or, often, chronic disease.

**Clinical pathology** Progressive anemia, parasite detection in blood by various methods, including polymerase chain reaction (PCR).

**Lesions** Not definitive but include pallor, emaciation, and enlargement of lymph nodes, spleen, and liver.

### Differential diagnosis list:

- Malnutrition
- Helminthosis
- East coast fever
- Babesiosis
- Anaplasmosis
- Hemorrhagic septicemia

**Treatment** Trypanocides such as Berenil, Samorin, Suramin, and Anttrycide, but drug resistance is a problem.

**Control** Integrated methods involving tsetse fly control, prophylaxis, good husbandry, and use of trypanotolerant breeds, no vaccine.

## ETIOLOGY

*Trypanosoma vivax*, *T. congolense*, *T. brucei*, and *T. simiae* are the four main species responsible for African trypanosomosis affecting virtually all domestic mammals. *T. vivax* and *T. congolense* mostly affect cattle, sheep, goats, and horses. Horses are also severely affected by *T. brucei brucei*, whereas pigs suffer mostly from *T. simiae*. All four species are members of the *Salivaria* group of trypanosomes and are transmitted cyclically via the mouthparts of tsetse flies—hence the name salivarian trypanosomes. Cyclical development in the vector is a result of the presence of kinetoplast DNA in these trypanosomes.

The morphology and movement of the trypanosomes are characteristic for each species and are helpful in making a diagnosis. In acute infections, *T. vivax* is usually numerous in blood samples and can be identified by its very fast movement in wet films. In stained smears, it is 20 to 26  $\mu$ m long, slender, and monomorphic, with a rounded posterior end, a terminal kinetoplast, and a long free flagellum, but no prominent undulating membrane. *T. congolense* is smaller, is sluggish in wet films, and often adheres to red blood cells by the anterior end. In stained smears, it is 9 to 18  $\mu$ m long, with a marginal kinetoplast, no free flagellum, and no prominent undulating membrane. *T. brucei* is large like *T. vivax*, but its rapid movement is in confined areas of the wet film. In stained smears, it is pleomorphic and may occur as long and slender forms up to 35  $\mu$ m,

Table 21-7 Summary of the trypanosomoses of domestic animals and humans

Disease	Distribution	<i>Trypanosoma</i> spp.	Main vector
<b>Animals</b>			
Nagana or African trypanosomosis (most mammals)	Tropical Africa	<i>T. brucei brucei</i> <i>T. congolense</i> <i>T. vivax</i> <i>T. simiae</i>	<i>Glossina</i> spp. Other biting flies
Surra (horses, camels, buffaloes)	Africa, Asia, South and Central America	<i>T. evansi</i>	Biting flies
Dourine (horses and donkeys)	Africa, Asia, South and Central America	<i>T. equiperdum</i>	None (venereal transmission)
Nonpathogenic (cattle and sheep)	Worldwide	<i>T. theileri</i> <i>T. melophagium</i>	Biting flies
<b>Humans</b>			
Rhodesian sleeping sickness	East, central, and southern Africa	<i>T. brucei rhodesiense</i>	<i>Glossina</i> spp.
Gambian sleeping sickness	Western and central Africa	<i>T. brucei gambiense</i>	<i>Glossina</i> spp.
Chagas' disease (also in dogs, cats, and pigs)	South and Central America, southern United States	<i>T. cruzi</i>	<i>Rhodnius</i> spp. <i>Triatoma</i> spp.

intermediate forms, or short and stumpy forms about 12  $\mu\text{m}$  long. The slender and intermediate forms have a long free flagellum, pointed posterior end, subterminal kinetoplast, and prominent undulating membrane, whereas the stumpy forms resemble *T. congolense* but are bigger and have a prominent undulating membrane. The strains or species of *T. brucei* infective to animals only are often referred to as *T. brucei brucei* to distinguish them from *T. brucei gambiense* and *T. brucei rhodesiense*, which are infective to humans. *T. simiae* is morphologically indistinguishable from *T. congolense*, and it is adapted to pigs, in which parasitemia can be very heavy (swarming).

## EPIDEMIOLOGY

### Occurrence

The epidemiology of African trypanosomiasis is determined mainly by the ecology of the tsetse fly found only in tropical Africa. However, *T. vivax* is also transmitted mechanically by biting flies and has been responsible for disease outbreaks in Costa Rica and some South American countries, including Bolivia, Brazil, and Venezuela, where it affects mainly cattle and sheep. In general, *T. congolense* and *T. vivax* are responsible for severe disease in cattle, sheep, and goats, and *T. brucei brucei* usually causes a subclinical infection in cattle but a severe disease in sheep, goats, horses, and, occasionally, pigs. *T. simiae* causes a hyperacute and highly fatal disease in exotic pigs and in camels. Warthogs act as its reservoir, and the parasite is not pathogenic to cattle, sheep, or goats.

### Prevalence

Infection rates reported in cattle in endemic areas vary considerably and could be over 60% in some herds. However, as a result of various control methods, including those under the auspices of the Pan African Tsetse and Trypanosomiasis Eradication Campaign (PATTEC), the prevalence of infection is decreasing in many African countries, particularly in West Africa. Recent surveys in the region report prevalence rates of 5% or less in cattle by parasite detection methods and higher rates with serology or with polymerase chain reaction (PCR) techniques detecting parasite nucleic acids. For example, prevalence studies in villages in Burkina Faso involving 2002 cattle, 1466 small ruminants, and 481 donkeys reported only a 0.77% infection rate in cattle, 0% in goats, and 0.6% in donkeys by routine parasitologic methods, whereas by serology, the rates were 34.2% for cattle, 20.9% for sheep, 8.5% for goats, and 5.8% for donkeys.<sup>1</sup> Seventy-five percent of the cases were attributable to *T. vivax* and 25% to *T. congolense*. In an Ethiopian study involving 1524 animals, the overall prevalence of infection was 5.5% by conventional parasitologic methods and 31.0% by PCR.<sup>2</sup> A major factor affecting

reported prevalence rates is the chronically low parasitemias in indigenous African zebu cattle, which often necessitates repeated sampling before an animal can be regarded as being uninfected. Using repeated PCR testing in East Africa, infection rates in 35 village cattle were found to be *T. brucei* (34.3%), *T. congolense* (42.9%), and *T. vivax* (29.9%).<sup>3</sup> Mixed infections with two or more species are common in endemic areas, and such infections are more readily detected by the PCR technique.<sup>4</sup> It should be mentioned that a positive serology does not necessarily imply current infection, whereas a positive PCR test, when properly carried out, indicates current or very recent infection because trypanosome DNA persists in host blood for only 14 days after successful treatment.<sup>5</sup> In general, it would seem that *T. vivax* is more commonly encountered and more pathogenic in West and Central Africa, whereas *T. congolense* appears more prevalent and more pathogenic in East and South Africa. Exceptions to this general rule are two recent reports, one from Mali,<sup>6</sup> and the other from Nigeria,<sup>7</sup> where *T. congolense* was found to be more prevalent than *T. vivax* in the herds studied.

Pigs and horses are less frequently affected than ruminants, perhaps because they are less exposed to tsetse flies than cattle that normally graze over long distances. The clinical disease in pigs is usually attributable to *T. simiae*, but there have been no reports of natural outbreaks of this form of trypanosomiasis in many years. Horses in Africa are affected by the three major species, and the disease syndrome is similar.

In Central and South America, *T. vivax* infections appear to be spreading to new areas, where they cause periodic outbreaks of serious disease mostly in cattle but also in horses.

### Morbidity and Case Fatality

Morbidity rates during outbreaks are variable and may reach 70% in cattle infected with *T. vivax* and up to 100% in pigs infected with *T. simiae*. Morbidity is usually much lower in sheep, goats, and horses because these are not often the preferred hosts for tsetse or are less exposed to tsetse challenge. Sheep and goats are more vigorous than cattle in defending themselves against successful feeding by tsetse flies.

Case fatality also depends on the trypanosome species, host, and its level of resistance. *T. simiae* is invariably fatal in exotic pigs. Some strains of *T. vivax* in East Africa cause similar heavy mortalities in exotic dairy cows, and infected horses are likely to die if left untreated. However, most infections in cattle in endemic areas run a chronic course and are not invariably fatal, but the animal may remain unproductive and unthrifty. West African strains of *T. vivax* are generally more pathogenic to cattle than East African strains, and *T. congolense* is generally

the more pathogenic species in East Africa. Subspecies of *T. congolense* are also recognized, with *T. congolense savannah* type being much more pathogenic than other types (*T. congolense forest* type, *T. congolense kilifi* type, and *T. congolense godfreyi*).

## Methods of Transmission

### Cyclical

African trypanosomes can be transmitted by 23 species of tsetse (*Glossina*) found only in sub-Saharan Africa between latitudes 14°N and 29°S, excluding areas of high altitude, extreme drought, or cold temperatures where tsetse cannot survive. The flies can be grouped according to their preferred habitats as savannah species, riverine species, and forest species. The savannah species (including *G. morsitans*, *G. austeni*, *G. pallidipes*, *G. swynnertoni*, and *G. longipalpis*) pose the greatest threat to livestock because they inhabit the grasslands where cattle are traditionally reared, they can easily adapt to other ecological niches, they feed primarily on cattle and pigs, and they are efficient vectors of trypanosomes. They are also the main vectors of Rhodesian sleeping sickness associated with *T. b. rhodesiense* in humans (Table 21-8). The riverine species (*G. palpalis*, *G. tachinoides*, and *G. fuscipes*) are important vectors of bovine and porcine trypanosomiasis, and of Gambian sleeping sickness as a result of *T. b. gambiense*. On the other hand, the 13 or so forest species (including *G. fusca*, *G. brevipalpis*, and *G. longipennis*) are not frequently incriminated vectors of animal trypanosomes even though their preferred food hosts are ruminants and suids.

The life cycle of trypanosomes in tsetse involves cyclical development for a varying length of time, depending on species and ambient temperatures, leading to the production of mature procyclic (metacyclic) parasites infective to the mammalian host. *T. vivax* completes its developmental cycle in the proboscis and pharynx of the fly and can be transmitted to a host within a week of the initial infective feed. The cycle of *T. congolense* involves the midgut and proboscis and is completed in about 2 weeks. That of *T. brucei* is more complex: it takes 3 or more weeks in the fly and involves the midgut and salivary glands. Once infected, flies remain so for life (1 to 2 months). It follows that for any fly, its vectorial capacity and efficiency are highest for *T. vivax* and least for *T. brucei*. Even then, infection rates in tsetse flies are generally low by conventional parasitologic methods of detection. Using the more sensitive PCR technique, 10.5% of 550 field-captured flies (*Glossina pallidipes*) were found to harbor trypanosome DNA in an endemic area in southwestern Zambia.<sup>8</sup>

### Noncyclical

After trypanosomes have been introduced into a herd, further transmission is possible

in the absence of *Glossina*. Biting flies such as *Tabanus*, *Stomoxys*, and *Hippobosca* are capable of mechanically transmitting blood-stream trypanosomes in their mouthparts when they feed on more than one host within a short interval. This is how *T. vivax* is spread in areas outside the tsetse belt in Africa and in Central and South America. Mechanical transmission can also occur through the needle during inoculations and in carnivores feeding on infected carcasses. There are occasional reports of intrauterine (vertical) transmission in animals and in human beings.

### The Carrier State

Reservoirs of infection are found in many wild animals, in trypanotolerant animals, and in chronically infected animals. Tsetse caught in and around game reserves tend to have relatively high infection rates, and the relative abundance of wildlife in East Africa compared with West Africa may explain, at least in part, why the prevalence of the disease appears to be declining more rapidly in the west.

### Risk Factors

#### Host Factors

The effect of infection varies with the host in that most wild and some domestic animals establish a balance with the parasite and remain as clinically normal carriers for long periods. Specifically, some breeds of cattle indigenous to Africa can tolerate light to moderate challenge with tsetse flies by limiting the multiplication of trypanosomes in their blood and also limiting the degree of anemia caused. The phenomenon is called **trypanotolerance**; it is both genetic and environmental in origin, and the level of tolerance varies. Thus the indigenous taurine breeds, such as the N'Dama, Baoule, and Muturu, are more tolerant than the West African zebu, and among East African zebu cattle, the Orma Boran and Maasai zebu have superior tolerance compared with Galana Boran and Friesian breeds. In a study involving N'Dama crossed with more susceptible Kenya-Boran animals reared under natural field situations, the trypanotolerant trait derived from the N'Dama was found to be primarily additive in nature, being expressed in heterozygous condition and in three-quarters Boran crosses.<sup>9</sup> In addition, females were more trypanotolerant than males. Thus the tolerance of the more productive but susceptible breeds can be improved by crossbreeding. However, because of the uncertain genetic makeup of animals within these so-called breeds and crossbreeds, the level of trypanotolerance may also vary with individual animals within a given category, and it can be overcome by heavy tsetse challenge, malnutrition, or other stress factors.

Trypanotolerance also occurs in some indigenous breeds of small ruminants but is less pronounced than in cattle. The breeds

include the Djallonke sheep, the West African Dwarf (WAD) sheep and goat, and the East African goat, whereas the Toggenburg, British Alpine, Saanen, Anglo-Nubian, and Sahel breeds of goats are fully susceptible. Because of unintentional and indiscriminate crossbreeding of the WAD goat populations with more susceptible breeds from the Sahel region, the former are becoming less trypanotolerant.<sup>10</sup>

### Environmental Factors

The density of tsetse population in an area and the level of tsetse contact with the host will determine the level of infection. This is further influenced by the vectorial capacity of the fly and the availability of its preferred host. For example, cattle are more attractive to tsetse flies than pigs, and pigs are more attractive than goats.<sup>11</sup> Trekking of livestock through tsetse-infested vegetation is a risk nomadic farmers face from time to time, and the risk is even greater where cattle routes converge, for example, at major bridges or watering holes. Agricultural and industrial developments generally lead to a lowering of tsetse density by destroying their habitat, whereas the establishment of game or forest reserves provides large numbers of preferred hosts or a suitable habitat for tsetse, respectively. Herds located near such reserves are therefore at a higher risk. So also are tourists visiting such game parks.

### Pathogen Factors

In cattle, *T. vivax* generally produces a higher level of parasitemia than other species. And because its life cycle in the tsetse is also shorter, *T. vivax* is more readily transmitted than the others when animals are newly introduced into a tsetse-infested area. Higher parasitemias also facilitate mechanical transmission. Conversely, *T. brucei* is infrequently detected by microscopic examination of cattle blood, even though infection can be confirmed through other, more sensitive diagnostic methods. Furthermore, some animals carry infection without showing clinical signs, especially if they are trypanotolerant, like the Muturu in Nigeria, or if infected with nonpathogenic genetic types, such as *T. congolense* kilifi type in cattle.

### Immune Mechanisms

Animals recovering from infection with one strain/serodeme or species of trypanosome are not immune to infection with another strain/serodeme or species. This is attributable to the ability of trypanosomes to periodically replace a monolayer or their protective coat of variant surface glycoproteins (VSGs) in an immunocompetent host through a process called **antigenic variation**. Each trypanosome cell expresses only one of many VSGs at a time, and the coat is continually shed and replaced to avoid the host immune system. During each peak parasitemia, a mixture of variable antigenic types of

parasites may be present, but the dominant VSG antigen determines the specific antibody response. These antibodies kill off the dominant population, leaving others with different antigens to emerge; these multiply and become dominant, and the process continues in cycles until the animal dies or the immune mechanisms catch up with the parasite and the animal recovers. This phenomenon is also responsible for the successive waves of parasitemia in infected animals.

The molecular mechanisms involved in the switching or activation of new VSGs are now being studied.<sup>12-13</sup> In *T. brucei*, the mechanisms involve DNA repair mechanism in that a double-strand break (DSB) initiates a switch in the expressed variant surface coat.<sup>14</sup> Furthermore, it has been shown that the DSB site determines the probability and mechanism of antigenic switching, and that DSBs can trigger switching via recombination or transcription inactivation.<sup>15</sup> The frequency of recombination is comparable between *T. congolense* and *T. brucei* but is much lower in *T. vivax*.<sup>13</sup> Following repeated episodes of infection and recovery (with or without treatment) in an endemic area, animals will encounter a variety of antigenic types and therefore become less susceptible to strains/serodemes in that area.

Infected animals are more susceptible to secondary infections by other microorganisms, particularly bacteria. The immune system of an infected animal is disrupted by mechanisms not fully understood, but they may vary with the species of animals. In ruminants, the state of immunosuppression is abrogated once the trypanosomes are eliminated by chemotherapy.

### Experimental Reproduction

Infection can be easily reproduced by inoculation of infected blood or other serous fluid into a susceptible host. Infected flies can also be fed on the host to transmit the disease. Several laboratory animal models of nagana and sleeping sickness are available, and lots of studies have been done with mice and rats. These studies help to elucidate the pathogenesis of the disease and approaches to chemotherapy and drug resistance.

### Economic Importance

Tsetse flies infest 10 million square kilometers of Africa, involving 38 countries and placing 50 million cattle at risk. Hence, nagana is still the most important disease of livestock in the continent. The added risk of human infections has greatly affected social, economic, and agricultural development of rural communities. Because nagana is a wasting disease, affected animals are chronically unproductive in terms of milk, meat, manure, and traction, and the mortality rate can be high, especially in exotic and more productive animals. The disease in Africa costs livestock producers and consumers an estimated US\$4.5 billion each year. The

anticipated losses as a result of *T. vivax* in South America exceed \$160 million. Furthermore, the disease may affect various immunization campaigns in endemic areas because it can cause immunosuppression.

### Zoonotic Implications

The animal pathogens (*T. vivax*, *T. congolense*, *T. simiae*, and *T. brucei brucei*) are not infective to humans, but animals can serve as reservoirs of *T. brucei rhodesiense* and *T. brucei gambiense*, the causes of human African trypanosomiasis (HAT), or sleeping sickness. *T. brucei brucei* is morphologically indistinguishable from the human pathogens, but when it is incubated in human serum, it is lysed and becomes non-infective to laboratory animals, unlike the human pathogens, which are human serum resistant.<sup>16</sup>

As in animals, human infections with *T. brucei gambiense* or *T. brucei rhodesiense* result from tsetse bites, generally in game parks, in forest reserves, along streams, or in other rural settings. The incidence of human infections fell to a few thousand cases per year in the 1960s and then started to rise as a result of relaxation of previous control measures and especially because of civil unrest forcing people to leave their homes to seek shelter in tsetse-infested areas. Currently, a total of 70 million people are at risk of infection. In 2012, over 175,000 cases were reported in 20 countries; *T. brucei gambiense* accounted for 82.2% of them, and *T. brucei rhodesiense* accounted for the remaining 17.8%.<sup>17</sup> High-risk countries are in Central Africa, especially the Democratic Republic of the Congo, Angola, the Central African Republic, and southern Sudan, where civil wars have hampered control efforts. During the period 2009 to 2013, most cases of Rhodesian sleeping sickness were reported from Uganda, Malawi, Tanzania, and Zambia<sup>18</sup> and from foreign tourists who had visited East African game parks. A comprehensive review of the human disease was published recently.<sup>18</sup>

A rash (chancre) develops at the site of tsetse bite in humans, and this is soon followed by fever, persistent headache, and swelling of lymph nodes, spleen, and liver. Weakness and signs of cardiac involvement may be noticed early in the Rhodesian form encountered in eastern and southern Africa. This form is rapidly fatal if it is not diagnosed early and treated promptly. The Gambian form is usually chronic and often asymptomatic for months before the patient gradually wastes away and dies from the disease or from secondary infections years later. It is encountered in West and Central Africa, including the northwestern part of Uganda. In both forms, the disease progresses from a hemolymphatic first stage (S1) to a meningo-encephalitic second stage (S2) corresponding to when parasites invade the cerebrospinal fluid (CSF) and brain across the blood-brain

barrier.<sup>19</sup> Stage 2 results in progressive non-suppurative meningo-encephalitis, causing the patient to fall asleep often—hence the name sleeping sickness.

### Biosecurity Concerns

There are no biosecurity concerns for nagana because tsetse flies require strict environmental conditions to survive and breed. However, because *T. vivax* can be transmitted mechanically by biting flies, this fact should be taken into consideration when infected animals are moved outside the tsetse zone in Africa and in South and Central America. People working with *T. brucei gambiense* and *T. brucei rhodesiense* should take precautions to avoid accidental inoculation of themselves or their coworkers with infected material in syringes or tsetse flies.

### PATHOGENESIS

Nagana in most domestic animal species is a progressive but not always fatal disease, and the main features are anemia, tissue damage, and immunosuppression. Metacyclic trypanosomes are inoculated intradermally as the fly feeds. They multiply at this site, provoking a local skin reaction (chancre), which is most pronounced in a fully susceptible host and may be slight or absent with some strains or species of trypanosomes. Within the chancre, metacyclic parasites change to trypomastigote form, enter the bloodstream directly or through the lymphatics, and initiate characteristic intermittent parasitemias associated with intermittent fever. The behavior of the parasites thereafter depends largely on the species of trypanosome transmitted and the host.

In the acute phase, *T. vivax* usually multiplies rapidly in the blood of cattle, sheep, and goats, and it is evenly dispersed throughout the cardiovascular system, whereas *T. congolense* tends to be aggregated in small blood vessels and capillaries of the heart, brain, and skeletal muscle. *T. congolense* parasitemias in ruminants is not usually as high as with *T. vivax*, even though the anemia may be more marked. Both species exert their effect mainly by causing severe anemia and mild to moderate organ damage in the form of cellular degeneration and perivascular mononuclear cellular infiltration. Very acute infections with *T. vivax* in cattle or with *T. simiae* in pigs result in fulminating parasitemia and disseminated intravascular coagulation, with hemorrhages leading rapidly to death. Such syndromes resemble septicemia, and anemia may not be severe.

*T. brucei brucei* and, less often, *T. vivax* have the added capability of escaping from the capillaries into the interstitial tissues and serous cavities, where they continue to multiply. Such infections result in more severe organ damage in horses, sheep, and goats, in addition to anemia. The cerebrospinal fluid and brain parenchyma

can be invaded by the parasites, resulting in a nonsuppurative meningo-encephalitis and encephalomalacia.<sup>20-21</sup> Parasites in the CSF are not easily reached by some drugs and may be a source of relapsing infection when they reinvade the bloodstream. In addition, pregnant animals may abort, and transplacental fetal infections occasionally occur.

The pathogenesis of anemia in trypanosomiasis has been studied extensively, and it may vary with the parasite, the host species, and the stage of infection.<sup>22-23</sup> The three mechanisms generally recognized in the development of anemia are (a) extravascular red cell destruction as a result of massive erythrophagocytosis in the spleen and liver at all stages of infection, (b) intravascular hemolysis in the acute stage, and (c) inadequate bone-marrow response (dys-hemopoiesis) in the chronic stage. Increased erythrophagocytosis occurs in activated macrophages that are induced by parasite-derived glycolipids to become hyperactive against trypanosomes and red blood cells. During the acute phase of infection, erythrophagocytosis may also be triggered by trypanosome transsialidases acting on erythrocyte membranes.<sup>24</sup> Intravascular hemolysis is less commonly reported but has been attributed to several factors, including hemolysins from parasites, cleavage of sialic acids from the red cell membrane, passive absorption of trypanosome molecules in the red cell membrane, and, more recently, oxidative stress from free radicals. In the chronic stage, bone-marrow response to ongoing red cell loss is poor, and this is attributed to increased sequestration of iron (as hemosiderin) in macrophages.<sup>25</sup> Thus, the pathogenesis of anemia in the chronic stage of nagana is analogous to that of anemia of chronic disease or chronic inflammation.<sup>22-23</sup>

Animals infected with any pathogenic trypanosome may develop concurrent and even fatal bacterial, viral, and other protozoan infections as a result of immunosuppression. This is thought to be attributable to trypanosome-induced B-cell apoptosis resulting in loss of protective antiparasite antibody responses and abolishment of memory responses against nonrelated pathogens.<sup>26</sup>

Trypanotolerant animals control parasitemias better and have less severe anemia and organ damage. They usually recover from the disease, but they may act as carriers. On the other hand, human beings have a sterile immunity to these parasites, except *T. brucei gambiense* and *T. brucei rhodesiense*.

### CLINICAL FINDINGS

Although anemia is the cardinal feature, there are no pathognomonic signs that would help in pinpointing a diagnosis of trypanosomiasis in farm animals. The general clinical picture is as follows, but there are many variations determined by the level of tsetse challenge, the species and strain of the

trypanosome, and the breed and management of the host. Acute episodes last for a few days to a few weeks, from which the animal dies or lapses into a subacute to chronic stage, or the illness may be chronic from the beginning. Chronic cases may run a steady course, may be interrupted by periodic incidents of severe illness, or may undergo spontaneous recovery.

The basic clinical syndrome appears after an incubation period of 8 to 20 days following the infective tsetse fly bite. Chancre is not readily noticed under field conditions. There is fever, which is likely to be intermittent or cyclic for weeks. Affected animals are dull, anorexic, and apathetic; have a watery ocular discharge; and lose condition. Superficial lymph nodes become visibly swollen, mucous membranes are pale, diarrhea occasionally occurs, and some animals have edema of the throat and underline. Estrus cycles become irregular, pregnant animals may abort, and semen quality progressively deteriorates. The animal becomes very emaciated and cachectic and dies within 2 to 4 months or longer. Thin, rough-coated, anemic, lethargic cattle with generalized lymph node enlargement are reported to have a “fly struck” appearance.

In general, *T. congolense* is more pathogenic to cattle in eastern and southern Africa, whereas *T. vivax* produces a more serious disease in most of West and Central Africa. However, severe outbreaks of *T. vivax* involving exotic dairy animals in East Africa occur; affected animals show mucosal petechiation, rhinorrhea, dysentery, and death after an illness of only a few weeks.

Mixed infections with more than one species of trypanosomes are common and are usually more severe. Furthermore, intercurrent bacterial, viral, or other parasitic infections may mask or complicate the basic clinical syndrome. Immune response to bacterial and some viral vaccines is also depressed unless trypanocidal therapy is given at the time of vaccination.

Clinical findings peculiar to the individual trypanosome are as follows:

- *T. vivax* affects all agricultural species except pigs. Acute and chronic outbreaks occur, anemia is severe, and fever is usually associated with high parasitemia. A chronic form of the disease is more usual in East Africa, but an acute hemorrhagic form can occur with exotic cattle. Furthermore, outbreaks in Brazil have been associated with nervous signs in cattle<sup>20</sup> and in sheep,<sup>27</sup> characterized by head pressing, lateral recumbency, paddling movements, and muscle tremors. *T. vivax* is less commonly seen in trypanotolerant cattle breeds.
- *T. congolense* affects all species, usually with an acute disease lasting 4 to 6 weeks, but some chronic cases occur, especially in West Africa. Anemia and

emaciation are severe. The savannah subspecies is more pathogenic than the other subspecies.

- *T. brucei brucei* affects all species with a subacute to chronic disease. In addition to fever and anemia, there is often marked subcutaneous edema and keratoconjunctivitis. Nervous signs are manifested in horses, pigs, and small ruminants by ataxia, circling, head pressing, and paralysis. Cattle show chronic clinical signs, and they can act as carriers.
- *T. simiae* affects exotic pigs with a fulminating infection leading to death in hours or a few days of first appearing ill. The clinical signs are fever, stiff gait, dyspnea, and cutaneous hyperemia, without significant anemia. However, no outbreak has been reported in decades.

### CLINICAL PATHOLOGY

A progressive drop in packed cell volume is a nonspecific but useful indicator of trypanosomosis in endemic areas. The classic method of confirming nagana diagnosis is to demonstrate parasites in a wet blood film and in a thin or thick blood smear stained with Giemsa. This is fairly reliable in the early stages of the disease when parasitemia is usually high and parasitemic peaks correspond with fever. As the disease progresses, parasitemias become infrequent and the intervals between peaks grow longer, even though the animal is still sick. To increase the accuracy of parasitologic diagnosis, it is now routine to concentrate the parasites in the buffy-coat layer of a microhematocrit capillary tube. The buffy layer is then examined directly at low power (Woo's method) or in a wet preparation with a dark-ground/phase-contrast microscope (Murray's method). Both tests are simple, sensitive, and applicable to field use on individual animals and in herds. Blood should be examined fresh but may be refrigerated for up to 24 hours, beyond which most parasites will die and disappear from the sample.

Blood can also be inoculated into experimental animals, usually rodents, but this is cumbersome and is accurate for only *T. brucei*, and possibly *T. congolense*, but not *T. vivax*.

During surveys, a series of tests can be used to detect antibodies in serum or other body fluids. The three tests used most often are the indirect immunofluorescent antibody test (IFAT), the capillary agglutination test (CAT), and the ELISA. These tests indicate past and current infections, are difficult to standardize for different laboratories, and are not species specific. The ELISA technique was modified to detect circulating trypanosome antigens (antigen-ELISA) using monoclonal antibodies that would distinguish between *T. vivax*, *T. congolense*, and *T. brucei*, and it would detect only current or very

recent infections. Results from field trials in Africa and South America have not been encouraging.

The polymerase chain reaction (PCR) technique is now being used to detect trypanosome DNA in blood, serum, and in tsetse tissues. The technique targets the gene encoding the small ribosomal subunit to identify and differentiate all clinically important African trypanosome species and some subspecies. The test is sensitive, economical, and suitable for large-scale epidemiologic studies, usually in combination with other tests. Dried blood spots on filter papers are also a useful source of DNA for the detection of trypanosomes.<sup>28</sup> PCR technology is currently being made available in some laboratories in endemic areas and has led to increased rates of detection.

Examination of the cerebrospinal fluid is used routinely in human sleeping sickness to establish the stage of infection to select the appropriate drug for treatment. In animals, CSF examination for parasites, turbidity, protein content, and leukocytes can be done at necropsy if there have been neurologic signs.<sup>21</sup>

### NECROPSY FINDINGS

#### Gross Pathology

The postmortem lesions are, like the clinical findings, not definitive. The carcass is marked by anemia, emaciation, and enlargement of the liver, spleen, and lymph nodes. Body-fat stores are depleted or show marked serous atrophy, especially around the heart and in bone marrow. The bone marrow may be red (active) in the acute stage, but it becomes pale and gelatinous (unresponsive) in the chronic stage. Subcutaneous edema, corneal opacity, and testicular degeneration may be present. Thickening of the meninges and softening of the brain have been reported in some cattle naturally infected with the South American *T. vivax*.

In acute cases, there will be a general congestion of the viscera and extensive hemorrhages in all tissues. Chronic cases show cachexia, often complicated with secondary bacterial pneumonia or other parasitic diseases.

#### Histology

Microscopic lesions are also not specific, except in very acute infections, in which clumps of trypanosomes mixed with fibrin thrombi are found in blood vessels. Lymphoid organs are usually hyperplastic and may show varying degrees of erythrophagocytosis and hemosiderosis. The interstitial tissues and perivascular spaces of various parenchymatous organs may contain a lymphoplasmacytic infiltrate. This tends to be most marked with *T. brucei*, in which the parasites often localize extravascularly in the interstitial tissue. A severe nonsuppurative meningoencephalitis, myocarditis, and dermatitis may result. Degenerative changes

may also be present in the liver, testis, ovary, brain, and pituitary gland.

### Specimens for Pathology

Smears from tissues, usually the cut surface of a lymph node or heart muscle, are examined for trypanosomes before or shortly after the animal dies. Trypanosomes will not be detectable if postmortem examination is delayed for even a few hours because the parasites die and disintegrate soon after the host dies. For PCR detection, blood or buffy coat is spotted on Whatman filter paper (Whatman No. 4) stored at room temperature and sent to the appropriate laboratory.<sup>27</sup> With *T. brucei*, smears of serous fluids, including the CSF, may contain many parasites even when they are undetectable in blood.

The following organs should be taken for histopathology: lymph nodes, spleen, liver, heart, kidney, brain, and any other organ showing gross lesions. The immediate cause of death is often a combination of trypanosome-induced anemia and a concurrent bacterial or parasitic infection.

### DIFFERENTIAL DIAGNOSIS

Diagnosis is based on detecting parasites in blood. Because parasitemias fluctuate, multiple samples from a herd or repeated sampling of a suspected case may be required before a specific diagnosis can be made. Furthermore, an infected animal may be suffering from a concurrent disease. Emaciation and anemia can also be associated with the following:

- Malnutrition
- Helminthosis
- Babesiosis
- Anaplasmosis
- East coast fever

Acute trypanosomosis may be confused with hemorrhagic septicemia and anthrax. Laboratory examination of blood, feces, and other tissues is required to confirm diagnosis.

### TREATMENT

#### TREATMENT AND CONTROL

##### Treatment

Diminazene aceturate (Berenil) (3.5–7 mg/kg IM) (R1 for ruminants, R-3 for equines)

Homidium chloride/bromide (Ethidium/Novidium) (1 mg/kg IM) (R-1 for ruminants and equines)

Isometamedium chloride (Samorin) (0.25–1 mg/kg IM) (R-1 for ruminants)

Quinapyramine sulfate (Antrycide) (5 mg/kg SC) (R1 for equines)

Suramin (Antrypol) (10 mg/kg IV) (R-2 for equines, camelids, 2–3 times weekly)

##### Control

Isometamedium chloride (2 mg/kg IM) (R-1)

Homidium chloride/bromide (1 mg/kg IM) (R-2)

Prothridium (2 mg/kg IM) (R-2)

Antrycide prosalt (7.4 mg/kg SC) (R-2)

Antrycide/Suramin complex (35 mg/kg SC) (R-2 for *T. simiae* in pigs)

The number of trypanocidal drugs available for treating and preventing infections in endemic areas is limited, and 35 million doses are administered yearly in Africa.<sup>29</sup> The drugs have been in the market for half a century or more; their range of therapeutic safety is small; many of them cause severe local reactions, especially in horses; and some may be fatal in high doses. Furthermore, because drugs are expensive and can now be purchased without prescription, inappropriate dosing, improper administration, and use of fake or poor-quality drugs are common. These, plus the fact that some drugs are used both prophylactically and therapeutically, have led to cases of drug resistance, which is universally regarded as a threat to livestock production and health.

Ideally, each country or region establishes a group of sanative drugs that are to be used only as a break in a course of one of the more common drugs. The sanative drug should provide moderate prophylaxis and avoid the development of resistance to the prime drug. These measures have not been well executed in many countries, especially with the privatization of veterinary practice in Africa. This may explain the increasing reports of multiple resistance to curative, sanative, and prophylactic drugs over the years.<sup>6,30–31</sup> On the other hand, a high prevalence of drug resistance to diminazene aceturate has been reported for *T. congolense* without a recent history of drug exposure.<sup>5</sup> The isolates were obtained from tsetse or wildlife in parks in Tanzania, Zambia, and South Africa. Furthermore, it has been observed that clones of *T. congolense* resistant to isometamedium chloride are more easily transmissible to tsetse flies (*G. morsitans*).<sup>32</sup> This may be another factor contributing to the high prevalence of drug-resistant strains in the African region.

Strains are regarded as resistant when they fail to respond to the drug or when they relapse in blood sometime after an apparent cure. More cases of relapses are likely to be observed with the more sensitive PCR method for blood examination. However, it has been observed that relapses, where the host controls the level of parasitemia to a level below the sensitivity of routine microscopic examination, do not affect the productivity of the host.<sup>33</sup> Relapses are more likely to occur if the commencement of treatment is delayed or the dose rate is inadequate. However, in field situations, there is hardly any regular monitoring of drug efficacy, and animals may be reinfected with the same or other species of trypanosomes soon after an otherwise effective cure.

The common drugs in use against trypanosomes are set out in the following discussion. The specific dose rates vary with animal species, the specific trypanosome, and the specific purpose (curative, prophylactic, or sanative).

- Diminazene aceturate (Berenil) is used widely against *T. vivax* and *T. congolense* as a curative and sanative drug at 3.5 to 7 mg/kg BW IM. It is well tolerated by ruminants, and it is one of the two recommended drugs for bovine trypanosomosis. It is not well tolerated by horses.
- Isometamidium (Samorin or Trypamidium) is the other preferred drug against *T. vivax* and *T. congolense* in ruminants. It is used as a curative and prophylactic drug at 0.25 to 1 mg/kg BW IM. At much higher doses (12.5 to 35 mg/kg BW) it can be used prophylactically against *T. simiae* in pigs but not without the risk of death from acute cardiovascular collapse.
- Homidium bromide (ethidium) and homidium chloride (novidium) are also widely used against *T. congolense* and *T. vivax* as curative and sanative drugs at 1 mg/kg BW IM.
- Pyrrithidium bromide (prothridium) is less widely used against *T. congolense* and *T. vivax* as prophylaxis at 2 mg/kg BW IM.
- Quinapyramine sulfate (Antrycide) is no longer used extensively in cattle. It is the preferred curative drug against *T. brucei brucei* in horses at 5 mg/kg BW IM. Quinapyramine sulfate and chloride (Antrycide prosalt) is used prophylactically at 7.4 mg/kg BW SC.
- Suramin (naganol) may also be used against *T. brucei* as a curative and prophylactic drug at 10 mg/kg BW in horses and camels.
- Antrycide–Suramin complex is the only other drug effective against *T. simiae* in pigs, and it is used prophylactically at 40 mg/kg BW.

### CONTROL

The control of trypanosomosis in endemic countries involves control of tsetse fly population, prophylactic treatment of animals at risk, good husbandry of animals, and use of trypanotolerant animals. There is no vaccine against the disease, and in spite of intensive research, vaccines appear unlikely in the near future because of the ability of trypanosomes to readily change their glycoprotein surface coat through the process of antigenic variation.

Control of tsetse has been successfully attempted in some African countries, but reinvasion is frequent if the land is not properly utilized. The earliest methods involved bush clearing and elimination of game animals on which tsetse feed. These methods were effective in eradicating or

controlling tsetse in some parts of the continent, especially in southern Africa, but they resulted in destroying valuable plant and animal resources and also led to soil erosion. More recent methods involved the use of insecticides, especially DDT and endosulfan, applied strategically in the form of ground and aerial spraying over large expanses of land. Because tsetse flies are sensitive to insecticides and no resistance has developed, considerable successes were achieved in some countries. Under the Pan African Tsetse and Trypanosomiasis Eradication Campaign (PATTEC) program, tsetse was eliminated from an area of over 10,000 km<sup>2</sup> in Botswana and Namibia in 2006 using a sequential aerial spraying technique to apply deltamethrin.<sup>34</sup> However, spraying insecticides is costly and harmful to the environment. These harmful effects are considerably reduced if the insecticides, for example, synthetic pyrethroids, are applied directly on the animal in the form of spray or pour-on formulation, or the recently described footbath.<sup>34-35</sup> The insecticides also reduce tick infestations in treated animals.

Other effective methods involve use of targets impregnated with insecticides and traps that attract and catch tsetse. These are simple and cheap and can be constructed and maintained by local communities. Furthermore, they do not pollute the environment and are suitable for both small- and large-scale farming. They have been used to drastically reduce tsetse fly population and incidence of trypanosomiasis in some countries.

Another method of control is the sterile male technique. Because the female tsetse only mates once in a lifetime, this technique is theoretically able to eradicate a targeted tsetse species in areas where other methods have been used to reduce its density. But it is expensive.

Finally, it should be stated that development of the land for agriculture, industries, highways, and so forth effectively destroys the habitat for tsetse flies. This is occurring in many parts of Africa, including Nigeria, with rapid economic activities and expanding human population.

Attempts at trypanosomiasis control have also been directed to prophylactic dosing with chemicals such as suramin, prothidium, and isometamidium (Samorin). Prophylaxis is used along with other methods in areas where there is a heavy tsetse challenge. The prophylactic effect is supplemented by the development of antibodies, and the total period of protection may be as long as 5 months. However, it is customary to give four or five treatments per year. The productivity response to this pattern of treatment is good if general husbandry is also adequate. The downside of this approach is that it is thought to be one of the factors leading to drug resistance in many countries, in

addition to the ready availability of fake and poor-quality drugs.

Trypanotolerant animals are being used to establish ranches in areas where tsetse challenge is not too heavy. These indigenous breeds are not well accepted in some countries because their productivity is generally low. To offset this, the breeds are increasingly being crossed with other indigenous and improved breeds. The crosses are more productive, and they retain the trait for trypanotolerance.<sup>9</sup>

For effective control of trypanosomiasis in Africa and in Central and South America, an integrated approach will mostly likely produce the desired results in each region. In the absence of a vaccine, control methods must combine reduced exposure to the vectors (large-scale tsetse trapping and pour-on applications) with strategic treatment of exposed animals (chemotherapy and chemoprophylaxis) along with use of trypanotolerant animals when feasible. The Pan African Tsetse and Trypanosomiasis Eradication Campaign launched in the last decade is applying many of these methods in different countries, with the hope of eliminating tsetse from Africa in the near future.

## SURRA (MAL DE CADERAS, MURRINA)

### SYNOPSIS

**Etiology** *Trypanosoma evansi* (synonym *T. equinum*), a subspecies of *T. brucei*, but transmitted mechanically by biting flies, mainly tabanids, and by vampire bats in Latin America.

**Epidemiology** Endemic disease of mainly horses, camels, and buffaloes in the tropics and subtropics, seasonality is related to fly population. Rare outbreaks in Spain and France.

**Clinical signs** Fever, progressive emaciation, anemia, subcutaneous edema, nervous signs, death. May be acute, but mostly subacute to chronic.

**Clinical pathology** Progressive anemia, parasite detection in blood by various methods, serology.

**Lesions** Not definitive but include pallor, emaciation, muscle atrophy of hindquarters in horses, lymphadenomegaly, and jaundice.

#### Differential diagnosis list:

- Nagana
- Malnutrition
- Helminthosis

- Babesiosis
- Anaplasmosis
- Hemorrhagic septicemia

**Treatment** Trypanocides as in nagana, but less effective.

**Control** Chemotherapy, no vaccine.

## ETIOLOGY

*Trypanosoma evansi*, the first pathogenic trypanosome to be identified in 1880 in India, belongs to the *brucei* group (subgenus *Trypanozoon*) but has lost its kinetoplast DNA (akinetoplastic) and is therefore not capable of cyclical development in tsetse *Glossina* spp.<sup>1</sup> The parasite is believed to have originated from a mutated form of *T. equiperdum* characterized by being dyskinetoplastic (has lost part of its kDNA). *T. evansi* was formerly referred to as *T. equinum*, *T. hippicum*, or *T. venezuelense* in South America. Worldwide, it is the most widespread species of pathogenic trypanosomes. In blood smears, *T. evansi* is morphologically indistinguishable from *T. brucei*, but at the molecular level, the structure of the kinetoplast DNA of *T. evansi* is different.

## EPIDEMIOLOGY

### Occurrence

Surra has a wide distribution in areas of Asia, Middle East, Central and South America, Africa north of the tsetse belt, and occasionally in Europe. The disease is called “mal de caderas” (meaning “sickness of the hips”) in South America, “murrina” in Panama, and “surra” in other parts of the world. In some countries, the incidence of surra increases significantly during the rainy season when there are large biting fly populations, the so-called surra season. The disease affects mainly camels and horses, but buffaloes and cattle are also affected. Some endemic areas have been identified in Las Palmas and the Canary Islands, and two recent outbreaks of the disease in Spain and France were traced to camel importation from the areas.<sup>2</sup> A two-part comprehensive review of *T. evansi* and surra has been published recently.<sup>3-4</sup>

### Morbidity and Case Fatality

Infection rates in camels, horses, and buffaloes in endemic countries vary considerably and can be as high as 100% in buffalo herds in high-risk areas.<sup>5</sup> During a recent outbreak in Spain, 76% of the camels, 36% of the donkeys, and 26% of the horses examined were affected.<sup>6</sup> Fewer cases are detected by standard parasitologic methods than by serology or PCR methods. The case fatality in horses and camels is nearly 100% if untreated, but it is much lower in cattle and buffaloes, where the disease tends to run a chronic course. Nonetheless, strains highly pathogenic for water buffaloes and cattle have been reported in the Philippines.<sup>7</sup>

## Method of Transmission

Several hematophagous flies can transmit *T. evansi* mechanically, but the most important is the horse fly (*Tabanus* spp.), followed by the stable fly (*Stomoxys* spp.). Transmission is enhanced when horses or camels congregate or are closely herded and when they have high numbers of parasites in their blood. In South America, the vampire bat also can transmit the disease in its saliva. The process can be mechanical as for flies but also biological in that parasitemia occurs in the bats, and the bats may die of the infection or recover and serve as carriers. Therefore vampire bats are simultaneously hosts, reservoirs, and vectors of *T. evansi*. Indigenous cattle, buffalo, and several species of wildlife may act as reservoirs of infection for horses and camels. Several workers in South America have incriminated capybaras, small marsupials, armadillos, feral pigs, and peccary as possible reservoirs of *T. evansi*.<sup>8-9</sup> Carnivores can also be infected peri-orally when they feed on an infected carcass.

## Immune Mechanisms

Immune mechanisms are related to antigenic variation of the parasite and production of antibodies by the host, as in *T. brucei* and all its subspecies. Infected animals are also immunosuppressed and respond poorly to vaccination. As with other trypanosome infections, the immunosuppressive effect is abrogated following successful antitrypanosome treatment.<sup>10</sup> The disease can be reproduced experimentally by blood inoculation.

## Zoonotic Implications

Humans are generally not susceptible to *T. evansi* infection. However, two cases of human infection and disease have been reported, one from India and the other from Egypt.<sup>11-12</sup> In the Indian case, the serum of the infected patient was found to have no trypanolytic activity, and this finding was linked to a lack of apolipoprotein L-1, the pathway in normal human serum for killing most trypanosomes.<sup>13</sup>

## Economic Importance

Surra is one of the most important diseases of camels in Africa and Asia, and outbreaks are increasingly being reported in South American horses and occasionally in European camels. Camel raising in Africa and buffalo production in Asia are particularly affected by the disease. As in nagana, losses are attributable to reduced productivity, infertility, abortion, mortality, and cost of treatment. In Indonesia, losses as a result of surra were estimated at more than US\$20 million in the 1980s. More recently, it has been estimated that in the Philippines, the total net benefit for surra control for herds in a typical village in an endemic area is \$158,000 per annum.<sup>14</sup>

## Biosecurity Concerns

There are no biosecurity concerns, except with regard to importation of carrier animals to nonendemic countries.

## PATHOGENESIS

Trypanosomes are inoculated into the host from the contaminated mouthparts of biting insects or the saliva of vampire bats. Parasites multiply in blood, causing anemia and spread to serous fluids and interstitial tissue, resulting in inflammatory changes just like those seen with *T. brucei*. The anemia of surra is probably similar to that of nagana. There is increased erythrophagocytosis and intravascular hemolysis resulting from lipid peroxidation of erythrocytes.<sup>15</sup> As for emaciation, it has been suggested that protein breakdown and lipolysis might contribute to the cachexia in infected horses.<sup>16</sup> In horses, *T. evansi* frequently invades the central nervous system, including the spinal cord, where it is less exposed to chemotherapeutic agents.

## CLINICAL FINDINGS

The main clinical findings are intermittent fever, progressive anemia, edema of dependent parts of the body, dullness, listlessness, loss of body condition despite a good appetite, nasal and ocular discharge, abortion, and infertility. In the late stages, there are marked nervous signs, including marked paraplegia, paralysis, delirium, and convulsions. In a recent outbreak involving horses in Brazil, the nervous signs were ataxia, blindness, head tilt, circling, head pressing, and paddling movements before death.<sup>17</sup> Surra is invariably fatal in camels and horses, with death occurring in days or months, but camels may exhibit chronic signs for years. These signs include a reduction in milk yield and capacity for work, and a high abortion rate in pregnant females. Abortion and high neonatal mortality characterized the camel outbreak in the Canary Islands.<sup>18</sup> In endemic areas, cattle and buffalo usually have a milder disease that may be exacerbated by stress from adverse climatic conditions, work, or intercurrent disease. Signs may include a reduction in milk yield and capacity for work, irregular estrus, a high rate of abortion and stillbirth, and poor semen quality in bulls. Outbreaks of a more severe disease in indigenous zebu cattle are reported from time to time.<sup>7</sup> In such cases, there may be nervous signs and high mortality rate.

## CLINICAL PATHOLOGY

As with tsetse-transmitted trypanosomosis, routine parasite detection is more reliable in the acute phase. Examination of wet blood films and stained smears of blood and lymph node should be carried out, and this should include the buffy-coat method. In the chronic phase, repeated sampling for some days may be required. In addition, suspected blood samples may be inoculated into rats or mice, both of which are highly susceptible.

A number of nonspecific serologic tests have been used, especially in areas where other forms of trypanosomes are not prevalent. These include the mercuric chloride, formol gel, or stilbamidine test for increased serum protein levels. Specific antibody detection tests are also available and include the direct card agglutination test (CAAT) for antibodies, the latex agglutination test (Suratex) for circulating antigens, the indirect fluorescent antibody test (IFAT), and the enzyme-linked immunosorbent assay (ELISA). Serologic tests are probably more sensitive than parasitologic methods in revealing the true extent of surra in camel herds.

Where the facilities exist, the PCR technique is more sensitive and specific and can detect trypanosome DNA antemortem in the cerebrospinal fluid and in brain tissue postmortem.<sup>19</sup>

### NECROPSY FINDINGS

The carcass is emaciated and pale and may be icteric but, as in *T. brucei* infections, there are no pathognomonic gross and microscopic lesions unless the parasites are detectable. Infected horses will show hindquarter muscle atrophy, splenomegaly, and lymphadenomegaly. Asymmetric leukomalacia has been described in naturally infected horses, but it is not clear whether or not this was a result of treatment with diminazene aceturate.<sup>15</sup> Microscopic changes are characterized by a lymphoplasmacytic infiltrate of various organs, including the brain and spinal cord. If the carcass is very fresh, trypanosomes can be detected in blood and CSF with routine microscopy, and in the parenchyma of central nervous system by immunoperoxidase method<sup>17</sup> or by PCR technique identifying parasite DNA.<sup>19</sup>

### DIFFERENTIAL DIAGNOSIS

Laboratory services are required to confirm a diagnosis; even then, without the use of molecular techniques, surra cannot be easily distinguished from *T. brucei* infection where both coexist. Clinical signs and gross and microscopic lesions of both diseases in horses and camels are identical. Specimens to take for laboratory diagnosis are blood, brain, spinal cord, lymph nodes, spleen, and liver.

### TREATMENT

#### TREATMENT AND CONTROL

##### Treatment

Quinapyramine sulfate (Quintricide) (5 mg/kg SC) (R-1 for camels)

Diminazene aceturate (Berenil) (3.5–7 mg/kg IM) (R-1 for ruminants, R-3 for equines)

Melarsomine (Cymerlasan) (0.25 mg/kg IM for camels and 0.5 mg/kg for cattle) (R-1)

Isometamedium chloride (Samorin) (0.25–1 mg/kg IM) (R-1 for ruminants)

Suramin (Antrypol) (10 mg/kg IV) (R-2 for equines, camelids, 2–3 times weekly)

##### Control

Isometamedium chloride (2 mg/kg IM) (R-1)

Antrycide prosalt (7.4 mg/kg SC) (R-2)

Suramin (Antrypol) (10 mg/kg IV) (R-2 for equines, camelids, 2–3 times weekly)

Drugs used for treating nagana could be used for surra, but the outcome is less favorable because of their low trypanocidal activity against *T. evansi* and their specific toxicity for camels and horses. Furthermore, the drugs are not able to cross the blood–brain barrier to reach parasites in the cerebrospinal fluid and nervous tissue. As a result, relapses are common and may present as drug resistance. Three Brazilian isolates of *T. evansi* tested for drug resistance were found to be fully susceptible to a single dose of suramin sodium at 10 mg/kg BM in mice.<sup>20</sup>

Quinapyramine sulfate (quintrycide) is used curatively for camels, and diminazene aceturate (Berenil) is used for horses. A water-soluble arsenical, melarsomine hydrochloride (Cymerlasan), given IM is recommended for camels at 0.25 mg/kg BW and for cattle at 0.5 mg/kg BW.<sup>21</sup> For both curative and prophylactic use, quinapyramine prosalt (trypacide), suramin (naganol), and isometamedium chloride (samorin or trypanidium) are recommended (see section on nagana or African trypanosomosis).

### CONTROL

Unlike in nagana, control measures are aimed primarily at the host rather than the vector, which is abundant. The measures include detection and treatment of infected animals, prophylactic treatment of susceptible animals, and their protection from biting flies and bats, where possible. As in nagana, there is no vaccine.

## Multi-Organ Diseases Due to Fungal Infection

### PROTOTHECOSIS AND CHLORELLOSIS (ALGAL BACTEREMIA)

Protothecosis and chlorellosis are rare pseudofungal diseases in animals caused by the opportunistic algae of the Chlorellaceae family, *Prototheca* spp. (achlorophyllous mutant) and *Chlorella* spp. (chlorophyll-containing green alga), respectively.<sup>1</sup> Asymptomatic systemic infections and lymphadenitis associated with the achlorophyllous alga *Prototheca zopfii* or the green alga *Chlorella* spp. are extremely rare in cattle and sheep. Peritonitis and lymphadenitis associated with *Scenedesmus* spp., which is closely related to *Chlorella* spp., occurs rarely in cattle.<sup>2</sup> More common is mastitis in cattle caused by *P. zopfii*, or the more recently recognized *Prototheca blaschkeae*.<sup>3</sup> Protothecosis in goats is caused by *Prototheca wickerhamii* and presents as chronic weight loss and signs of respiratory disease.<sup>4</sup> Infections are considered opportunistic, with the exception of increased risk for disseminated infection in sheep grazing sewage-contaminated pasture. Lesions are typically granulomas.<sup>5</sup> Diagnosis is based on demonstration of alga in granulomatous lesions predominantly in the lymph nodes.<sup>1</sup> PCR-based testing is available.

## COCCIDIOIDOMYCOSIS

### ETIOLOGY

*Coccidioides immitis* is associated with the disease in all species, including humans. *Coccidioides posadasii* appears to be increasingly recognized as a pathogen.<sup>1</sup>

### EPIDEMIOLOGY

Coccidioidomycosis is a comparatively benign disease of farm animals, usually causing no apparent illness, although disseminated or overt pulmonary disease is associated with a high case-fatality rate in horses.<sup>2</sup> Sporadic cases are recorded in all species but are most common in dogs and in cattle and, to a much less extent, in pigs, sheep, and horses. Pulmonary coccidioidomycosis has been described in a 13-day-old foal. Approximately 4% of horses in areas in which the disease is endemic have serum antibodies to *C. immitis*.<sup>2</sup> The disease tends to affect young to middle-aged animals (median age of 8 years in affected horses), presumably because they are naïve to the infection, with older animals likely to have been exposed and subsequently resistant to the disease.<sup>2</sup> Case-fatality rates are low for mares with abortion (~0%) and animals with superficial abscesses compared with a fatality rate greater than 90% in horses with pneumonia and pleural effusion, or with pneumonia and at least one extrapulmonary site of disease.

The disease is enzootic in the southwestern United States, and up to 20% of cattle finished in feedlots in the area may harbor the fungus. The incidence of the disease in humans in the area provides a major problem in public health. It is not contagious, with infection occurring by inhalation of spores of the fungus, which grows in the soil, and possibly by ingestion and through cutaneous abrasions. The disease is common in dogs and is reported in aquatic wildlife (walrus), rhinoceros, and a koala (in San Diego, California).<sup>3-6</sup>

### CLINICAL FINDINGS

Clinical manifestations of infection in any species can include fever, abortion, pneumonia, pleural effusion, severe weight loss, osteomyelitis, and external abscessation.<sup>2</sup>

In horses, findings include weight loss up to severe emaciation, a fluctuating temperature, persistent cough, muscle pain, and superficial abscesses, often recurring, and most commonly in the pectoral area. Increased lung sounds, wheezing, and dullness are audible over the ventral chest. Other signs include edema of the legs, anemia, and intermittent colic as a result of internal abscesses and peritoneal adhesions. Liver rupture may cause death. Affected sheep

show fever and abscesses in peripheral lymph nodes.

### CLINICAL PATHOLOGY

A leukocytosis is usual, and there can be increases in serum or plasma markers of inflammation (serum amyloid A, fibrinogen).

Fungal cultures or biopsies can be positive for *C. immitis*. *Coccidioides* spp. grows within 2 to 5 days on several media, although fungal culture should be restricted to bio-safety level 3 laboratories.<sup>7</sup> A PCR assay is available to detect and determine the species of *Coccidioides* involved in the disease.<sup>1</sup>

Microscopic examination of tissues or of transtracheal or bronchoalveolar lavage fluids, lymph nodes, and pleural fluid exudates can be performed using KOH (or KOH-ink), lactophenol cotton blue, H&E, Papanicolaou, PAS, and methenamine silver stains.<sup>7</sup>

Serologic tests (i.e., agar gel immunodiffusion [AGID] assays and ELISA for the detection of IgM and IgG antibodies) may assist the diagnosis of coccidioidomycosis. Serum antibody titers are highest in animals with disseminated or pulmonary disease and lowest in animals with localized disease or abortion.<sup>2</sup>

### NECROPSY FINDINGS

The lesions produced in cattle and pigs are granulomatous, contain a cream-colored pus, are sometimes calcified, and are found in the bronchial, mediastinal, and, rarely, the mesenteric, pharyngeal and submaxillary lymph nodes and in the lungs. In a neonatal foal, the lungs were diffusely infiltrated with a miliary pattern of multiple, coalescing, pale-tan to red, irregularly shaped, slightly raised, firm foci, 0.1 to 0.5 cm in diameter.

### DIFFERENTIAL DIAGNOSIS

Microscopic or cultural examination may be used to identify the disease. Isolation of the organism or detection of DNA by polymerase chain reaction (PCR) is preferred.<sup>1</sup>

#### Differential diagnosis list:

- Cattle and pigs—tuberculosis
- Sheep and goats—caseous lymphadenitis
- Horses—*C. pseudotuberculosis* infection, pneumonia and pleuropneumonia, metastatic *Streptococcus equi* infection

### TREATMENT

Administration of azole compounds (fluconazole, itraconazole, voriconazole) or amphotericin B is advised, although the efficacy of these compounds remains to be determined.<sup>7</sup> Animals treated with these compounds must be monitored for adverse effects, including nephropathy induced by amphotericin.

Because infection occurs by the inhalation of soil-borne spores, control of dust in feedlots may help to prevent the spread of

the disease. Dust control is a major factor in prevention of human coccidioidomycosis because there is no vaccine or effective therapeutic agent available, and the eradication of *C. immitis* from the soil is not practicable.

## PARACOCIDIOIDOMYCOSIS (PARACOCIDIOIDES INFECTION)

Paracoccidioidomycosis in humans caused by *Paracoccidioides brasiliensis* is endemic in parts of South and Central America.<sup>1,2</sup> The disease affects mainly men, causing oral mucosal lesions and disseminated granulomatous disease.<sup>3</sup> There is serologic evidence of widespread exposure of horses,<sup>4</sup> free-ranging pigs,<sup>5</sup> dairy cattle,<sup>6</sup> sheep,<sup>7</sup> and goats<sup>8</sup> in endemic regions, but no reports of disease caused by this organism in large animals. Pigs appear to be resistant to the disease.<sup>5</sup> The organism was identified in tuberculous lesions obtained at slaughter from cattle in Kenya, but the etiologic role for *B. brasiliensis* was unclear.<sup>9</sup>

## RHODOTORULUA SPP. INFECTION

Infection by *Rhodotorula* spp. is a rare cause of disease in humans and animals.<sup>1</sup> In large animals it is associated with pneumonia and fungemia in sheep.<sup>2</sup>

### REFERENCES

1. Wirth F, et al. *Interdisc Pers Infect Dis*. 2012;46:5717.
2. Chitko-McKown CG, et al. *Transbound Emerg Dis*. 2014;61:E76.

## HISTOPLASMOSIS

Histoplasmosis, associated with infection with *Histoplasma capsulatum*, is a rare systemic mycosis in farm animals, with a high prevalence in specific geographic localities, such as the Ohio River and Mississippi River system and areas of South and Central America, Mediterranean countries, Asia,

Africa, and Australia. Cases have been recorded in horses, cattle, and pigs. The disease is relatively common in cats and dogs and occurs in a wide variety of other species, including wildlife and humans.<sup>1-4</sup>

The fungus is able to survive for periods as long as 4 months in soil and water. Infection occurs by the inhalation of contaminated dust, and primary invasion usually takes place in the lung. The disease can spread from animals to humans. Attempts at experimental infection in cattle, sheep, horses, and pigs have resulted in nonfatal infections, unless the agent is given intravenously, but the test animals become positive to the histoplasmin cutaneous sensitivity test.

Clinical syndromes vary greatly and include pneumonia with dyspnea and nasal discharge, hepatic insufficiency with jaundice and anasarca, placentitis with abortion, and widespread lesions in neonates, especially foals. Infections in horses can be evident as intra-abdominal masses.<sup>5</sup>

As a diagnostic aid for herd or area, the histoplasmin skin test appears to be satisfactory. Keratitis attributable to *Histoplasma* spp. has been described. Histoplasmosis may be secondary to yersiniosis in the horse.

Necropsy lesions are as variable as the clinical syndrome and include gross hepatic enlargement containing necrotic foci, pulmonary consolidation and granulomatous pneumonia, and enlargement of splanchnic lymph nodes. Aggregation of the fungal bodies in lymphoid tissue and other tissues in which large numbers of phagocytes are in residence is characteristic of the disease; the lesions consist of groups of macrophages packed with fungal cells. Fungal culture can yield the organism.

Triazoles (e.g., fluconazole, itraconazole) or imidazoles (e.g., ketoconazole) appear to be sensible choices for pharmacologic therapy, but efficacy has not been demonstrated. The treatment of choice for histoplasmosis in dogs and cats is itraconazole, either alone or in combination with ketoconazole or amphotericin B.<sup>3</sup> Voriconazole is also used, but without documented efficacy in large case series in dogs or cats.

The disease associated with infection with *H. farciminosum* is dealt with under the heading "Epizootic Lymphangitis."

## CRYPTOCOCCOSIS (EUROPEAN BLASTOMYCOSIS, TORULOSIS)

Infection with the yeast *Cryptococcus neoformans* or *C. gattii* (the *C. neoformans*-*gattii*

complex) occurs in most species, including humans, cattle, horses, goats, dogs and cats, and wildlife, either as a generalized disease, sometimes with localization in particular tissues, or as a granulomatous meningoencephalitis.<sup>1-7</sup> In humans, pulmonary lesions are more likely with *C. gattii* infection, and neurologic disease more likely with *C. neoformans*.<sup>4</sup> *C. neoformans* is a basidiomycetous fungus with a worldwide distribution, commonly found in soil contaminated with avian feces.<sup>8</sup> Two pathogenic variants of *C. neoformans* are *C. neoformans* var. *neoformans* and *C. neoformans* var. *gattii*, and these variants are separate species, based on DNA sequence analysis, but are not distinguishable by the routinely performed and rapidly available *C. neoformans* capsular antigen latex agglutination titer.<sup>8</sup>

The frequency of disease or animal risk factors are not reported. Of 260 horses examined in an area in which the disease was considered endemic (Vancouver Island, Canada), 4 had cryptococcus isolated from nasal swabs and none had detected serum antibody titers to the organism.<sup>9</sup>

Nervous system involvement is manifested by stiffness, hyperesthesia, blindness, or incoordination. Clinical signs in cattle include multifocal neurologic deficits manifested by hypermetria, ataxia, depression, circling, impaired vision, head pressing, low head carriage, wide-based stance, and falling to the side or backward.<sup>4,10</sup> Systemic involvement includes cases of myxomatous lesions of nasal mucosa, pulmonary abscess or pneumonia, jejunal granuloma, lymphadenitis, osteomyelitis, placentitis with abortion, and systemic involvement in the fetus. *C. neoformans* is a cause of bovine mastitis. The disease can manifest as sinonasal granulomas in horses with local extension to the cranial vault.<sup>3</sup>

CSF of affected animals is xanthochromic, with elevated white cell count and markedly increased protein concentration.<sup>8</sup> Cryptococci can be detected in cerebrospinal fluid of animals with neurologic disease by microscopic examination of the fluid, or detection of serum or CSF antibodies to the organism (detected by latex agglutination test).<sup>8</sup>

Successful treatment of neurologic disease in horses is by administration of triazole antifungals, such as fluconazole (14 mg/kg PO once, and then 5 mg/kg PO q24h) for weeks to months;<sup>8</sup> or, for sinonasal granulomas, a combination of systemic therapy with fluconazole, debulking of the lesions in the nasal cavity, and intralesional injection of fluconazole, amphotericin, and/or formalin,<sup>3</sup> or irrigation of the nasal sinuses with enilconazole.<sup>11</sup>

## NORTH AMERICAN BLASTOMYCOSIS

The fungus associated with North American blastomycosis, an important disease in humans<sup>1</sup> and dogs,<sup>2</sup> is *Blastomyces dermatitidis*, which is genetically diverse, having over 100 haplotypes divided into two important genetic groupings (Groups 1 and 2), although it has yet to be fully classified.<sup>3,4</sup> More veterinary isolates are in Group 2 than in Group 1, with some haplotypes in each group being identified in only human infections (Group 1) or animals (Group 2).<sup>4</sup> The asexual phase is called *Blastomyces dermatitidis* and its sexual phase, *Ajellomyces dermatitidis*.<sup>1</sup> The organism affects both animals and humans; although it does not appear to be zoonotic (direct transfer of infection from animals to humans), caution should be exercised when treating animals with the disease. Presence of disease, or prevalence of antibodies to the organism, can be indicative of endemicity of infection in geographic areas.

The disease is relatively common in dogs in the upper Midwest of the United States, but it is rare in horses and other large animals.<sup>5</sup> It is reported in horses, goats, sheep, alpaca, and cattle and in miscellaneous other species such as ferrets.<sup>4,6-10</sup> The disease is reported, although infrequently, worldwide, with cases in animals recorded in Italy,<sup>11</sup> West Africa,<sup>6</sup> India, and South America, in addition to well-recognized foci in North America.<sup>4</sup>

Risk factors for large animals are not identified.

There is little information on the pathogenesis of this disease in large animals. In humans and dogs, infection is either by inhalation of organism, with subsequent development of granulomatous pneumonia, or it follows direct infection of skin, presumably through wounds or macerated dermis, resulting in skin lesions. Infection from either site can then become systemic, with pulmonary infection disseminating to other organs, including the brain, urogenital tract, viscera, and skin. Infection originating in the skin can spread to other organs.<sup>1,5</sup> Systemic infection in dogs is associated with increases in concentration or activity of markers of systemic inflammation and hypercoagulability.<sup>12</sup>

The disease in horses can affect the skin (Fig. 21-3), bones,<sup>8</sup> temporomandibular joint, mammary gland, and both thoracic and abdominal organs. Skin lesions in horses

**Fig. 21-3** Lesions of blastomycosis in horse demonstrating combination of verrucous, raised, hairless lesions (black arrow) and subcutaneous lesions (white arrow). (Reproduced with permission from Funciello B, et al. *Equine Vet Educ* 2014;26:458.)

occur mainly in the skin of perianal, perivulvar, neck, pectoral, inguinal areas, ventrum, mammary gland, and hindlegs,<sup>5</sup> and are typically of either of two forms, or a mix of each (Fig. 21-3): subcutaneous nodules or verrucous, irregularly shaped lesions with hair loss and crusty raised margins.<sup>5,11</sup> The verrucous lesions are often located over subcutaneous abscesses. Skin lesions can be ulcerated and have draining tracts from deeper lesions.

The pulmonary form is reported in sheep,<sup>7</sup> disseminated disease with clinical manifestations of central neurologic dysfunction in an alpaca,<sup>10</sup> and granulomatous disease resembling tuberculosis in cattle.<sup>13</sup>

Organisms can occasionally be identified as budding yeast bodies in the exudate of ulcerative lesions or draining tracts. Demonstration of organism in typical lesions confirms the disease. *B. dermatitidis* antigens can be detected in urine of animals with blastomycosis.<sup>8,14</sup> The degree of antigenuria has diagnostic utility in dogs, being moderately sensitive but highly specific for the presence of the disease, and is useful in monitoring response to therapy, decisions on cessation of pharmacotherapy, and monitoring for recrudescence of infection.<sup>14</sup>

Differential diagnoses include tuberculosis (especially in cattle), metastatic *S. equi* in equids, equine multinodular pneumonia, neoplasia, and abscesses caused by *C. pseudotuberculosis*.

Treatment consists of surgical debulking or debridement of accessible solitary lesions and administration of antifungal agents. Treatment of choice in dogs and humans is administration of itraconazole or fluconazole or, in cases of severe infection, amphotericin B.<sup>5</sup> Successful treatment of cutaneous

blastomycosis in a horse involved administration of fluconazole (14 mg/kg PO loading dose followed by 5 mg/kg PO once daily) for 5 weeks.<sup>11</sup> Discontinuation of therapy resulted in recrudescence of infection, which was resolved by further administration of the drug. Use of potassium iodide (20 mg/kg PO every 24h) was not efficacious in preventing recrudescence of infection. Antifungal therapy should be continued for months. Monitoring of efficacy of therapy by measurement of urine *B. dermatitidis* antigens in urine might be useful in large animals, as it is in dogs and humans.<sup>14</sup>

## Multi-Organ Diseases Due to Metabolic Deficiency

### SODIUM AND/OR CHLORIDE DEFICIENCY

A dietary deficiency of sodium is most likely to occur in the following instances:

- During lactation, as a consequence of losses of the element in the milk, in rapidly growing young animals fed on low-sodium, cereal-based diets
- Under very hot environmental conditions where large losses of water and sodium occur in the sweat and where the grass forage and the seeds may be low in sodium
- In animals engaged in heavy or intense physical work and in animals grazing pastures on sandy soils heavily fertilized with potash, which depresses forage sodium levels

Naturally occurring salt deficiency causing illness in grazing animals is uncommon except under specific circumstances. The most commonly cited occurrences are on alpine pastures and heavily fertilized pasture leys. Pasture should contain chloride at least 0.15 g/100 g dry matter (DM), and clinical signs are evident after about 1 month on pasture containing 0.1 g chloride/100 g DM. Under experimental conditions,

lactating cows give less milk until the chloride deficiency is compensated. After a period of up to 12 months there is considerable deterioration in the animal's health, and anorexia, a haggard appearance, lusterless eyes, rough coat, and a rapid decline in body weight occur. High-producing animals are most severely affected, and some may collapse and die. The oral administration of sodium chloride is both preventive and rapidly curative. Experimental sodium depletion in horses for up to 27 days has no deleterious effect on general health.

In dairy cattle on a sodium-deficient diet, there is polyuria; polydipsia; salt hunger; pica, including licking dirt and each other's coats and drinking urine; loss of appetite and weight; and a fall in milk production. Urination is frequent, the urine has a lower-than-normal specific gravity, and the urine concentrations of sodium and chloride are decreased and the potassium increased. The salivary concentration of sodium is markedly decreased, the potassium is increased, and the salivary sodium:potassium ratio is decreased. The concentrations of serum sodium and chloride are also decreased, but the measurement of urinary or salivary sodium concentration is a more sensitive index of sodium intake than plasma sodium concentration. Of these, it is urinary sodium that is depressed first and is therefore the preferred indicator in cattle and horses. The polyuria associated with severe sodium depletion may be an antidiuretic hormone insensitivity as a result of lack of an effective countercurrent mechanism and hyperaldosteronism.

Supplementation of salt to dairy cows on a pumice soil in New Zealand resulted in a 12.8% increase in milk yield with unaltered composition. The cows were grazing ryegrass/clover pastures averaging 0.05% sodium, whereas the recommended concentration for dairy cows is 0.12%. Measurement of the sodium content of the pasture is the most simple and reliable method of diagnosing salt deficiency compared with saliva sodium:potassium ratio. It is considered likely that sodium deficiency will become more prevalent on dairy farms in the future and that there are cost-effective benefits to using salt where deficiencies occur.

Experimental restriction of chloride in the diet of dairy cows in early lactation results in a depraved appetite, lethargy, reduced feed intake, reduced milk production, scant feces, gradual emaciation, and severe hypochloremia and secondary hypokalemic metabolic alkalosis. Lethargy, weakness, and unsteadiness occur after about 6 weeks on the chloride-deficient diet. Bradycardia is also common. The concentration of chloride in cerebrospinal fluid is usually maintained near normal, whereas the serum concentrations decline. The experimental induction of a severe, total body chloride deficit by the provision of a low-chloride

diet and the daily removal of abomasal contents results in similar clinical findings to those described previously and lesions of nephrocalcinosis.

The **diagnosis of salt deficiency** is dependent on the clinical findings, analysis of the feed and water supplies, serum levels of sodium and chlorine, and determination of the levels of sodium in the saliva, urine, and feces of deficient animals. The concentration of sodium in saliva is a sensitive indicator of sodium deficiency. In cattle receiving an adequate supply of sodium and chlorine, the sodium levels in saliva vary from 140 to 150 mmol/L; in deficient cattle the levels may be as low as 70 to 100 mmol/L. The levels of sodium in the urine are low, with a reciprocal rise in potassium. The serum sodium levels are less reliable, but licking begins when the level falls to 137 mmol/L, and signs are intense at 135 mmol/L.

The biochemical methods have been evaluated to estimate the sodium intake of dairy cows. Groups of cows were given 10 to 20, 30 to 50, or 70 to 100 g salt per day, and two groups were given salt ad libitum either in bowls or in salt blocks. The concentrations of sodium and potassium were measured in serum and urine. Cows receiving 70 to 100 g salt daily and those in the ad libitum group had higher urinary sodium concentrations than the other groups. Those receiving 10 to 20 g/day had a higher urinary ratio of potassium:sodium in their urine than all other groups, in which the ratio decreased as the level of supplementary salt increased.

**Experimentally induced sodium deficiency in young pigs** causes anorexia, reduced water intake, and reduced weight gains.

The provision of salt in the diet at a level of 0.5% is considered to be fully adequate for all farm animal species. Under practical conditions, salt mixes usually contain added iodine and cobalt. In some situations, the salt mixes are provided on an ad libitum basis rather than adding them to the diet. However, voluntary consumption is not entirely reliable. The daily amount consumed by animals having unrestricted access to salt can be highly variable and often wasteful. Two factors influencing voluntary salt intake are the physical form of the salt and the salt content of the water and feed supplies. Some cattle consume much more loose than block salt, although the lower intakes of block salt may be adequate. Also, animals dependent on high-saline water for drinking consume significantly less salt than when drinking nonsaline water. Voluntary salt consumption is generally high in cows on low-sodium pastures, which are low inherently or as a result of heavy potash fertilization. Lactating gilts may require 0.7% salt in their diets, and energy efficiency in feedlot cattle may be improved by feeding high levels (5% of diet) of salt in the diet of finishing steers.

## MAGNESIUM DEFICIENCY

Magnesium (Mg), the second most abundant intracellular cation, plays a vital role as a cofactor for many enzymes, acts as a modulator of ion channels, and affects many cellular processes, such as neuromuscular excitability and secretion of hormones, and antagonizes the actions of  $\text{Ca}^{2+}$ .<sup>1-3</sup> Magnesium deficiency or depletion causes disturbances in a multitude of physiologic processes and is evident from severe clinical disease and death, in hypomagnesemic tetany of cattle, through to reduced production and impaired health.<sup>2,4</sup> Nutritional deficiency of magnesium plays a role in causing lactation tetany in cows and hypomagnesemic tetany of calves, and these diseases are dealt with in [Chapter 18](#) on metabolic diseases. Magnesium deficiency in late pregnant dairy cows can predispose to periparturient hypocalcemia by impairing the secretion of parathyroid hormone (PTH). In both diseases, there are complicating factors that may affect the absorption and metabolism of the element.

Hypomagnesemia occurs in up to 50% of adult horses hospitalized for severe gastrointestinal disease such as colic, acute diarrhea, and infectious respiratory disease.<sup>5</sup> Serum magnesium concentrations of healthy horses vary with age, parturition, lactation, and sex.<sup>6</sup> Cattle with any one of a number of diseases that decrease feed intake,<sup>2,3</sup> or magnesium absorption, are at increased risk of magnesium deficiency. Postpartum cows with retained placenta have lower concentrations of Mg, and some other minerals, than do postpartum cows without retained placenta.<sup>7</sup> Dairy cows at risk of hypokalemia and supplemented by oral administration of KCl might be at increased risk of magnesium deficiency because of the competitive inhibition of increased ruminal potassium concentrations on magnesium absorption from the rumen.<sup>8</sup>

Magnesium is an essential constituent of rations for recently weaned pigs. Experimentally induced deficiency causes weakness of the pasterns, particularly in the forelegs, causing backward bowing of the legs, sickled hocks, approximation of the knees and hocks, arching of the back, hyperirritability, muscle tremor, reluctance to stand, continual shifting of weight from limb to limb, and eventually tetany and death. A reduction in growth rate, feed consumption and conversion, and levels of magnesium in the serum also occurs. The requirement of magnesium for pigs weaned at 3 to 9 weeks of age is 400 to 500 mg/kg of the total ration.

Diagnosis of magnesium deficiency is challenging because measurement of serum magnesium concentration is not a reliable indicator of whole-body magnesium status.<sup>9</sup> Plasma Mg makes up only 0.3% of total body Mg, and concentration of Mg in plasma is held constant over a wide range of Mg

intakes and is only weakly correlated with the functionally important intracellular pools of Mg.<sup>1,4,9</sup> Increasing or decreasing renal magnesium excretion primarily regulates the extracellular Mg concentration, and whole-body Mg status can be monitored rather by assaying total urinary Mg excretion. Because the collection of all urine produced over a 24-hour period is difficult or impossible in practice, urinary magnesium concentration can be measured in a spot sample. However, urinary magnesium concentration is markedly affected by urine volume and can be difficult to interpret. Estimates of magnesium status can be obtained by measuring urine creatinine and magnesium concentrations, measuring plasma magnesium and urine concentrations, and calculating urinary fractional excretion of Mg, thereby avoiding the need for collection of all urine produced over a 24-hour, or other prolonged, period.<sup>1,4</sup> Fractional excretion of Mg is a more sensitive indicator of Mg availability than is plasma, or serum, Mg concentration and a better predictive indicator of the need for supplementation.<sup>4</sup> Methodology for determining magnesium status in cattle and horses is described. A method in cattle involves collection of basal blood and urine samples 60 minutes before starting a magnesium challenge infusion (2.5 mg/kg BW in 250 mL of 0.9% saline was infused at 2.1 mL/min for 120 min) with blood and urine samples collected at 30-minute intervals until 60 minutes after the end of the infusion. Urinary fractional clearance (FC) of magnesium is calculated using the formula:

$$FC\%(Mg) = \frac{[Cr]_{pl}}{[Cr]_u} \times \frac{[Mg]_u}{[Mg]_{pl}} \times 100$$

The reference interval is generally considered to be 2.64% to 43.6% for cows at the end of lactation. Herds with mean fractional clearance of Mg less than 10% are likely to have a deficient Mg status and might benefit from Mg supplementation.<sup>4</sup> A magnesium challenge test can reveal cows with low total body magnesium content because these cows retain much of the infused magnesium, with consequent unchanged fractional clearance values, whereas cows with adequate magnesium status have an increase in fractional clearance of the electrolyte.<sup>4</sup>

Feeding of a magnesium-deficient diet for 29 days in young horses did not result in detectable changes in total or ionized magnesium concentrations in serum, but magnesium excretion over 24 hours and fractional clearance of magnesium in urine were markedly reduced.<sup>9</sup>

## COPPER DEFICIENCY

## SYNOPSIS

**Etiology** Primary deficiency as a result of inadequate copper in the diet. Secondary copper deficiency is associated with antagonistic factors, particularly excess molybdenum and sulfur, which form thiomolybdates in the rumen. Thiomolybdates can bind copper in the rumen, or, if insufficient copper is present, they are absorbed (especially tetra-thiomolybdate) and bind to several enzymes and compounds that have diverse biological activities. Dietary iron forms complexes with copper in the rumen, and so can exacerbate this process.

**Epidemiology** Herd or flock problem, mainly in young growing ruminants (cattle, sheep, goats, and farmed deer) on pasture in spring and summer. Primary deficiency occurs in sandy and heavily weathered soils; secondary in peat or muck soils high in molybdenum. Feed and water supplies may also contain molybdenum, sulfate, and iron salts, which interfere with copper absorption and metabolism. Some breeds of sheep, and possibly Simmental cattle, are more susceptible.

**Signs** Unthriftiness, altered hair color, chronic diarrhea in molybdenosis (secondary deficiency), chronic lameness, neonatal ataxia in newborn lambs (swayback) if ewes are copper deficient in mid-pregnancy, delayed ataxia in older lambs (enzootic ataxia), anemia in more prolonged deficiency, falling disease in adult cattle (now rare).

**Clinical pathology** Low plasma and liver copper, low ceruloplasmin, anemia.

**Necropsy findings** Demyelination in enzootic ataxia, anemia, emaciation, hemosiderosis, osteodystrophy, cardiomyopathy.

**Diagnostic confirmation** Low liver and plasma copper, response to treatment.

**Differential diagnosis** Copper deficiency must be differentiated from herd problems associated with the following:

- Unthriftiness as a result of intestinal parasitism
- Malnutrition as a result of energy–protein deficiency
- Lameness caused by osteodystrophy (calcium, phosphorus, and vitamin D imbalance)
- Anemia as a result of sucking lice
- Neonatal ataxia in lambs (congenital swayback and enzootic ataxia) from border disease; cerebellar hypoplasia (daft lamb disease); hypothermia; meningitis
- Sudden death as a result of other causes

**Treatment** Oral slow-release bolus or capsule, parental copper glycinate, oral copper sulfate.

**Control** Oral dosing with controlled-release glass bolus or capsule with copper oxide needles; supplementation pasture by top-dressing with copper sulfate; parenteral administration of copper at strategic times; remove sulfates from water supply; genetic selection may be an option.

## ETIOLOGY

Copper (Cu) deficiency may be primary, when the intake in the diet is inadequate, or secondary (“conditioned”), when the dietary intake is sufficient but the absorption of copper and its utilization by tissues is impeded.

## Primary Copper Deficiency

The amount of Cu in the diet may be inadequate when the forage is grown on deficient soils, typically sandy or weathered soils, or soils in which the Cu is unavailable.

## Secondary Copper Deficiency

This is the predominant deficiency; the amount of Cu in the diet is adequate, but other dietary factors (mainly molybdenum, sulfur, and iron, but also manganese and zinc) interfere with the availability and utilization of Cu (Table 21-8). A dietary excess of molybdenum (Mo) is the most common factor, and a high intake can induce Cu deficiency even when the Cu content of the pasture is quite high. A higher Cu intake can overcome this effect. Conversely, supplementing the diet with Mo can be used to counteract a dangerously high intake of Cu. There are species differences in response to high Cu and Mo intake, with sheep being much more susceptible to Cu toxicity and cattle more susceptible to excess Mo.

Zinc, lead, calcium carbonate, and manganese are other conditioning factors. For example, using zinc sulfate to control facial eczema decreases plasma Cu, which can be corrected by the injection of copper glycinate. On the other hand, in New Zealand the administration of selenium to sheep on Cu-deficient pastures increases Cu absorption and can improve the growth rate of lambs.

Dietary inorganic sulfate, in combination with Mo, has a profound effect on the absorption of Cu by ruminants. For example, sheep consuming a complete diet low in sulfur and Mo, and with modest Cu (12 to 20 mg/kg DM), may die of Cu toxicity, whereas others grazing pasture of similar Cu content but high in Mo and sulfur can give birth to lambs affected with swayback. Increasing the sulfate concentration of a sheep diet from 0.1% to 0.4% can potentiate a Mo content as low as 2 mg/kg (0.02 mmol/kg) and reduce absorption of Cu below normal. Increasing sulfate in the diet also decreases absorption of selenium, and thus deficiencies of both Cu and selenium can occur in areas with soils deficient in both elements, especially when sulfate is added in the form of superphosphate fertilizer. Such combined deficiencies are becoming more common with higher applications of fertilizer that enable higher stocking rates on improved pastures. Interactions between Cu, selenium, and sulfates

**Table 21-8** Conditions associated with secondary copper deficiency

Disease	Country	Species	Liver copper	Probable initiating factor
Swayback	Britain, United States	Sheep	Low	Unknown
Renguerra	Peru	Sheep	Low	Unknown
Teart	Britain	Sheep and cattle	Unknown	Molybdenum
Scouring disease	Holland	Cattle	Unknown	Unknown
Peat scours	New Zealand	Cattle	Low	Molybdenum
Peat scours	Britain	Cattle	Unknown, low blood Cu	Unknown
Peat scours	Canada	Cattle	Unknown	Molybdenum
Salt sick	Florida (United States)	Cattle	Unknown	Unknown
“Pine” (unthrifty)	Scotland	Calves	Low	Unknown

must be considered when animals fail to respond to treatment unless both Cu and selenium are provided.

## EPIDEMIOLOGY

### Occurrence

Copper deficiency is endemic in ruminants worldwide and causes diseases of economic importance that can render large areas of otherwise fertile land unsuitable for grazing by ruminants of all ages, particularly young, rapidly growing animals. Based on surveys of serum and plasma Cu in cattle herds in Britain, Cu deficiency remains a serious problem requiring constant vigilance. It is estimated that clinical signs of Cu deficiency develop annually in about 0.9% of the cattle population in the United Kingdom. In some surveys, the lowest concentrations of serum Cu were in heifers being reared as heifer replacements. Although heavy mortalities can occur in affected areas, the major loss is from the failure of animals to thrive. Enzootic ataxia may affect up to 90% of a lamb flock in badly affected areas, with most of these lambs dying of inanition. In falling disease, up to 40% of cattle in affected herds may die.

Copper deficiency is the most common trace-element deficiency in farmed deer in New Zealand, producing mainly enzootic ataxia but also osteochondrosis.

### Geographic Distribution

#### Primary Copper Deficiency

Disease caused by a primary deficiency of Cu occurs in grazing livestock in many parts of the world, including enzootic ataxia of sheep in Australia, New Zealand, and the United States, licking sickness, or *liksucht*, of cattle in Holland and falling disease of cattle in Australia (now rarely seen). Copper deficiency is endemic in the Salado del Sur River basin in Buenos Aires Province, Argentina, affecting over 50% of beef cattle.

Concurrent deficiencies of both Cu and cobalt in Australia ("coast disease") and Florida in the United States ("salt sickness"), characterized by the appearance of clinical signs of both deficiencies in all ruminant species, are controlled by supplementation with both Cu and cobalt.

In the United States, Cu deficiency is not restricted to a single region, with a third of 256 beef herds classified as deficient or marginally deficient based on a survey of serum Cu concentrations. Approximately 50% of the producers used Cu supplements, but a significant proportion of cattle from those herds were classified as marginally deficient or deficient.

In Canada, a survey of cattle at slaughter in Saskatchewan found that 67% had a liver Cu less than 25 mg copper/kg dry weight (DW). However, this indicator of deficiency is now obsolete, with concentrations less than 10 mg Cu/kg DW (160  $\mu\text{mol}$  Cu/kg DW), or 40 mg Cu/kg fresh weight

(FW) (630  $\mu\text{mol}$  Cu/kg FW) indicative of Cu deficiency in ruminants.<sup>1</sup> The concentrations of Cu in the liver of fetuses were proportional to the liver Cu concentrations in the dams, progressively decreasing in the dam during gestation and increasing in the fetus to meet postnatal requirements of the calf because cow milk is a poor source of Cu.

Copper deficiency has been diagnosed in captive musk-oxen in Canada, and it causes anemia in sucking pigs and reduced growth rate and cardiac disease in growing pigs. Adult horses are unaffected, but abnormalities of the limbs and joints of foals reared in Cu-deficient areas do occur.

### Secondary Copper Deficiency

Diseases caused by secondary Cu deficiency, mostly as a result of high dietary intakes of Mo and sulfate, are listed in Table 21-8. They include syndromes characterized by ataxia, abnormal wool or hair, diarrhea (peat scours, teart), or unthriftiness. Anemia develops after severe or prolonged Cu deprivation.

Swayback and enzootic ataxia of lambs is induced by feeding pregnant ewes a diet deficient in Cu or high in Mo and sulfur. Two phases of rapid myelination of the central nervous system occur in sheep, the first during midpregnancy, and then in the spinal cord a few weeks after birth. Consequently, the timing of the ataxia in lambs and goat kids depends on when the induced Cu deficiency occurs; neonatal ataxia corresponds with deficiency during midpregnancy, delayed ataxia when deficiency occurs in late pregnancy or soon after birth. Heavy top-dressing of pasture with lime may predispose lambs to swayback. The central nervous system of calves undergoes a slow, progressive myelination, and so they are not affected by neonatal ataxia.

A dietary excess of Mo is known to be the conditioning factor in the diarrheic diseases; "peat scours" in Australia, New Zealand, California, and Canada; and "teart" in Britain.

In Canada, high concentrations of Mo (21–44 mg/kg DM) have been identified in forage on reclaimed mining areas in British Columbia, but cattle can graze these areas for short periods (12 weeks) each year without developing secondary Cu deficiency. Animals given a Cu supplement had no differences in weight gain, liver Mo, or serum and milk Cu and Mo, suggesting that the upper tolerable dietary concentrations of 5 to 10 mg molybdenum and the minimum safe Cu:Mo ratio of 2:1, described by the National Research Council, may not be universal.

Moose sickness, also known as "Alvsborg disease" and "wasting disease," has affected up to 4% to 5% of moose (*Alces alces* L.) in Sweden. The appearance of the disease coincided with heavy liming of wetlands, lakes, and forests during the 1980s, undertaken to counteract the deleterious effects of acid rain. The increase in soil pH caused by the

liming reduced the availability of Cu and increased the availability of Mo. Copper deficiency may also be a factor contributing to the decline of moose in northwestern Minnesota, with deficient or marginally deficient concentrations of liver copper in 69% of moose found dead. Low liver Cu concentrations have also been recorded in ill-thrifty moose in Norway.<sup>2</sup>

### Seasonal Occurrence

Primary Cu deficiency occurs most commonly in spring and summer, coinciding with the lowest concentration of Cu in the pasture. The Cu status of beef and dairy cattle can vary quite widely each month, with higher rainfall usually associated with a lower availability of Cu.

Secondary Cu deficiency may occur at other times, depending on the concentration of the conditioning factors, predominantly Mo or sulfur, in the forage. For example, the Mo content of herbage may be highest in the autumn or spring, when rains stimulate the growth of legumes.

### Risk Factors

Several factors influence the plasma and tissue concentrations of copper in ruminants, including the following:

- Breed, age, and growth of animal
- Demands of pregnancy and lactation
- Dietary factors—type of pasture or feed source, season
- Soil characteristics and concentration of minerals—particularly Mo and sulfur, which can form thiomolybdates and reduce the availability of Cu by binding with it in the rumen or with biological compounds in the plasma and tissues

### Animal Factors

#### Age

Young animals are more susceptible to primary Cu deficiency than adults. Calves of dams fed deficient diets may show signs at 2 to 3 months of age, with clinical signs more severe in calves and yearlings, less severe in 2-year-olds, and less important in adults. Enzootic ataxia is primarily a disease of neonatal or suckling lambs whose dams receive insufficient dietary copper during mid- or late-pregnancy. Ewes with a normal Cu status take some time to lose their liver reserves, and thus they do not produce affected lambs for at least 6 months after starting to graze Cu-deficient pastures. The predominance of Cu deficiency in suckling lambs indicates the importance of fetal stores and the inadequacy of milk as a source of Cu. Milk from normal ewes contains 3.1 to 9.4  $\mu\text{mol/L}$  (20 to 60  $\mu\text{g/dL}$ ) Cu, but with severe deficiency this may be reduced to 0.16 to 0.31  $\mu\text{mol/L}$  (1 to 2  $\mu\text{g/dL}$ ).

### Breed and Species Susceptibility

There are marked genetic differences in the Cu metabolism of sheep breeds; Welsh

Mountain and Texels can absorb Cu 50% more efficiently than Scottish Blackface, and Texel cross Blackface 145% more efficiently than pure Blackface lambs. The susceptibility to Cu deficiency, or protection from Cu poisoning, is influenced from birth by genetic effects. These affect Cu status of the lamb at birth, through the maternal environment controlled by the dam's genes and the effect of the lamb's own genes. These genetic differences have physiologic consequences, reflected in differences in the incidence of swayback, both between and within breeds, and in effects on growth and possibly on reproduction. The differences are attributable to genetic differences in the efficiency of absorption of dietary Cu.

In sheep, the existence of genes determining plasma Cu has been shown by the continued selection for high and low concentrations in closed lines of a single breed. Ram selection was made on the basis of plasma Cu concentrations at 18 and 24 weeks of age, with this trait having a heritability of 0.3, similar to that calculated for Angus cattle.<sup>3</sup> The high-line ewes retain more Cu in the liver than the low-line ewes, caused by a positive correlation between the concentration of Cu in plasma and the efficiency of absorption.

Genetic variation in the Cu metabolism of sheep has important physiologic consequences. The incidence of swayback may vary from 0% to 40% between different breeds within the same flock, with the incidence more closely related to differences in the concentration of Cu in the liver than in blood. When high and low female lines are placed on improved and limed pasture, which can induce a severe Cu deficiency, swayback, dullness, lack of vigor, and mortality are evident in lambs soon after birth. At 6 weeks of age the mortality rate was higher in the lambs from the low-Cu line and they were 2 kg lighter than those from the high-Cu line.

Goats are more prone to Cu deficiency than sheep, probably as a result of lower accumulation of liver Cu. The dietary requirement for goats is 8 to 10 ppm Cu. However, an intake of Cu that could cause toxicity in sheep (100 to 150 ppm) enhanced growth rate and immune function and did not cause toxicity in Boer crossbred goats.<sup>4</sup>

Cattle are less efficient absorbers of Cu, with evidence for genetic differences between breeds growing stronger. For example, certain breeds, such as Simmental and Charolais, may have higher Cu requirements than other breeds, such as Angus. Based on an assessment of liver Cu, diets containing 4.4 or 6.4 mg of Cu/kg DM did not meet the requirements of either Angus or Simmentals during gestation and lactation or growth, but the addition of 7 mg of copper/kg DM to both diets met the requirements of both breeds. Similar to sheep, these differences are

probably related to differences in Cu absorption.

### *Fetal Liver Copper*

During gestation, the concentration of Cu in the ovine and bovine fetal liver progressively increases, whereas it decreases in the maternal liver. The bovine fetus obtains Cu by placental transfer, and thus at birth the liver concentration of Cu is initially high and then declines to normal adult levels within a few months. Placental transfer is less efficient in sheep, and thus lambs are often born with low liver reserves, making them susceptible to Cu deficiency.

In deficient cattle, the accumulation of liver Cu in the fetus continues independent of the dam's liver Cu until the fetus is about 180 days, after which it gradually declines. In contrast, the liver Cu concentration in fetuses from dams on adequate diets continues to increase. Thus during the last month of pregnancy the daily requirement for Cu in cattle increases to about 70% above maintenance requirements, so the dietary allowance of 10 mg/kg DM increases to 25 mg/kg DM during pregnancy.

Colostrum is rich in Cu, allowing the newborn to absorb Cu and increase its hepatic stores. The Cu content of milk then declines rapidly and is usually unable to meet the requirements of the suckling neonate. Young milk-fed animals absorb about 80% of Cu intake, but this efficiency declines rapidly as the rumen becomes functional, when only 2% to 10% of available Cu is absorbed.

### *Dietary Factors*

#### *Pasture Composition*

The absorption (or availability) of Cu is influenced by the type of diet; the presence of other substances in the diet, such as Mo, sulfur, and iron; the interaction between the type of diet and the chemical composition of the diet; and the genetic constitution of the animals. Copper is well-absorbed from diets low in fiber, such as cereals and Brassicas. However, it is poorly absorbed from fresh pasture, although conservation as hay or silage generally improves its availability. This explains why Cu deficiency is predominantly a problem of grazing ruminants but only rarely seen in housed animals fed diets with adequate Cu.

#### *Molybdenum and Sulfur*

Only small increases in the molybdenum (Mo) and sulfur (S) concentration of grass will cause major reductions in the availability of Cu. This is especially so for ruminants grazing improved pastures in which the Mo and S concentrations are increased. The Cu content of feedstuffs should be expressed in terms of available copper concentration, using appropriate equations, which permits a more accurate prediction of clinical disease and can be used for more effective control strategies.<sup>1</sup>

The effect of Mo and S on the availability of copper in grass is changed by conservation; at a given concentration of S, the antagonistic effect of Mo is proportionately less in hay than in fresh grass. At a low concentration of Mo, the effect of S is more marked in silage than in fresh grass, but the use of formaldehyde as a silage additive may weaken the Cu-S antagonism. Thus herbage high in Mo should be used for conservation when possible, and sulfuric acid should not be used as an additive for silage unless accompanied by a Cu salt because it significantly raises the S concentration of the silage.

An Mo-induced secondary copper deficiency in cattle has occurred when motor oil containing Mo bisulfide was spilled onto pasture.

#### *Copper in the Diet*

In general, pasture containing less than 3 mg/kg DM of copper will result in signs of deficiency in grazing ruminants. Concentrations of 3 to 5 mg/kg DM are marginal, whereas greater than 5 mg/kg DM (preferably 7 to 12) is safe unless Mo-S interactions cause secondary copper deficiency. These complex interactions require an examination of each particular set of circumstances. For example, plant Mo concentrations are directly related to the soil pH. Grasses grown on strongly acidic Mo-rich soils have low Mo (<3 mg/kg DM), whereas those growing on alkaline Mo-poor soils may contain up to 17 mg/kg DM. Thus conditioned copper deficiency can be related to enhanced levels of plant-available Mo rather than the absolute soil levels. Heavily limed pastures are often associated with a less-than-normal intake of Cu and a low copper status of sheep grazing them.

Secondary copper deficiency is also recorded in pigs when drinking water contains very large amounts of sulfate.

#### *Dietary Iron*

Dietary iron can interfere with Cu metabolism.<sup>1,5</sup> Concentrations of iron in silage and pasture forage can range from 500 to 1500 mg/kg DM or higher and can induce Cu deficiency in ruminants when Cu intake is marginal or Mo and S intake is increased. Ruminants obtain iron from ingested soil and mineral supplements. In areas where hypocuprosis is likely to occur, the risk can be minimized by avoiding mineral supplements with high iron content, minimizing the use of bare winter pasture, and avoiding excessive contamination of silage with soil during harvesting. The effect of soil ingestion on Cu deficiency can vary, which is understandable given the differences in soil physical and chemical composition (principally pH, Fe, Mo, and S).<sup>6</sup>

#### *Stored Feeds*

Livestock that are housed for all or part of the year have a different dietary intake of Cu

compared with those on pasture. Concentrates and proprietary feeds usually contain adequate Cu, whereas pasture is more likely to be deficient, especially in early spring when the grass growth is lush. Consequently, silage may be Cu deficient, but hay is more mature and usually contains more of all trace elements and minerals, and hence housed animals are usually protected against Cu deficiency for a few weeks after they come out onto pasture in the spring. In these circumstances, young, rapidly growing animals will be the first affected by hypocuprosis.

#### Soil Characteristics

**Copper Deficiency.** In general, there are two types of soil in which Cu deficiency occurs. First are the sandy soils, poor in organic matter and heavily weathered, such as on the coastal plains of Australia and marine and river silts (these are often deficient in other trace elements, especially cobalt). The second important group is "peat" or muck soils reclaimed from swamps, which are more commonly associated with Cu deficiency in the United States, New Zealand, and Europe. These soils may have an absolute deficiency of Cu, but more commonly it is not available to plants, and so they do not contain adequate amounts of Cu.

The cause of the lack of availability of the copper is uncertain, but is probably a result of the formation of insoluble organic copper complexes. An additional factor is the production of secondary copper deficiency on these soils because of their high content of molybdenum. The concentration of Cu in a range of soils and plants is summarized in Table 21-9.

**Molybdenum Excess.** Pastures containing less than 3 mg/kg DM of molybdenum (Mo) are usually safe, but disease may occur at 3 to 10 mg/kg DM if the intake of Cu is low. Pastures containing greater than 10 mg/kg DM of molybdenum are of high risk unless the diet is supplemented with Cu. Soil Mo

may be as high as 10 to 100 mg/kg, which can be exacerbated by the application of Mo in fertilizer to increase the fixation of nitrogen by legumes.

In the United Kingdom, much farming land is underlain by marine black shales, which are rich in Mo, and hence there is a high concentration of Mo in soil and pastures, and secondary Cu deficiency is common. Secondary Cu deficiency also occurs in cattle in many parts of Canada. For example, large areas of west-central Manitoba are underlain by molybdeniferous shale bedrocks, and soils can contain up to 20 mg/kg of molybdenum.

In New Zealand, some peat soils or the heavy application of Mo in superphosphate to stony soils can produce pastures with a Mo concentration of 3.5 to 20 mg/kg DM, which can induce Cu deficiency. For example, increasing the pasture Mo concentrations from 2 to 4.6 mg/kg DM significantly reduced serum and liver Cu concentrations in grazing red deer, and reduced growth rate occurred when pasture Mo was greater than 10 mg/kg DM. However, an assessment of the elemental composition of pastures found that 95% of pastures from over 800 farms in New Zealand had a Mo content less than 2 mg/kg DM.<sup>7</sup> This, combined with increasing reports of lethal Cu toxicity in dairy herds associated with overly exuberant supplementation, suggests that Mo-induced copper deficiency may not be as widespread as thought.

#### PATHOGENESIS Effects on Tissues

Copper is incorporated into and essential for the activity of many enzymes, cofactors, and reactive proteins.<sup>1</sup> Some pivotal functions of major enzymes include cellular respiration (cytochrome oxidase), protection from oxidants (superoxide dismutase [SOD], ceruloplasmin), the transport of iron (ceruloplasmin [ferroxidase I] and hepcidin [ferroxidase II]), conversion of tyrosine to melanin

(tyrosinase), and the formation of collagen and elastin (lysyl oxidase). Consequently, the consequences of Cu deficiency are diverse but relate to decreased function of Cu metalloenzymes and Cu-binding proteins.

SOD acts as an antioxidant by the dismutation of superoxide anions ( $O_2^-$ ), producing molecular oxygen and hydrogen peroxide ( $H_2O_2$ ), with the latter usually metabolized by glutathione peroxidase and catalase. The ferroxidase activity of ceruloplasmin mediates the oxidation of ferrous ions ( $Fe^{2+}$ ) to the ferric state ( $Fe^{3+}$ ), thereby preventing ferrous ion-dependent formation of hydroxyl radicals ( $OH^\cdot$ ) via the Fenton reaction. In Cu-deficient animals, the activities of SOD and glutathione peroxidase are decreased, causing increased oxidative damage to cells from lipid peroxidation. Ceruloplasmin is the predominant Cu-containing protein in plasma, but it also acts as an antioxidant by scavenging free radicals in many tissues.

The pathogenesis of most of the lesions seen with Cu deficiency is explained in terms of faulty tissue oxidation associated with the failure of these enzyme systems. This role is exemplified by failure of myelination, which produces swayback and enzootic ataxia, or wool abnormalities ("steely wool") in deficient sheep, after myelination is complete. Reduced growth (abnormal bone and cartilage) is also influenced by reduced lysyl oxidase activity, decreased pigmentation (white bands in the wool of pigmented sheep, changed coat color in cattle) by reduced tyrosinase activity, and a terminal anemia by reduced ferroxidase activity.

#### Changes in Gene Expression

Differences in the expression of genes associated with Cu metabolism have been demonstrated in Cu-deficient cattle, including less duodenal Cu transporter 1 (*Ctrl*) and up-regulation of genes in the liver of Cu-deficient fetuses (antioxidant 1 [*Atox1*]), cytochrome c oxidase assembly protein 17 (*Cox17*), and copper metabolism MURR domain 1 (*Commd1*).<sup>8</sup> In naturally occurring Cu deficiency of Angus cattle in Argentina, cytogenetic analysis of peripheral lymphocyte cultures found a significant increase in the frequency of abnormal metaphases in moderate to severely deficient groups.

#### Wool

Loss of crimp causes "stringy" or "steely" wool with reduced tensile strength, which is most obvious in Merinos. This follows inadequate keratinization, probably as a result of imperfect oxidation of free thiol groups. Provision of Cu to affected sheep is followed by oxidation of these free thiol groups and a return to normal keratinization within a few hours.

#### Body Weight

Poor growth is a feature of the later stages of Cu deficiency, more often associated with

**Table 21-9** Copper levels of soils and plants in primary and secondary copper deficiency

Condition	Area	Soil type	Soil copper (mg/kg)	Plant copper (mg/kg DM)
Normal	—	—	18–22	11
Primary copper deficiency	Western Australia	Various	1–2	3–5
	New Zealand	Sand	0.1–1.6	3
	New Zealand	Peat	—	3
	Holland	Sand	—	<3
Secondary copper deficiency	New Zealand	Peat	5	7
	Britain	Peat	—	7–20
	Britain	Limestone	—	12–27
	Britain	Stiff clay	—	11
	Ireland	Shale deposits, peat	—	—
	Holland	Sand	—	>5
	Canada	Burned-over peat	20–60	10–25

excess Mo, when the impairment of tissue oxidation causes interference with intermediary metabolism and loss of condition or failure to grow in sheep, cattle, and deer. This can be accompanied by poor feed-conversion efficiency if Mo-induced Cu deficiency begins in utero.<sup>9</sup>

### Diarrhea

The pathogenesis of diarrhea in Mo-induced secondary Cu deficiency (peat scours, tear) is uncertain. There are no histologic changes in gut mucosa of naturally affected cattle, although villous atrophy was recorded in severe experimental cases. Sheep and goats are far less susceptible to diarrhea induced by molybdenosis, although it can occur.

### Anemia

Anemia develops with severe or prolonged Cu deficiency and is associated with the role of Cu in the formation of hemoglobin. Hemosiderin deposits in the tissues of deficient animals suggest that Cu is necessary for the recycling of iron released from the normal breakdown of hemoglobin. There is no evidence of excessive hemolysis. Heinz-body anemia, an indicator of oxidative stress, can occur when Cu- or selenium-deficient lambs are moved onto rape (*Brassica napus*). The unusual relationship between Cu deficiency and postparturient hemoglobinuria seen in New Zealand has not been explained.

### Bone

Bone abnormalities vary considerably between and within species of ruminants.<sup>1</sup> The osteoporosis that occurs in some natural cases of Cu deficiency is caused by the depression of osteoblastic activity. In experimentally induced primary Cu deficiency, the skeleton is osteoporotic, and there is a significant increase in osteoblastic activity. There is a marked overgrowth of epiphyseal cartilage, especially at costochondral junctions and in metatarsal bones. This is accompanied by beading of the ribs, enlargement of the long bones, and an impairment of collagen formation. When the Cu deficiency is secondary to dietary excesses of Mo and sulfate, the skeletal lesions are quite different and characterized by widening of the growth plate and metaphysis and active osteoblastic activity.

In foals, Cu deficiency causes severe degenerative disease of cartilage, characterized by breaking of articular and growth-plate cartilage through the zone of hypertrophic cells, resulting in osteochondrosis of the articular-epiphyseal complex (A-E complex). The incidence and severity of osteochondrosis in foals can be decreased by supplementation of the diets of mares during the last 3 to 6 months of pregnancy and the first 3 months of lactation. Foals from nonsupplemented mares have separation of the thickened cartilage from the subchondral bone. Clinical, radiographic, and

biochemical differences occur between copper-deficient and Cu-supplemented foals, and there may be a relationship between low Cu intake in rapidly growing horses, inferior collagen quality, biomechanically weak cartilage, and osteochondritis.

Copper is essential for the function of lysyl oxidase, which produces aldehydic groups on hydroxylysine residues as a prerequisite for eventual cross-link formation in collagen and elastin. Similar lesions in foals have been attributed to zinc toxicity from exposure to pasture polluted by smelters. Experimentally, the addition of varying amounts of zinc to the diet of foals containing adequate Cu will result in zinc-induced Cu deficiency, but there are no effects with zinc intakes up to 580 ppm, and it is suggested that 2000 ppm or higher is necessary to affect Cu absorption in horses.

### Connective Tissue

Copper is a component of the enzyme lysyl oxidase, secreted by the cells involved in the synthesis of the elastin component of connective tissues, and has important functions in maintaining the integrity of tissues such as capillary beds, ligaments, and tendons. Naturally occurring examples of connective tissue dysfunction are rare, but lesions of osteochondrosis described in young farmed red deer and wapiti-red deer hybrids in New Zealand also have defective articular cartilage.<sup>1</sup>

### Heart

The myocardial degeneration of falling disease, now rarely seen, may be a terminal manifestation of anemic anoxia, or it may be a result of interference with tissue oxidation. In this disease, it is thought that the stress of calving and lactation contribute to the development of heart block and ventricular fibrillation when there has already been considerable decrease in cardiac reserve. Experimentally induced Cu deficiency in piglets causes cardiac pathology and electrical disturbances and a marked reduction in growth and hematocrit.

### Blood Vessels

Experimentally induced Cu deficiency has caused sudden death as a result of rupture of the heart and great vessels in a high proportion of pigs fed a Cu-deficient diet. The basic defect is degeneration of the internal elastic laminae. There is no record of a similar, naturally occurring disease. A similar relationship appears to have been established between serum Cu levels and fatal rupture of the uterine artery at parturition in aged mares.

### Pancreas

Lesions of the pancreas may be present in normal cattle with a low blood copper status.<sup>1</sup> The lesions consist of an increase in dry matter content and reduced concentrations of protein and Cu in wet tissue; cytochrome

oxidase activity and protein:RNA ratio are also decreased. There are defects in acinar basement membranes, splitting and disorganization of acini, cellular atrophy and dissociation, and stromal proliferation.

### Nervous Tissue

Copper deficiency halts the formation of myelin and causes demyelination in lambs, probably by a specific relationship between Cu and myelin sheaths. Defective myelination can commence in the midterm fetus, causing lesions in the cerebrum, with lambs affected at birth (congenital swayback), or lesions in the white matter of the spinal cord in delayed cases of enzootic ataxia (the predominant form in goats and deer). This distribution reflects peaks of myelin development at those sites, at 90 days of gestation and 20 days after birth. Copper deficiency interferes with the synthesis of phospholipids, and anoxia may also be involved in demyelination. Anemic anoxia is more likely in highly deficient ewes, and anemic ewes produce a higher proportion of lambs with enzootic ataxia. However, there is often no anemia in ewes that produce lambs with the more common subacute form of nervous disease. Severely deficient ewes tend to have lambs affected at birth, whereas the lambs of less severely deficient ewes have normal myelination at birth and develop demyelination later.

### Reproductive Performance

There is no clear evidence that Cu deficiency causes infertility in dairy cows, and both improvement and impairment of fertility have been reported in normocupremic cows given parenteral Cu.<sup>1</sup> Copper glycinate given to dairy cattle does not affect the average interval in days between calving and first observed heat, services per conception, or first-service conception rate compared with untreated cows in the same population. Experimentally, the addition of Mo to the diet of heifers delayed the onset of puberty, decreased the conception rate, and caused anovulation and anestrus in cattle without accompanying changes in Cu status or live-weight gain. Thus the presence of Mo rather than low Cu status may affect the reproductive performance of cattle. It is inadvisable to ascribe poor reproductive performance to subclinical hypocuprosis on the evidence of low blood Cu alone, and other factors, such as management and energy and protein intake, should be examined.

### Immune System

Copper has an important role in the immune response, but the precise mechanism is not well understood. In secondary Cu deficiency in cattle, induced by 30 ppm molybdenum and 225 ppm sulfate, the intracellular copper content of peripheral blood lymphocytes, neutrophils, and monocyte-derived macrophages was reduced between 40% and 70%.

In Cu deficiency, serum ceruloplasmin activity is decreased to 50% of control values, and superoxide dismutase and cytochrome c oxidase activities of leukocytes are significantly reduced. Thus Cu deficiency alters the activity of several key enzymes that mediate antioxidant defense and ATP formation. These effects may impair cellular immune function and make animals more susceptible to infection.

Copper deficiency decreases humoral and cell-mediated immunity and reduces nonspecific immunity regulated by phagocytic cells, such as macrophages and neutrophils. The decreased resistance to infection in deficient sheep responds to treatment with Cu, but also genetic selection, with mortalities from birth to 24 weeks of age 50% lower in lambs genetically selected for high concentrations of plasma Cu compared with those selected for low concentrations. Experimental viral and bacterial infections of cattle can also cause a rapid, although transient, increase in serum ceruloplasmin and plasma Cu in Cu-replete animals, suggesting a major protective role for copper in infectious diseases. These changes evolve from an interleukin-1-mediated increase in hepatic synthesis and release of ceruloplasmin, an acute-phase protein. The concentration of Cu in organs involved in immune regulations, such as the liver, spleen, thymus, and lung, is substantially reduced by Cu deficiency, again suggesting that deficient animals have a greater risk of infection than Cu-adequate ones. However, experiments using low-Cu diets, with or without supplemental Mo, did not alter specific indicators of immunity in stressed cattle.

The severity of Cu depletion needed for immune dysfunction is less than that required to induce clinical signs of Cu deficiency, and endogenous Cu may contribute to the regulation of both nonimmune and immune inflammatory responses. Low-molecular-weight complexes may have an antiinflammatory effect in animal models of inflammation, and it is postulated that the increased plasma Cu-containing components seen during inflammatory disease represent a physiologic response.

In experimental coliform mastitis in Holstein heifers fed 20 mg Cu/kg DM, from 60 days prepartum to day 42 of lactation, the clinical response but not duration of mastitis was reduced compared with animals receiving 6.5 mg Cu/kg DM. In a subsequent experiment, supplementation a basal diet of 7.1 mg Cu/kg DM with 10 mg/kg Cu DM with an organic supplement (Cu proteinate) tended to be more effective than an inorganic one (with Cu sulfate), although somatic cell count, plasma Cu, and plasma ceruloplasmin were not significantly different.<sup>10</sup>

### Development of Clinical Signs

In experimental Cu deficiency in calves, beginning at 6 weeks of age, hypocupremia

developed at 15 weeks, growth retardation from 15 to 18 weeks, rough hair coat at 17 weeks, diarrhea at 20 weeks, and leg abnormalities at 23 weeks. Thus the appearance of clinical signs correlated reasonably well with the onset of hypocupremia and was indicative of a severe deficiency. However, even with severe clinical signs, histologic abnormalities may only be quite minor.

In another study, beginning at 12 weeks of age, clinical signs of Cu deficiency did not develop until after 6 months, with musculoskeletal abnormalities including a stilted gait, "knock-kneed" appearance of the forelimbs, overextension of the flexors, splaying of the hooves, and swellings around the metacarpophalangeal and carpometacarpal joints. Changes in hair pigmentation occurred after about 5 months of deficiency, and diarrhea occurred between 5 and 7 months after deficiency. The diarrhea stopped within 12 hours after oral administration of 10 mg of Cu.

### Copper–Molybdenum–Sulfate Relationship

The interaction between copper (Cu), molybdenum (Mo), and sulfur (S), and its effects on health and production in ruminants, is unique among mammals.<sup>1</sup> Molybdenum and sulfate, alone or in combination, can affect Cu metabolism. Much of the Cu released in the rumen is precipitated with sulfides ( $S^{2-}$ ) to form Cu sulfide (CuS). In addition, whether derived from organic or inorganic sources, Mo and S bind with Cu in the rumen to form thiomolybdates.<sup>5</sup> These compounds have two effects. First, they reduce the amount of Cu available for absorption, with the Cu–thiomolybdate complexes binding to particulate matter in the digesta and reducing the proportion of Cu absorbed to 1% of that ingested. Second, thiomolybdates can be rapidly absorbed and reversibly bound to Cu in biological compounds, including ceruloplasmin, cytochrome oxidase, superoxide dismutase, and tyrosine oxidase. This induces a secondary Cu deficiency (technically a thiomolybdate toxicosis), with tetrathiomolybdate ( $MoS_4^{2-}$ ) by far the most potent of the thiomolybdates.<sup>5</sup> Thus, secondary (conditioned) Cu deficiency occurs when the dietary intake of Cu is adequate but absorption and utilization of Cu are not. These effects also occur in the fetus, interfering with Cu storage in the fetal liver. In cattle, reduced growth rate and changes in the hair texture and color occur after 16 to 20 weeks of supplementation with Mo, accompanied by decreased feed intake and reduced efficiency of feed utilization.

In addition to the Mo–S–Cu relationship, additional interactions with iron (Fe), selenium (Se), Zinc (Zn), and manganese (Mn) can occur. Iron reduces absorption of Cu by adsorption of Cu into insoluble iron compounds and down-regulation of a Cu carrier

(DMT).<sup>1</sup> In calves, liver and plasma concentrations of Cu decrease and become severely deficient within 12 to 16 weeks of including iron in the diet. In sheep, the administration of Se to sheep on Cu-deficient pastures improves the absorption of Cu.

The toxicity of dietary Mo is determined by the ratio of the dietary Mo to dietary Cu. The critical ratio of Cu:Mo in animal feeds is 2.0, and feeds or pasture with a lower ratio may induce a secondary copper deficiency. For example, in some regions of Canada the Cu:Mo ratio varies from 0.1 to 5.3, with a higher critical ratio of 4 to 5 recommended for safety.

### Copper Utilization

Sulfate and molybdate interfere with mobilization of Cu from the liver, inhibition of Cu intake by the tissues, inhibition of Cu transport (both into and out of the liver), and inhibition of the synthesis of Cu storage complexes and ceruloplasmin.

Clinical signs of hypocuprosis, such as steely wool, occur in sheep on diets containing high levels of Mo and sulfate, even though blood Cu concentrations are high. This suggests that Cu is not available, and hence blood Cu rises in response to this demand.

### Hepatic Storage

If animals are receiving a Cu-deficient diet, and thus Cu is removed from the liver, those supplemented with molybdate plus sulfate retain more Cu in the liver than do animals not being supplemented. This supports the hypothesis that, together, molybdate and sulfate impair the movement of Cu into or out of the liver, possibly by affecting copper transport. Sulfate alone exerts an effect, with an increased intake reducing hepatic storage of both Cu and Mo.

### Phases of Copper Deficiency

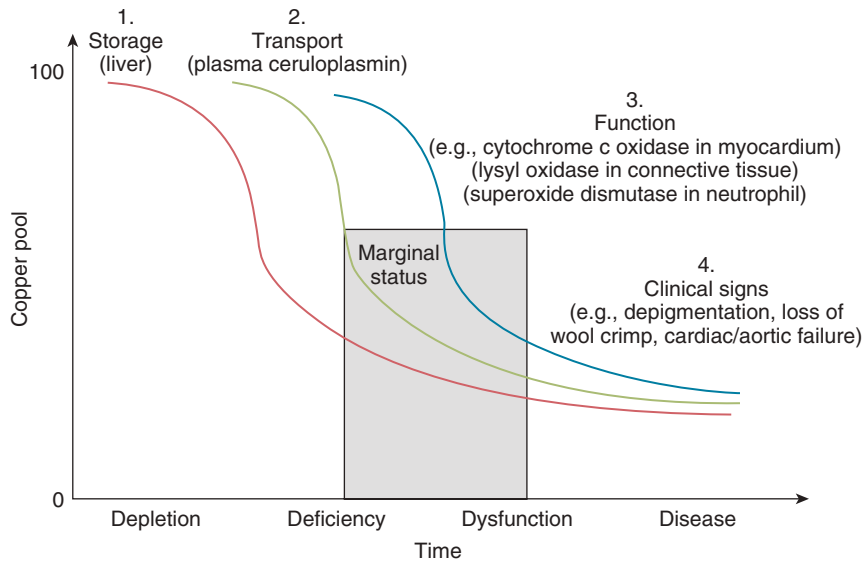

The development of a deficiency can be divided into four phases (Fig. 21-4):

1. Depletion
2. Deficiency (marginal)
3. Dysfunction
4. Disease

During the depletion phase, there is loss of Cu from storage, principally liver storage, but the plasma concentrations of Cu remain constant. With continued dietary deficiency the concentrations of Cu in the blood decline during the phase of marginal deficiency. However, it may be some time before the concentrations or activities of copper-containing enzymes in the tissues begin to decline, and it is not until this happens that the phase of dysfunction is reached. There may be a further lag before the changes in cellular function are manifested as clinical signs of disease.

### CLINICAL FINDINGS

The general effects of Cu deficiency are the same in sheep and cattle, but in addition to

**Fig. 21-4** The biochemical changes that lead to copper deficiency and disease. (From Suttle NF. The mineral nutrition of livestock, 4th ed., Wallingford, Oxon: CAB International, 2010: 255-305.).

these general syndromes there are specific syndromes more or less restricted to species and to areas. Following is a general description of disease caused by Cu deficiency, then details of specific syndromes of enzootic ataxia, swayback, falling disease, peat scours, teart, and unthriftiness (pine).

## Cattle

### Subclinical Hypocuprosis

No clinical signs occur, plasma Cu is marginal (<9.0 mmol/L [57 mg/dL]), and there is a variable response after supplementation with Cu. Surveys in some Cu-deficient areas show that about 50% of beef herds and 10% of dairy herds within the same area have low blood Cu associated with a low dietary intake from pasture (natural forages). Deficiency will only be suspected if production is monitored and found to be suboptimal.

A feature of subclinical hypocuprosis under field conditions is the wide variation in increased growth rate when cattle of the same low-Cu status are given supplementary Cu.

### General Syndrome

#### Primary Copper Deficiency

Primary deficiency causes unthriftiness, decreased milk production, and anemia in adult cattle. The coat becomes rough, and its color is affected, with red and black cattle changing to a bleached, rusty red. In severely deficient states, which are now uncommon, calves grow poorly, and there is an increased tendency for bone fractures, particularly of the limbs and scapula. Ataxia may occur after exercise, with a sudden loss of control of the hindlimbs and the animal falling or assuming a sitting posture and then returning to normal after rest. Itching and hair-licking are also seen in Cu-deficient cattle.

Although diarrhea may occur, persistent diarrhea is not a characteristic of primary Cu deficiency, and its occurrence should arouse suspicion of molybdenosis or helminthiasis. In some areas, affected calves develop stiffness and enlargement of the joints and contraction of the flexor tendons, causing them to stand on their toes. These signs may be present at birth or before weaning. Unlike in sheep, paresis and incoordination are not seen.

An increased occurrence of postparturient hemoglobinuria is also recorded in New Zealand, but it is not well understood.

#### Secondary Copper Deficiency

Signs can be similar to primary Cu deficiency, although anemia is less common, probably as a result of the relatively better Cu status in secondary deficiency. For example, anemia occurs in peat scours of cattle in New Zealand when the Cu intake is marginal. However, with increased Mo intake, there is a tendency for diarrhea, particularly in cattle.

### Falling Disease

The characteristic behavior in falling disease is for apparently healthy cows to throw up their heads, bellow, and fall. In most cases death is instantaneous, but some cattle struggle on their sides for a few minutes, with intermittent bellowing, paddling, and attempts to rise. Rare cases show signs for up to 24 hours or more. These animals periodically lower their heads and pivot on the front legs, with sudden death usually occurring during one of these episodes.

### Peat Scours ("Teart")

Persistent diarrhea, with watery, yellow-green to black feces with an inoffensive odor, occurs soon after the cattle start grazing

affected pasture, in some cases within 8 to 10 days. Defecation often occurs without lifting of the tail. Severe debilitation is common, although appetite remains. The hair coat is rough, with depigmentation manifested by reddening or gray flecking, especially around the eyes in black cattle. These signs vary greatly from season to season, and spontaneous recovery is common. Affected animals usually recover in a few days following treatment with Cu.

### Unthriftiness (Pine) of Calves

The earliest signs are a stiff gait and ill-thrift. The epiphyses of the distal ends of the metacarpus and metatarsus may be enlarged and resemble the epiphysitis of rapidly growing calves deficient in vitamin D or calcium and phosphorus. The epiphyses are painful on palpation, and some calves are severely lame. The pasterns are upright, and the animals may appear to have contracted flexor tendons. Progressive ill-thrift and emaciation progress and can lead to death in 4 to 5 months. Gray hair occurs, especially around the eyes of black cattle, and diarrhea may occur in a few cases.

## Sheep

### General Syndrome

#### Primary Copper Deficiency

Abnormalities of the wool are the first, and often only, sign in areas of marginal deficiency. Fine wool loses its crimp and luster, assuming a straight, "steely" appearance. This is more obvious in Merinos but can occur in meat breeds with broader and plainer wool. Dark wool loses pigment to become gray or white, often in bands coinciding with the seasonal occurrence of Cu deficiency. Anemia, scouring, unthriftiness, and infertility may occur in conditions of extreme deficiency, but in sheep the characteristic findings are swayback or enzootic ataxia in lambs. Reduced growth, diarrhea, and increased mortality are seen in lambs genetically selected for low plasma Cu when they are grazed on improved and limed pastures. Osteoporosis with fractures of the long bones is also recorded with Cu deficiency that was not severe enough to cause enzootic ataxia.

### Swayback and Enzootic Ataxia in Lambs and Goat Kids

Swayback and enzootic ataxia have a lot in common, but there are subtle differences in their clinical signs and epidemiology.

Swayback is the only true manifestation of a primary deficiency of Cu in the United Kingdom. Its prevalence can vary considerably, reflecting genetic differences in Cu metabolism, both between and within breeds of sheep. A congenital cerebrospinal form occurs when the Cu deficiency is extreme. Affected lambs are born dead or weak and are unable to stand and suckle. They have spastic paralysis, are more uncoordinated with erratic movements compared with

enzootic ataxia, and are occasionally blind. There is softening and cavitation of the cerebral white matter, which corresponds to demyelination of the cerebral cortex commencing around day 120 of gestation. Progressive (delayed) spinal swayback is characterized by a stiff and staggy gait and hindlimb incoordination, and it appears at 3 to 6 weeks of age. In Wales, a third form in older lambs is associated with cerebral edema. It resembles the more usual delayed form, but it develops suddenly with onset of recumbency and death within 1 to 2 days.

Enzoootic ataxia occurs in unweaned lambs. In severe outbreaks, lambs may be affected at birth, but most cases occur at 1 to 2 months of age. The severity of the paresis decreases with increasing age at onset. Lambs affected at birth or within the first month usually die within 3 to 4 days, whereas older lambs may survive for 3 to 4 weeks or longer. However, surviving lambs always have some ataxia and atrophy of the hindquarters. The first sign of enzootic ataxia is incoordination of the hindlimbs, often when the lambs are mustered. Cardiac and respiratory rates are greatly increased by exertion, and incoordination progressively becomes more severe and may be obvious after walking only a few meters. There is excessive flexion of joints, knuckling of the fetlocks, wobbling of the hindquarters, and finally falling. The hindlegs are affected first, and the lamb may be able to drag itself about in a sitting posture. When the forelegs are eventually involved, recumbency persists, and the lamb dies of starvation. However, there is no true paralysis because the lamb is able to kick vigorously, even in the recumbent stage, and appetite is unaffected.

### Goats

Enzoootic ataxia attributable to Cu deficiency occurs in goat kids. The disease is similar in most respects to that in lambs, except cerebellar hypoplasia is a frequent finding in goats. Kids may be affected at birth, or the clinical signs may be delayed until the animals are several weeks of age.

### Other Species

#### Deer

Enzoootic ataxia of red deer is quite different from the disease in sheep in that it develops in weaned deer and adults. Clinical signs include ataxia, swaying of the hindquarters, a dog-sitting posture, and, eventually, hindlimb paresis. This is associated with demyelination of the spinal cord and neuronal degeneration in the midbrain.

Osteochondrosis of young, farmed deer in New Zealand is characterized by lameness, one or more swollen joints, an abnormal “bunny-hopping” gait, and “cow-hocked” stance. In Australia, secondary Cu deficiency of red deer during drought was associated with weight loss in lactating hinds and steely hair coats of reduced luster, similar to steely

wool of Cu-deficient sheep. This was associated with the high sulfur content of the diet, possibly exacerbated by ingestion of iron from increased soil ingestion when supplementary feed was trailed onto the ground.

### Pigs

Naturally occurring enzootic ataxia has occurred in 4- to 6-month-old growing pigs, with posterior paresis progressing to complete paralysis in 1 to 3 weeks. Liver Cu concentration was 3 to 14 mg/kg (0.05 to 0.22 mmol/kg), but dosing with Cu salts had no effect on the clinical condition. Copper deficiency in piglets 5 to 8 weeks of age has been described, characterized by ataxia, posterior paresis, nystagmus, inability to stand, paddling of the limbs, and death in 3 to 5 days. Lesions included demyelination of the spinal cord and degeneration of the elastic fibers of the walls of the aorta and pulmonary arteries.

Including 125 to 250 mg/kg of Cu (as Cu sulfate) in the diet of growing pigs (11 to 90 kg) fed ad libitum results in slight improvements in growth rate and feed efficiency, but has no significant effect on carcass characteristics. The addition of Cu causes a marked increase in liver Cu, which is a potential food hazard, and so it is recommended that Cu supplementation be limited to starter and grower diets fed to pigs weighing less than 50 kg.

### Horses

Adult horses are not affected by Cu deficiency, but there are anecdotal reports of limb abnormalities in foals. Foals in Cu-deficient areas may be unthrifty and slow-growing, with limb stiffness, enlarged joints, and contraction of the flexor tendons, which causes the animal to stand on its toes. Signs may be present at birth or develop before weaning, but there is no ataxia or involvement of the central nervous system. Affected foals recover slowly after weaning but can display ill-thrift for up to 2 years.

In Australia, geophagia (soil eating) in horses has been associated with higher concentrations of iron and Cu in soil, suggesting that these elements are a stimulus for geophagia.

### CLINICAL PATHOLOGY

The laboratory evaluation of the copper status of farm animals can be complex, with biochemical values often difficult to interpret and correlate with the clinical state of animals as they progress through the phases of Cu depletion, marginal deficiency, dysfunction, and disease (Fig. 21-4). Consequently, testing is usually undertaken on a herd basis, rather assessing the Cu status of individual animals. Guidelines for the laboratory diagnosis of primary and secondary Cu deficiency in cattle and sheep are summarized in Table 21-10.

**Table 21-10** Concentrations of copper in plasma, liver, milk, and hair; dietary intake and ratios of copper and its antagonists in normal, marginal, and copper-deficient situations

Species and tissue	Normal	Marginal	Primary [secondary] copper deficiency
<b>Cattle</b>			
Plasma ( $\mu\text{mol/L}$ ) <sup>A</sup>	10–20	3–9	<8 (often 1.6–3.2)
Adult liver ( $\mu\text{mol/kg DW}$ ) <sup>B</sup>	380–1600	160–380	<160
Milk (mg/L)	0.05–0.20	0.02–0.05	0.01–0.02
Hair (mg/kg)	6.6–10.4	4–8	1.8–3.4 [5.5]
<b>Sheep</b>			
Plasma ( $\mu\text{mol/L}$ )	10–20	3–9	1.6–3.2 [6.3–11]
Adult liver ( $\mu\text{mol/kg DW}$ )	350–3140	100–300	10–100
Milk	3.1–9.4	0.3–3.0	0.16–0.30
<b>Deer</b>			
Plasma ( $\mu\text{mol/L}$ )	>8	5–8	<5
Adult liver ( $\mu\text{mol/kg DW}$ )	>400	240–400	<240
<b>Pasture {forage}<sup>I</sup></b>			
Cu (mg/kg DM)	10 <sup>D</sup>	6–8 [4–6]	
Cu:Mo ratio	>2.0 (beef cattle growth)–4.0 (to prevent swayback) <sup>C</sup>	1.0–3.0 [0.5–2.0] <sup>E</sup>	
Fe:Cu ratio	15–20	–	[50–100]

<sup>A</sup>Divide by 15.7 to convert to  $\mu\text{g/mL}$ ; neonatal liver from 3000–6000  $\mu\text{mol/kg DW}$ .

<sup>B</sup>Multiply by 4 to convert to fresh weight.

<sup>C</sup>This ratio is quite variable and influenced by other antagonists (Fe, S, Mn, and Zn).

<sup>D</sup>When dietary Mo is < 1.5 mg/kg.

<sup>E</sup>When dietary Mo is < 8 mg/kg for sheep and < 1.5 mg/kg for cattle.

**Herd Diagnosis.** The diagnosis of copper deficiency in a herd is based on the collection and interpretation of the history, clinical examination of affected animals, laboratory tests on blood and liver samples, and examination of the environment, including analysis of the feed, water, and, occasionally, soil.

When collecting samples for analysis, it is important to avoid contamination, which can occur with Cu-distilled water, vial caps, specimen containers, and other endogenous sources of Cu. Intercurrent disease may also affect plasma Cu concentrations.

**Treatment Response Trial.** A comparison between a group of animals treated with Cu and a similar group not treated is often a cost-effective and desirable approach. Variables include growth rates, mortality, and reproductive performance.

**Copper Status of Herd or Flock.** To assess the copper status of herd or flock, a standard practice is to take blood samples at random from at least 10% of clinically affected and 10% of normal animals. However, this may be inappropriate when there is a wide variability in the blood Cu within a herd. In some cases a 10% sample may be too large, whereas in others too small. The minimal sample size for random samples from a finite population of a normal continuously distributed variable can be calculated as follows:

$$\{n = t_{cv} - 2 / [(N1)E_2 t_{cv} - 2]\}$$

where  $n$  = minimal sample size;  $N$  = herd size;  $t$  = Student's  $t$  value;  $cv$  = coefficient of variation; and  $E$  = allowable error.

Initial testing can be used to estimate the variability of serum or plasma Cu concentration within a herd, which will help calculate a minimum sample size for more detailed investigations. This may differ between each class of animal according to age, diet, and production status, so a range of groups should be sampled if appropriate. Follow-up samples can be taken from the same animals following therapy or the institution of control measures.

### Laboratory Diagnosis

Historically, laboratory tests for Cu deficiency in cattle and sheep have centered on the measurement of blood and liver Cu. However, because of the relationships summarized in Fig. 21-4, estimates of serum or plasma Cu, by themselves, are not reliable as the sole indicator of Cu status. Within an affected herd, clinically normal animals may have normal or marginal values, whereas unthrifty animals may have marginal or deficient values. Furthermore, when either the normal animals with marginal values or the unthrifty animals with the marginal or deficient values are treated with Cu, there may or may not be an improvement in weight gain, as might be expected in the former, or

improvement in clinical condition in the latter. Consequently, liver samples, collected either by biopsy or at slaughter, can be used to more accurately assess Cu status.

In addition, for most mammalian species values for serum and plasma Cu are interchangeable. However, this is not the case for bovid ruminants, including cattle, sheep, and goats, where there is a significant and variable loss of Cu into the clot. The 95% limits of agreement are similar for sheep and goats, with serum Cu values being from 70% to 104% and 66% to 100% of the corresponding plasma Cu, respectively.<sup>11</sup> However, unlike cattle, sequestration of Cu into the clot in sheep and goats is proportional to the concentration of Cu. Thus although plasma is the preferred sample, the effect of using serum to assess marginal deficiencies is probably minimal, provided the results are not used to assess individual animals. It is recommended that experimental studies should use plasma Cu to estimate the acellular fraction of Cu in blood. In cattle, the difference between serum and plasma Cu is unrelated to Cu status, and thus plasma is the preferred sample, but the difference between serum and plasma ceruloplasmin is proportional to Cu status.<sup>12</sup> Sequestration of Cu into the clot does not occur in deer.<sup>13</sup>

### Interpretation of Laboratory Results

The liver is the main storage site of Cu, and so the first sign of depletion is a decline in liver Cu (Fig. 21-4). Concentrations of liver Cu in replete neonatal calves and lambs are much higher than those in adults: 3000 to 6000  $\mu\text{mol/kg}$  DW (190 to 380  $\text{mg/kg}$  DW), which corresponds to 750 to 1500  $\mu\text{mol/kg}$  fresh weight (FW) (50 to 95  $\text{mg/kg}$  FW).

When liver reserves of Cu are close to being exhausted, ceruloplasmin synthesis decreases and plasma Cu falls.<sup>1</sup> Broad guidelines are that an average value less than 9  $\mu\text{mol/L}$  (57  $\mu\text{g/dL}$ ) indicates marginal deficiency, but plasma Cu may have to fall to below 3  $\mu\text{mol/L}$  (19  $\mu\text{g/dL}$ ) before there is dysfunction and lost production in sheep and cattle. However, there is considerable biological variation according to species, breed, the time during which depletion has occurred, and the presence of intercurrent disease.

Estimates of Cu in liver and blood are of diagnostic value, but they should be interpreted with caution because clinical signs of deficiency may appear before there are significant changes in these measures. Conversely, the plasma Cu may be very low in animals that are otherwise normal and performing well. For example, in the Netherlands the Cu status of groups of dairy heifers was monitored at regular intervals for 18 months. One group was supplemented with Cu sulfate, and the other was not. The concentrations of Cu and Mo in pasture were within normal limits for the Netherlands: 7 to 15  $\text{mg Cu/kg}$  DM and less than 5  $\text{mg Mo/}$

$\text{kg DM}$ . The concentration of Cu in both blood and liver was below the reference ranges used in that country (6 to 15  $\mu\text{mol/L}$  in blood and > 470  $\mu\text{mol/kg}$  [30  $\text{mg/kg}$ ] DW in liver), but no clinical signs of Cu deficiency occurred, and there were no differences in growth rate and reproductive performance. This highlights that the ranges used to indicate marginal and deficient Cu status can vary between veterinary laboratories, and the thresholds for marginal status may often be set too high.

### Cattle and Sheep

The internationally recognized threshold for Cu deficiency in the plasma of cattle and sheep is 9.4  $\mu\text{mol/L}$ . A plasma Cu concentration between 3.0 and 9.0  $\mu\text{mol/L}$  (19 to 57  $\mu\text{g/dL}$ ) is interpreted as marginal deficiency, and less than 3  $\mu\text{mol/L}$  (19  $\mu\text{g/dL}$ ) is interpreted as a functional deficiency or hypocuprosis. In both species, 11  $\mu\text{mol/L}$  is associated with adequate liver Cu (790 to 3750  $\mu\text{mol/kg}$  DW [50 to 240  $\text{mg/kg}$ ]). A decrease to 9.3  $\mu\text{mol/L}$  can indicate liver Cu values of 315 to 790  $\mu\text{mol/kg}$  DW (20 to 50  $\text{mg/kg}$  DW), which is interpreted as marginal in some areas, and a plasma Cu less than 7.9  $\mu\text{mol/L}$  (50  $\mu\text{g/dL}$ ) is associated with low liver Cu.

Of the two measures, liver Cu is the most informative about deficiency because the concentration of Cu in plasma can remain normal long after liver stores start to decrease and early signs of Cu deficiency appear. Normal concentrations of Cu in adult liver are 1570 and 3140  $\mu\text{mol/kg}$  DW (100 and 200  $\text{mg/kg}$  DW) for cattle and sheep, respectively. Those from 160 to 380  $\mu\text{mol/kg}$  DW (11 to 24  $\text{mg/kg}$  DW) are classed as marginal, and less than 160  $\mu\text{mol/kg}$  DW (10  $\text{mg/kg}$  DW) as low. However, the lower critical value is influenced by species and breed. In New Zealand, a liver Cu concentration of 45 to 95  $\mu\text{mol/kg}$  FW (180–380  $\mu\text{mol/kg}$  DW) in dairy cattle is interpreted as marginal. It is recommended that at least 10 to 12 samples of liver need to be collected at slaughter or biopsy to reliably estimate the liver Cu status of a herd.<sup>14</sup>

Nevertheless, because the liver is the primary storage organ for Cu, estimates of liver Cu indicate a state of depletion rather than deficiency. Consequently, there is no rigid threshold for liver Cu below which the performance and health of livestock will definitely be impaired, and a broad range of values may coincide with a marginally deficient state (say, 80 to 380  $\mu\text{mol/kg}$  DW). In sheep, the concentration of copper throughout the liver is uniform, and thus a single biopsy sample is representative of the whole liver. The frequency of biopsy does not affect Cu concentration, and there is little variability between successive samples.

In calves, the concentration of liver Cu copper varies according to age and class (dairy or beef). In calves submitted for

necropsy, liver Cu concentrations were up to 940  $\mu\text{mol/kg}$  FW (60 mg/kg) higher in dairy than beef calves. The concentration increased to 2 months old, declined until 9 months of age, and then increased again. Thus interpreting liver Cu concentration in calves should account for both age and production class.

Copper concentrations in the kidney cortex may be useful because they have a narrower normal range, 200 to 300  $\mu\text{mol/kg}$  DW (12.7 to 19.0 mg/kg). Thus concentrations less than 200  $\mu\text{mol/kg}$  DW in the kidney may be an indicator of dysfunction.

The difficulties interpreting plasma Cu led to the use of plasma copper-protein complexes, especially ceruloplasmin, which in normal cattle contains more than 80% of the plasma Cu. There is a high correlation between plasma Cu and plasma ceruloplasmin activity (0.83 for cattle and 0.92 for sheep). However, although estimating ceruloplasmin is less complicated and quicker, it is an enzymatic assay and thus inherently more variable than plasma Cu.<sup>1</sup> In cattle, normal plasma ceruloplasmin concentrations range from 15 to 35 IU/L, but calculating a simple ratio of ceruloplasmin activity/plasma Cu does not appear to improve the diagnostic capability of these tests.<sup>15</sup> Estimates for Cu and ceruloplasmin are higher in plasma than serum, with less Cu associated with ceruloplasmin in serum (55%) compared with plasma (66%). In experimental primary Cu deficiency of calves, decreased plasma ceruloplasmin activity occurred at least 80 days before clinical signs of deficiency.

Erythrocyte superoxide dismutase (ESOD), a Cu-containing enzyme, has been used to assess Cu status. In deficient animals the activity of this enzyme decreases more slowly than plasma or liver Cu, and thus it may be a better measure of impending hypocuprosis. ESOD activity ranges from 2 to 5 U/mg hemoglobin in marginal and less than 2 U/mg hemoglobin in functional Cu deficiency.

Anemia can occur in advanced cases of primary copper deficiency, with hemoglobin being as low as 50 to 80 g/L and erythrocytes  $2$  to  $4 \times 10^{12}/\text{L}$ . A high proportion of cows in affected herds may have a Heinz-body anemia without evidence of hemoglobinuria, with the severity of the anemia related to the degree of hypocupremia.

Copper concentrations in milk and hair are lower in deficient cattle compared with normal ones, and thus estimating the Cu content of hair is an acceptable diagnostic test. It also provides a progressive record of the dietary intake of Cu, and it decreases when additional dietary Mo is fed.

### Horses

A threshold of 16  $\mu\text{mol/L}$  is used to distinguish between the normal and subnormal values of plasma Cu in horses, but many

healthy horses have serum values between 12 and 16  $\mu\text{mol/L}$ . Estimates of liver Cu from slaughtered horses varied widely about a mean of 114  $\mu\text{mol/kg}$  FW, and a threshold of 52.5  $\mu\text{mol/kg}$  FW was proposed to distinguish deficient and marginal concentrations. The mean liver and plasma Cu concentrations of horses fed diets containing 6.9 to 15.2 mg Cu/kg DM were 270 to 330  $\mu\text{mol/kg}$  DW and 22.8 to 28.3  $\mu\text{mol/L}$  (3.58 to 4.45  $\mu\text{g/dL}$ ), respectively, but there was no simple mathematical relationship between plasma and liver Cu concentrations.

### Farmed Red Deer (*Cervus Elaphus*)

Suggested reference ranges for deficient, marginal, and adequate serum Cu in deer are less than 5, 5 to 8, and greater than 8  $\mu\text{mol/L}$ , respectively, and for liver Cu are less than 60, 60 to 100, and greater than 100  $\mu\text{mol/kg}$  FW, respectively. Enzootic ataxia and osteochondrosis occur when liver Cu is less than 60  $\mu\text{mol/kg}$  fresh tissue and serum Cu concentrations less than 3 to 4  $\mu\text{mol/L}$ . Growth responses to supplementation are equivocal when blood Cu is less than 3 to 4  $\mu\text{mol/L}$ , but responses are significant when they are 0.9 to 4.0  $\mu\text{mol/L}$ . No antler growth or body-weight response to copper supplementation occurred when blood ceruloplasmin activity was 10 to 23 IU/L (equivalent to serum Cu of 6 to 13  $\mu\text{mol/L}$ ) and liver Cu was 98  $\mu\text{mol/kg}$  FW.

### NECROPSY FINDINGS

The characteristic gross findings in Cu deficiency of ruminants are anemia and emaciation. Hair and wool abnormalities may be present, as described in the section on clinical findings. Extensive deposits of hemosiderin can cause darkening of the liver, spleen, and kidney in most cases of primary Cu deficiency and in the secondary form if the Cu status is sufficiently low. In lambs, there may be severe osteoporosis and long-bone fractures. Osteoporosis is less evident in cattle but can be confirmed radiographically and histologically. In naturally occurring secondary Cu deficiency in cattle, associated with high dietary molybdenum and sulfate, there is widening of the growth plates as a result of abnormal mineralization of the primary spongiosa, resulting in a grossly rachitic appearance to the bones.

The most significant histologic finding in enzootic ataxia is degeneration of axons and myelin within the cerebellar and motor tracts of the spinal cord, with chromatolysis of neurons in a variety of locations within the central nervous system. In a few extreme cases, and in most cases of swayback, myelin loss also occurs in the cerebrum, with destruction and cavitation of the white matter. In these cases there is marked internal hydrocephalus, and the convolutions of the cerebrum are almost obliterated. In affected lambs, acute cerebral edema, with marked brain swelling and

cerebellar herniation reminiscent of polioencephalomalacia, may accompany the more typical myelopathy and multifocal cerebral leukomalacia.

In falling disease, the heart is flabby and pale, there is generalized venous congestion, and the blood may appear watery. The liver and spleen are enlarged and dark. Histology reveals atrophy of the cardiac muscle fibers and considerable cardiac fibrosis. Deposits of hemosiderin are present in the liver, spleen, and kidney.

Necropsy findings associated with Cu deficiency in nonruminant species are not well documented. Degenerative changes with subsequent rupture of the aorta have been induced experimentally in pigs, but this has not been described as a naturally occurring disease. Myelopathy with white-matter changes similar to those of enzootic ataxia has also been reported in 4- to 5-month-old Cu-deficient pigs. Musculoskeletal changes similar to those described for calves have also been reported in foals with hypocuprosis.

Ideally, necropsy examinations should include assays for Cu, and also Mo if a secondary deficiency is suspected. In primary deficiency the concentration of Cu in liver will usually be low (see Table 21-10), whereas in secondary Cu deficiency there may be elevated kidney Cu and high concentrations of Mo in the liver, kidney, and spleen (see Table 21-10).

### Samples for Confirmation of Diagnosis

- **Biochemistry**—50 g liver, kidney (ASSAY [Cu] [Mo])
- **Histology**—formalin-fixed samples of long bone (including growth plate), skin, liver, and spleen. Enzootic ataxia/swayback: half of midsagittally sectioned brain, lumbar, and cervical spinal cord. Falling disease: heart (several sections), bone marrow, spleen (light microscopy).

### DIFFERENTIAL DIAGNOSIS

Clinical findings are most common in young, rapidly growing ruminants. They include a herd problem of unthriftiness and progressive weight loss, changes in hair coat color or texture of wool, chronic lameness, neonatal ataxia in lambs and kids, and terminal anemia. Chronic diarrhea is characteristic in adult cattle on pastures with excess Mo. A combination of plasma and liver Cu, and possibly serum Mo, is used to distinguish between Cu deficiency and other diseases.

Several herd or flock problems in cattle and sheep may resemble both primary and secondary Cu deficiency. A key indicator of Cu deficiency is that many animals are affected at the same time with a chronic debilitating disease complex, under the same dietary and seasonal circumstances.

The differential diagnosis of mineral and vitamin responsive disorders in beef cattle herds with suboptimal performance should investigate three major areas: malnutrition (lack of feed), chronic infectious disease, and lack of specific micronutrients.

#### Cattle

Unthriftiness and progressive weight loss may be attributable to protein–energy malnutrition; examination of the diet will reveal if it is deficient.

**Changed hair coat color** in young, rapidly growing cattle is caused only by Cu deficiency.

**Chronic lameness** in young, rapidly growing cattle may be caused by a calcium, phosphorus and vitamin D imbalance, determined by evaluating the diet and examining the long bones at necropsy or by radiography. Radiographic changes in cattle with secondary Cu deficiency are widened, irregular epiphyseal plates with increased bone density in the metaphysis, and metaphyseal lipping. These are similar to those described for rickets and secondary nutritional hyperparathyroidism.

**Chronic diarrhea** in young cattle may be attributable to intestinal parasitism; fecal egg counts and response to therapy are diagnostic. Diarrhea in a group of adult cattle on pasture known to be high in Mo is probably attributable to secondary Cu deficiency; response to therapy is diagnostic.

Winter dysentery of cattle, salmonellosis, coccidiosis, and mucosal disease are acute infectious diseases characterized by diarrhea, but have other distinctive signs and clinicopathologic findings. Johne's disease can cause diarrhea with a retained appetite, but cattle are usually 4 years or older. Many poisons cause diarrhea in ruminants, particularly arsenic, lead, and salt, but there are usually additional diagnostic signs and evidence of access to the poison. Assay of feed and tissues helps confirm a diagnosis of poisoning.

**Peat scours** is usually diagnosed if there is an immediate response to oral dosing with a copper salt.

**Falling disease** occurs only in adult cattle and must be differentiated from other causes of sudden death. Poisoning by the gidgee tree (*Acacia Georginae*) produces a similar syndrome.

#### Sheep and goats

**Unthriftiness and abnormal wool** or hair as a flock or herd problem are characteristic of Cu deficiency in sheep and goats, which must be differentiated from protein–energy malnutrition, intestinal parasitism, cobalt deficiency, and external parasites.

**Lameness in lambs** several weeks of age must be differentiated from nutritional osteodystrophy as a result of deficiencies or an imbalance of calcium, phosphorus, and vitamin D and stiff lamb disease as a result of enzootic muscular dystrophy.

**Neonatal ataxia** caused by congenital swayback and enzootic ataxia in newborn lambs and kids as a result of maternal Cu deficiency must be differentiated from border disease of newborn lambs, characterized by an outbreak of newborn lambs with hairy fleece and tremors, cerebellar hypoplasia (daft lamb disease), and hypothermia.

## TREATMENT

The treatment of Cu deficiency is relatively simple, but if advanced lesions are already present in the nervous system or myocardium, complete recovery will not occur. Oral dosing with 4 g of Cu sulfate for 2- to 6-month-old calves, or 8 to 10 g for mature cattle, given weekly for 3 to 5 weeks, is recommended for the treatment of primary or secondary Cu deficiency. Parenteral injections of copper glycinate may also be used.

If feasible, the diet of affected animals can also be supplemented with Cu. Copper sulfate may be added to the mineral–salt mix at 3% to 5% of the total mixture. A commonly recommended mixture for cattle is 50% calcium–phosphorus mineral supplement, 45% cobalt-iodized salt, and 3% to 5% Cu sulfate. This mixture is offered free of choice, or it can be added to a complete diet at the rate of 1% of the total diet.

## CONTROL

### Dietary Requirements

The minimum dietary Cu requirements for cattle and sheep are often cited as 10 mg copper/kg DM and 5 mg/kg DM, respectively. However, this is overly simplistic because the requirement to prevent subclinical or clinical Cu deficiency depends on the presence of interfering substances in the diet, such as Mo, S, and Fe, which can cause the absorption of Cu to vary from 0.01 (1% of Cu ingested) to 0.10. Absorption is also influenced by age, physiologic state, and the genotype of the animal.<sup>1</sup> For example, in sheep the requirement has been modified from 5 mg/kg DM in 1975 to 7 to 11 mg/kg DM in 1985, 1.0 to 8.6 mg/kg DM in 1980 and then 4.3 to 28.4 mg/kg DM in 1999. The latter estimate was more detailed, assuming different absorption of Cu from different feedstuffs (0.06 from roughage, 0.03 from grasses, and 0.015 from grass with increased Mo [ $>5$  mg/kg DM]), assuming increased Cu absorption in neonates that decreased in older animals, and allowing for the demands of the lamb in pregnant ewes (0.2 mg/d for a 4-kg lamb). The latest estimate from the NRC uses a factorial method to estimate requirements for sheep.<sup>1,16</sup>

There is insufficient data to do more detailed estimates for goats or deer, but they probably have increased requirements compared with sheep and thus are more similar to cattle (8–10 mg/kg DM).<sup>1,16,17</sup> Concentrations of Cu that could cause toxicity in sheep do not cause toxicity in goats, and some data show a stimulatory effect on

growth of 100 to 300 ppm Cu in the diet of Nubian goats.

Under some circumstances, providing additional Cu to feedlot cattle can adversely affect performance, with as little as 20 mg Cu/kg DM reducing growth in finishing steers. Adding 10 or 20 mg Cu/kg DM of a high-concentrate diet containing 4.9 mg Cu/kg DM altered lipid and cholesterol metabolism in steers, but it did not alter ruminal fermentation. Reducing cholesterol and altering the fatty acid composition of beef, from saturated to unsaturated fats, has potential health benefits for humans, but this has yet to be exploited.

### Copper Toxicity

Sheep are more susceptible to Cu toxicity than cattle, and hence preventing excess supplementation or accidental overdosing and monitoring of dietary intake of Cu are essential. As an example, in a Canadian study, 50% of cull ewes and 40% of market lambs had concentrations of liver Cu that were high to toxic.

Excessive or unnecessary supplementation with Cu is associated with Cu toxicity in many developed countries, with serious outbreaks described in dairy cattle that had recently been dried off.<sup>18,19</sup> In the United Kingdom, submissions to veterinary laboratories for chronic Cu poisoning increased from negligible before 2000 to 0.23% and 0.66% of all submissions in 2005 and 2007, respectively. In one case, high-yielding Jersey cows were identified at higher risk and had an estimated Cu intake of 50 mg/kg DM.<sup>18</sup> In New Zealand, deaths were associated with elevated concentrations of Cu in the liver (3990  $\mu$ mol/kg FW) and kidney (440  $\mu$ mol/kg FW) in Jersey cattle fed palm kernel expeller, which contains a high concentration of Cu (20 to 29 mg/kg DM).<sup>19</sup> Removing all Cu supplements and feeding 200 mg Mo/head per day as sodium molybdate reduced the average concentration of liver Cu from 3100 to 1320  $\mu$ mol/kg FW within 26 days.<sup>19</sup>

Another presentation of excess Cu intake in lactating dairy cattle is a subclinical hepatopathy with no clinical disease. Affected cows received an average of 963 mg Cu/d from a mineral supplement, with total dietary intake of Cu of high- and low-producing cows being 1325 and 1250 mg/day, respectively, compared with their estimated requirement of 290 and 217 mg/cow per day. Consequently, excessive supplementation with Cu may be a significant problem in dairy herds, even those without overt clinical signs of toxicity.

### Copper Supplementation

Copper can be supplied by several different methods. The following dose rates are recommended for the control of primary Cu deficiency, and they may have to be increased or given more frequently for secondary Cu

deficiencies. In these cases, it is often necessary to determine the most satisfactory dosing strategy through a field trial.

### Oral Dosing

Oral dosing with 1 g Cu sulfate will prevent swayback in lambs if the ewes are dosed weekly throughout pregnancy, then lambs can be protected after birth by dosing with 35 mg of Cu sulfate every 2 weeks. However, such regular oral dosing is time consuming and no longer widely practiced, especially in large, extensively managed flocks in which labor efficiency is an essential determinant of profitability.

Copper sulfate is considered a better supplement than Cu oxide or injectable Cu if cattle consume diets containing excess Mo, or Mo plus S.

### Dietary Supplementation

Copper sulfate may be mixed with other minerals into a **mineral premix**, which is then incorporated into the concentrate part of the ration. The final concentration of Cu is usually adjusted to provide an overall intake of at least 10 mg/kg DM in the final ration. Thus, if the forage components of the ration contain much less than 10 mg/kg DM, the concentrate ration may need to contain a higher Cu concentration. Where a secondary Cu deficiency is attributable to excess Mo in the forage, up to 1200 mg Cu (approximately 5 g of hydrated Cu sulfate) is added to the concentrate daily.

For sheep grazing toxic lupin stubble, signs of lupinosis may be exacerbated by supplementing with 10 mg Cu/kg DM as Cu sulfate, and thus additional Cu should not be fed unless there are suitable amounts of Mo and S in the ration.

If animals are not receiving concentrates, an alternative is to provide free access to a mineral mixture or **salt-lick** containing Cu sulfate (0.25% to 0.5% for sheep and 2% for cattle; typically added to iodized salt, cobalt, calcium, phosphorus, and other trace minerals). This will supply sufficient Cu, provided there is an adequate intake of the mixture, although this is often highly variable between individuals and thus may not be the case.

In some areas, an effective method of administering copper is by the **top-dressing** of pasture with 5 to 10 kg Cu sulfate/ha, although the amount required will vary according to soil type, rainfall, and stocking rate. Early studies in Australia found that 5 to 7 kg Cu sulfate/ha was effective for 3 to 4 years, whereas in New Zealand hill country, 3 kg/ha increased pasture Cu for only 100 days.<sup>1</sup> Copper poisoning may occur if live-stock are turned onto pasture while the Cu salt is still on the leaves, and thus treated pasture should be left unstocked for 3 weeks or until the first heavy rain. Chronic copper poisoning may also occur if the soil Cu status increases sufficiently as a result of repeated applications over a number of years.

In New Zealand the top-dressing of pastures grazed by farmed red deer was compared with oral administration of copper oxide wire particles. Pastures top-dressed with Cu sulfate at a rate of 12 kg/ha in mid-March increased the Cu status of weanling hinds, whereas top-dressing in mid-March and dosing hinds with 10 g copper oxide in late July effectively increased the Cu status of pregnant hinds, and it also significantly improved the Cu status of the progeny of yearling hinds from birth to weaning.

Addition of Cu salts to **drinking water** is usually impractical because it corrodes metal piping, and it is difficult to maintain the correct concentration of Cu in large bodies of water. However, systems have been devised to automatically supplement drinking water for short periods, and such systems have effectively controlled Cu deficiency in cattle. Calves can tolerate copper in milk replacers at a concentration of 50 ppm, but there is no advantage in providing more than 10 ppm.

Copper can also be provided in **molasses-based supplements**. However, the high sulfur content of the molasses may affect the availability of Cu, through the formation of Cu sulfide and thiomolybdates in the rumen, and actually decrease liver Cu concentrations. Consequently, a dietary Cu concentration greater than 10 ppm may be necessary to ensure absorption of Cu in beef cattle fed molasses-based supplements.

### Removal of Sulfates

The removal of sulfates from drinking water by purification using reverse osmosis may be beneficial, with beef cows drinking desulfated water having an increased availability of Cu compared with those drinking water with a high concentration of sulfates.

### Parenteral Injections of Copper

To overcome the difficulty of frequent individual dosing or top-dressing of pasture, the periodic injection of compounds that gradually release Cu is used and has given good results. These injections can be given at strategic times, avoid fixation of Cu by Mo and sulfides in the alimentary tract, and are commonly used for the prevention of swayback in lambs.

The following have been evaluated under field conditions: Cu calcium ethylenediamine tetraacetate (copper calcium edetate), Cu methionate, Cu heptonate, Cu glycinate, Cu oxyquinoline sulfonate, and Cu phenylalanine complex. The criteria used to compare these compounds are minimal damage at the injection site, satisfactory liver storage (90% to 100% of the administered dose), and the safety margin between therapeutic and toxic doses. The typical dose of Cu in these compounds is 400 mg for cattle and 150 mg for sheep.

Copper heptonate (25 mg of Cu in 2 mL of preparation) given by IM injection to ewes in midpregnancy is not toxic and will prevent

swayback in lambs. The Cu is removed from the injection site within 7 days, with most transferred to the liver and little or no deposition in skeletal muscle. Injection of 1 to 2 mg Cu/kg BW as heptonate has increased liver Cu to values associated with copper toxicity (13,000 to 52,000  $\mu\text{mol/kg DM}$ ). In sheep on pasture with high Mo content, a single IM injection of copper heptonate (37.5 mg Cu to adults, or 25 mg Cu to weaners) increases liver Cu reserves for at least 9 and 3 months, respectively. It was an acceptable alternative to copper oxide wire particles for preventing copper deficiency in sheep in southern Australia, but it is no longer available.

Copper calcium edetate increases blood Cu within hours and increases liver Cu within a week after injection. However, because of this rapid absorption, toxicity can occur with accidental overdosing. Some unexplained deaths also occurred in groups of treated sheep, and thus it is important to reduce handling and other stress during and after treatment. Marked local reactions occur at the site of injection; thus, SC injection is preferable, especially in animals to be used for meat. This treatment has a small risk of precipitating blackleg in cattle.

For sheep, a single injection of 45 mg of Cu as copper glycinate in midpregnancy is sufficient to prevent swayback in the lambs.

Cu calcium edetate or Cu oxyquinoline sulfonate given SC to sheep increases the concentration of Cu in whole blood, serum, and urine within 24 hours. In contrast, the injection of copper methionate increases the concentration of Cu in blood more gradually over 10 days, and there is no increase in urinary copper. After the injection of any of these three compounds, there is a steady increase in serum ceruloplasmin activity over 10 to 20 days, followed by a slow fall to the activity before treatment at 40 days. The lower toxicity of Cu methionate compared with Cu calcium edetate or Cu oxyquinoline sulfonate is a result of the slower absorption and transport of the Cu to the liver and kidney. Deaths have also occurred in sheep following the parenteral administration of diethylamine oxyquinoline sulfonate at recommended doses, with signs of hepatic encephalopathy and an acute, severe, generalized, centrilobular hepatocellular necrosis at necropsy. The use of Cu disodium edetate at the recommended dose rates in calves has caused deaths associated with liver necrosis and clinical signs of hepatic encephalopathy.

A single dose of Cu glycinate (120 mg for cows, 60 mg Cu for calves) will maintain adequate Cu concentrations for about 60 to 90 days. Milk is a poor source of Cu, particularly from Cu-deficient cows, but even treated cows can have insufficient Cu in their milk. Consequently, calves on pasture will often need a Cu supplement because they cannot increase or maintain their stores of liver Cu from marginal or deficient pastures. Copper reserves accrue in fetal liver at the

expense of the dam's liver Cu, and thus newborn calves usually have sufficient liver Cu and will not need treatment until they are 6 weeks old. In pregnant cows, Cu supplementation should be timed to provide for the higher Cu requirement for Cu from the demands of the fetal liver during the last trimester.

One dose of Cu glycinate is sufficient when cattle are grazing forage with less than 3 mg/kg DM of Mo and less than 3 g/kg DM of S. With higher concentrations of Mo and S, repeated injections (or, alternatively, slow-release boluses) are often needed. The injectable copper may be supplemented by the use of 1% Cu sulfate in a mineral supplement, which will provide adequate Cu for cows, but calves may not consume enough mineral and may need multiple injections. The supplementation required to prevent a decrease in serum Cu during the grazing season will vary according to the concentration of dietary Mo and S and their effect upon the absorption of Cu.

In Canada, 100 mg of Cu as copper edetate, 120 mg copper glycinate, and 120 mg of copper methionate all improved and maintained an adequate Cu status for 90 days in deficient cattle. Copper methionate was least acceptable because of the severity of reactions at the injection site.

In horses, 100 mg and 250 mg copper edetate given IM to mares during months 9 and 10 of gestation had no effect on the liver concentration of their foals at birth, and thus would have little or no effect on the occurrence and severity of developmental bone and joint disease associated with Cu deficiency in newborn foals.

### Slow-Release Treatments

There is a risk of Cu toxicity from mineral supplements because of variable ingestion of the supplement, and from injectable Cu compounds because it is difficult to control the rate at which the Cu is released. This risk, and a more constant supplementation with Cu, can be overcome by using slow- or controlled-release devices.

### Glass Bolus

Soluble glass boluses are available for use in sheep and cattle in the United Kingdom and Europe, but not in New Zealand or Australia. They lodge in the rumen and release Cu at a uniform rate for up to 8 months, although the rate of dissolution is increased by the lower rumen pH associated with concentrate feeding. It is proposed that the additional rumen available Cu is complexed with thiomolybdates in the rumen, preventing absorption of thiomolybdates and their binding to biologically active compounds in blood and tissues, although there appears to be no direct experimental confirmation of this hypothesis. Commercially available glass boluses typically contain 13.4% Cu, 0.5% cobalt, and 0.3% selenium, with two boluses given to

cattle greater than 100 kg (a 100-g bolus) or one to sheep greater than 25 kg (a 33-g bolus).

### Copper Oxide Needles

Copper oxide wire particles ("needles"), incorporated into a soluble polyethylene glycol capsule and given orally, are a safe and effective way of controlling Cu deficiency in ruminants. These are relatively cheap, and a single treatment can be effective for an entire grazing season. The needles are gradually released from the rumen-reticulum and lodge in the folds of the abomasum, where they gradually release Cu for up to 100 days or more. The absorbed Cu is transported to and stored in the liver. An additional minor benefit may be some limited efficacy against gastrointestinal parasites in the abomasum (*Ostertagia* and *Haemonchus*), particularly newly ingested larvae.

### Sheep

The response is dose dependent, with liver Cu peaking 10 weeks after administration of 2.5 to 20 g per animal, and then declining linearly over the next 40 weeks. A dose of 0.1 g/kg live weight (5 g) did not induce copper toxicity in the susceptible North Ronaldsay breed.

A single dose of 2 g cupric oxide needles maintained normal blood and liver Cu, prevented signs of ill-thrift, and improved growth rate in 3- to 5-week-old lambs grazing newly established, limed pastures. Copper oxide needles given to ewes in early pregnancy increases their liver Cu throughout gestation and in early lactation and the Cu status of their lambs from birth to 36 days old. Serum copper concentration was not affected by treatment, but a marked rise was observed in all lambs between birth and 10 weeks of age.

The administration of Cu oxide needles to ewes in the first half of pregnancy prevents swayback in their lambs, and when given at parturition it prevents hypocupremia for up to 17 weeks in animals grazing pasture known to have excess Mo and S. Treatment of ewes at parturition also increased the concentration of Cu in milk during early lactation. However, this increase in milk Cu will not prevent hypocupremia and hypocuprosis in lambs, which can be treated with cupric oxide needles at 6 weeks of age.

Some breeds of sheep are more susceptible to Cu toxicity because they accumulate Cu in the liver, and thus it is important not to exceed the recommended dosage. A dose of 4 g of Cu oxide needles has been used for the prevention of swayback in goats.

### Cattle

Commercial capsules have 39% Cu oxide and in many countries are available in a 20-g dose for adults and a 10-g dose for calves. A dose of 20 g will maintain adequate Cu status for at least 5 months in lactating cows, and it prevented decreased growth and

hypocupremia in young cattle weighing 190 kg for 70 days. The currently recommended doses for beef cattle are 10 g for calves and yearlings less than 200 kg and 20 g for cattle greater than 200 kg, which will provide protection for at least 6 months.

### Farmed Red Deer

The need for Cu supplementation in young deer is not clear-cut. For example, 5 g of Cu oxide wire particles given to 4- to 7-month-old deer in New Zealand had no effect on live-weight gain despite hypocupremia in 38% of untreated deer, which gained weight at similar rates to those with adequate plasma Cu. In another study, 20-g boluses of Cu oxide wire particles did not significantly alter velvet weight, daily velvet growth rate, days from casting to removal, grade or value velvet, or the live weight gain of 2-year-old stags. Growth responses to supplementation are equivocal when blood Cu is less than 3 to 4  $\mu\text{mol/L}$ , but responses are significant when they are 0.9 to 4.0  $\mu\text{mol/L}$ .

### Genetic Selection

It is possible to manipulate trace-element metabolism by genetic selection. For example, the selection of sheep based on plasma concentration of Cu resulted in two divergent sets of progeny within 5 years, one with a high Cu status, the other low, which resulted in clinical signs of Cu deficiency in the low group and protection in the high. This has not been exploited in commercial production.

### Summary and Guidelines

Several rules of thumb are important and useful:

- Cattle are more susceptible to Cu deficiency than sheep.
- Sheep are more susceptible to Cu toxicity than either cattle or goats.
- The newborn calf is protected against neonatal hypocuprosis by donations from the dam, but newborn lambs assume the same copper status as the ewe.
- In general, a dietary intake of Cu equivalent to 10 mg/kg DM will prevent the occurrence of primary copper deficiency in both sheep and cattle.
- Diets containing less than 6 mg/kg DM will cause hypocuprosis.
- Diets with Cu:Mo ratios of less than 3:1 are conducive to secondary Cu deficiency (<2:1 for deer and goats).

## RIBOFLAVIN DEFICIENCY (HYPORIBOFLAVINOSIS)

Although riboflavin is essential for cellular oxidative processes in all animals, the occurrence of deficiency under natural conditions is rare in domestic animals because actively growing green plants and animal protein are good sources, and some synthesis by alimentary tract microflora occurs in all species. Synthesis by microbial activity is sufficient for the needs of ruminants, but a dietary source is required in these animals in the preruminant stage. Milk is a very good source. Daily requirements for pigs are 60 to 80 µg/kg BW, and 2 to 3 g/ton of feed provides adequate supplementation. The trend toward confinement feeding of pigs has increased the danger of naturally occurring cases in that species.

On experimental diets the following syndromes have been observed:

- Pigs: slow growth, frequent scouring, rough skin, and matting of the hair coat with heavy, sebaceous exudate are characteristic. There is a peculiar crippling of the legs with inability to walk and marked ocular lesions, including conjunctivitis, swollen eyelids, and cataract. The incidence of stillbirths may be high.

- Calves: anorexia, poor growth, scours, excessive salivation and lacrimation, and alopecia occur. Areas of hyperemia develop at the oral commissures, on the edges of the lips, and around the navel. There are no ocular lesions.

## CHOLINE DEFICIENCY (HYPOCHOLINOSIS)

Choline is a dietary essential for pigs and young calves. Calves fed on a synthetic choline-deficient diet from the second day of life develop an acute syndrome in about 7 days. There is marked weakness and inability to get up, labored or rapid breathing, and anorexia. Recovery follows treatment with choline. Older calves are not affected. On some rations, the addition of choline increases daily gain in feedlot steers, particularly during the early part of the feeding period.

Supplementation of 20 g/day of rumen-protected choline to dairy cows 14 days before parturition increased milk production during the first month of lactation and the concentration of choline in milk, but it did not affect fat or protein concentration in the milk or plasma levels of glucose, β-hydroxybutyrate, cholesterol, and non-esterified fatty acids (NEFAs). The NEFA concentrations at the time of parturition were lower in treated animals than in controls, indicating improved lipid metabolism. Choline also increased α-tocopherol plasma concentrations. There does not appear to be a difference in effect of rumen-protected and unprotected choline supplements to dairy cattle when energy-related metabolites are evaluated.<sup>1,2</sup>

In pigs, ataxia, fatty degeneration of the liver and a high mortality rate occur with severe deficiency. Enlarged and tender hocks have been observed in feeder pigs. For pigs, 1 kg/ton of food is considered to supply sufficient choline.

Congenital splayleg of piglets has been attributed to choline deficiency, but adding choline to the ration of the sows does not always prevent the condition.<sup>3</sup>

## Multi-Organ Diseases Due to Toxicity

### SNAKEBITE

#### SYNOPSIS

**Etiology** Venom injected into victim by a bite with specially adapted fangs.

**Epidemiology** Isolated bites primarily during summer months. A rare clinical disease in large animals.

**Clinical pathology** Venom detectable in blood (coagulopathy), urine (hematuria, myoglobinuria, anuria, oliguria), body tissues (hemorrhage, ecchymosis, necrosis), and fluids generally.

**Lesions** Varies depending on snake; may be local swelling and tissue necrosis.

**Diagnosis confirmation** Based on detection of venom in body tissues or fluids.

**Treatment** Injection of type-specific antivenin (antivenom).

**Control** Difficult.

## ETIOLOGY

At least six toxic actions can result from snake venoms, and different snakes have varying combinations of toxins in their venoms (Table 21-11). The toxins include necrotizing, anticoagulant, and procoagulant fractions and neurotoxic, cardiotoxic, myotoxic, nephrotoxic, cytotoxic, and hemolytic, and hemorrhagic fractions.<sup>1</sup> Although there is often insufficient venom (composed of multiple toxins) injected to cause death in large animals, a serious secondary bacterial infection may occur in the local swelling and cause the subsequent death of the animal. Additionally, blood degradation products may be associated with coagulopathic insults resulting in secondary renal complications. The common venomous snakes include vipers, such as *Crotalus* spp. (rattlesnakes and other pit vipers of North America, Mexico, and Central and South America), the true vipers (e.g., *Vipera berus* [common European viper, the United Kingdom's only venomous snake]), and multiple other viper species, such as Africa's gaboon vipers (*Bitis* spp.) and Asia's Russell's vipers (*Daboia* spp.), and the elapid snakes, including coral snakes (*Micrurus* spp.) in the Americas, cobras (*Naja* spp.) and mambas (*Dendroaspis* spp.), and most of Australia's venomous snakes, including *Notechis scutatus* (tiger snake), *Oxyuranus* spp. (taipans), and *Pseudonaja (Demansia) textilis* (common brown snake).<sup>1-4</sup>

## EPIDEMIOLOGY

The incidence of snakebite is controlled by the geographic distribution of the snakes and their numbers. Asia, India, Africa, Central and South America, Australia, and the southern United States are areas in which snake populations are large. In general, the morbidity rate in farm animals is low, although a mortality rate from 9% to 25% has been recorded in horses<sup>5</sup> and 31% to 58% in New World camelids (llamas and alpacas).<sup>6,7</sup>

## Risk Factors

### Animal Risk Factors

Most snakebite incidents occur during the summer months, and bites are mainly near

**Table 21-11** Venomous snakes of importance: taxonomy, geographic range, and major venom effects (Prepared by Daniel E Keyler, Pharm. D., FAACT)

Family/genus	Common names	Geographic range	Chief venom effects
<b>Atractaspididae</b>			
<i>Atractaspis</i>	Burrowing asps	Africa	Vasoconstriction, myocardial
<b>Colubridae</b>			
<i>Dispholidus</i>	Boomslang	Africa	Coagulopathy, hemorrhage
<i>Philodryas</i>	Cobra-verde	C, S America	Coagulopathy, hemorrhage
<i>Rhabdophis</i>	Keelbacks	Asia	Coagulopathy, hemorrhage
<i>Thelotornis</i>	Twig snake	Africa	Coagulopathy, hemorrhage
<b>Elapidae</b>			
<i>Acanthophis</i>	Death adders	Australia	Paralysis
<i>Bungarus</i>	Kraits	SE Asia	Paralysis
<i>Dendroaspis</i>	Black/green mamba	Africa	Paralysis
<i>Hemachatus</i>	Rinkhals	Africa	Paralysis, local necrosis
<i>Hoplocephalus</i>	Broad-headed snakes	Australia	Coagulopathy
<i>Micropechis</i>	Small-eyed snake	New Guinea	Paralysis, anticoagulant, myolysis
<i>Micrurus</i>	Coral snakes	N, C, S America	Paralysis
<i>Naja</i>	Cobras/spitting cobra	Africa/Asia	Paralysis, corneal ulceration
<i>Notechis</i>	Tiger snakes	Australia	Paralysis, coagulopathy, myolysis
<i>Ophiophagus</i>	King cobra	Asia	Paralysis
<i>Oxyuranus</i>	Taipan	Australia	Paralysis, coagulopathy, myolysis
<i>Pseudechis</i>	Mulga/black snakes	Australia	Coagulopathy, myolysis
<i>Pseudonaja</i>	Brown snakes	Australia	Coagulopathy, paralysis
<i>Tropidechis</i>	Rough-scaled snake	Australia	Coagulopathy, paralysis, myolysis
<b>Hydrophiidae</b>			
<i>Astrotia</i>	Sea snakes	Indo-Pacific Oceans	Paralysis, myolysis
<i>Pelamis</i>		Pacific Oceans	
<i>Laticauda</i>		Indo-Pacific Oceans	
Many other genera			
<b>Viperidae:</b>			
<b><i>Crotalinae</i> (pit vipers)</b>

<i>Bothrops</i>	Lanceheads	C, S America	Coagulopathy, necrosis
<i>Calloselasma</i>	Malayan pit viper	Asia	Coagulopathy, necrosis
<i>Crotalus</i>	North American rattlesnakes, tropical rattlesnake	N America C, S America	Coagulopathy, necrosis Paralysis, myolysis
<i>Hypnale</i>	Hump-nosed vipers	Asia	Local necrosis, renal
<i>Lachesis</i>	Bushmaster	C, S America	Coagulopathy, necrosis
<i>Sistrurus</i>	Massasauga, pygmy	N America	Hemorrhage, local necrosis
<i>Trimeresurus</i>	Green pit vipers	SE Asia	Coagulopathy, necrosis
<b><i>Viperinae</i> (true vipers)</b>			
<i>Bitis</i>	Gaboon/puff adder	Africa	Cardiovascular, coagulopathy
<i>Causus</i>	Night adders	Africa	Local necrosis
<i>Cerastes</i>	Horned vipers	Africa/Asia	Coagulopathy, necrosis
<i>Daboia</i>	Russel's vipers	SE Asia	Coagulopathy, myolysis, renal
<i>Echis</i>	Carpet, saw-scaled	N Africa/Asia	Coagulopathy, necrosis
<i>Vipera</i>	adders, asps, European vipers	Eurasia	Cardiovascular, coagulopathy necrosis, paralysis

C = central; N = North; S = South; SE = Southeast.

the head because of the inquisitive behavior of the bitten animal.<sup>7</sup> Pigs are not highly susceptible but not, as generally believed, because of their extensive subcutaneous fat depots. Sheep may be bitten on the udder, but their long wool coat is generally effective as a protective mechanism on other parts of the body. Cows may be less represented because of their large size and the large venom dose required to cause death. Horses, however, appear to be much more susceptible to venom than any other species.<sup>8</sup>

## PATHOGENESIS

The effects of snakebite (envenomation) depend on the size and species of the snake, the quantity of venom injected, the route of venom delivery with the bite (e.g., subcutaneous, intramuscular, intravenous), the size of the bitten animal, and the location of the bite, particularly with reference to the thickness of the hair coat and the quantity of subcutaneous fat. As a general rule, the venom is injected by fangs, which leave a bite mark comprised of a row of small punctures with two large punctures outside them. An exception is the coral snake and other elapids, which typically chew to inoculate the venom. The bites may be visible on hairless and unpigmented skin but can only be seen on reflection of the skin at necropsy in many instances. Nonpoisonous snakes may bite animals, but the bite mark is typically (but not always) in the form of two rows of small punctures.

The toxins in venom include the following<sup>1,2</sup>:

- **Cardiotoxins**, causing coronary artery vasoconstriction/vasodilatation and direct myocardial effects, leading to hypotension and arrhythmias
- **Cytolins**, which are associated with tissue necrosis, including platelets, leading to intravascular coagulation and anticoagulation
- **Hemolysins/hemorrhagins**, causing blood cell lysis and degradation of blood components and increased permeability of vascular tissues, leading to fluid shifts
- **Myotoxins**, causing selective ion channel blockade, rhabdomyolysis, myoglobinemia, and myoglobinuria
- **Nephrotoxins**, causing direct nephrotic damage, acute tubular necrosis, renal cortical necrosis, and renal failure
- **Neurotoxins**, causing pre- and postsynaptic blockade and neurotransmitter destruction, with flaccid paralysis, pupillary dilation, and paralytic respiratory failure

The overall effect of a venomous bite by a snake depends on the mix of specific venom components and the dose delivered.<sup>4</sup> The actual dose delivered is highly variable, but also depends on the size of the snake and the period of time since the snake last expended

venom with a bite. Tiger snake venom contains neurotoxins and procoagulants.<sup>4</sup> Death adder venoms contain only neurotoxin; Australian brown snakes have procoagulant and some neurotoxin. Rattlesnake venom is associated with necrosis of arterioles and arteriolar thrombus formation, and in most species it contains an anticoagulant, causing a bleeding diathesis.<sup>2</sup> The Mojave rattlesnake *Crotalus scutulatus* and the neotropical and tropical rattlesnakes (*Crotalus durissus* spp.) are exceptions.

### CLINICAL FINDINGS

Bites by adder-type snakes (viperids) are associated with a local swelling and rapidly developing pain, which is usually sufficient to produce signs of excitement and anxiety. Bites on the head may be followed by swellings of sufficient size to cause dyspnea. If sufficient neurotoxin has been injected, a secondary stage of excitement occurs and is followed by marked dilation of the pupils, salivation, hyperesthesia, tetany, depression, recumbency, and terminal paralysis. In small animals, death may occur as a result of asphyxia during convulsions in the excitement stage of the disease. In animals that recover, there is usually local tissue sloughing at the site of the swelling.

Rattlesnake (*Crotalus* spp.) bites are reported primarily in North America, and affected animals include horses,<sup>5,9,10</sup> New World camelids,<sup>6,7</sup> cattle, and sheep. In horses, the most commonly reported signs are swelling around the bite site, which may be severe and result in respiratory distress, tissue necrosis, and evidence of a coagulopathy (spontaneous bleeding from eyes, ears, injection site, tracheotomy site).<sup>5,9</sup> Venom-associated cardiac abnormalities include tachycardia and arrhythmias, including atrial fibrillation, ventricular premature contractions, and second- and third-degree arterio-ventricular (AV) block.<sup>9,10</sup> Clinical signs in New World camelids include facial swelling, respiratory distress, tachypnea, hyperthermia, tachycardia, lethargy, and recumbency.<sup>6,7</sup> Rattlesnake bite in calves is associated with restlessness, teeth grinding, vomiting, hypersalivation, dyspnea, ataxia, and convulsions.

Bites by cobra-type snakes (elapids) may be associated with local swelling in animals that survive the effects of the neurotoxin.<sup>2,4</sup> They may develop significant localized tissue necrosis, and they frequently develop bacterial infection 3 to 4 days later. The major effects following bites of cobra-type snakes are excitement, with convulsions, respiratory depression, and death resulting from asphyxia. The signs appear quickly or may be delayed, and death occurs usually in up to 48 hours in horses. In calves, the effects of the neurotoxin are manifested by marked pupillary dilation, excitement, and incoordination, followed by paralysis.

Clinical signs in horses bitten by tiger snakes (*Notechis scutatus*) in Australia

include anxiety, diffuse muscle tremors, tachycardia, tachypnea, and profuse sweating.<sup>4</sup> The gait is stiff and short. In another case, muscle tremors were obvious in the standing patient, disappeared when the animal became recumbent, and reappeared upon arising. Foals bitten by brown snakes (*Pseudonaja textilis*) in Australia show similar signs to those associated with tiger snake envenomation. Common signs include drowsiness, drooping of eyelids and lips, partial tongue paralysis, muscle tremors and weakness leading to recumbency, and, in some, pupillary dilation. Respiration becomes labored and abdominal in nature. Sweating and inability to suck, swallow, or whinny occur late in the course. Adults also show an inability to swallow, with salivation and accumulation of food in the mouth.

### CLINICAL PATHOLOGY

There are numerous clinicopathologic abnormalities associated with snake envenomation, with most of them dependent on the species and weight of animal affected, specific snake, and potency of venom.<sup>1</sup> Hematologic alterations include abnormalities in red and white blood cells and platelets. Venom-induced consumptive coagulopathies (VICCs) similar to DIC occur, in particular with venom from the Australian brown snakes (*Pseudonaja* spp.) and taipans (*Oxyuranus* spp.).<sup>1,11</sup> Increases in BUN and creatinine, creatine kinase, and liver enzymes occur, as do decreases in albumin, potassium, and calcium.<sup>1,4,5,7</sup> Horses with myocardial damage show elevations in cardiac troponin I (cTnI), which may be delayed for several days to weeks after envenomation.<sup>9,10</sup>

An ELISA for identification of venom in blood, urine, or other body tissue or fluid is available in Australia.<sup>4</sup> It is highly accurate, suitable for field or office use, and immediate, but it is expensive. It is limited to the snake species for which reagents are available.

### NECROPSY FINDINGS

Postmortem findings are specific to each snake. In general, local swellings at the site of the bite are a result of exudation of serous fluid and inflammatory reaction to venom components, which is often deeply blood-stained. Fang marks are usually visible on the undersurface of the reflected skin. A horse dying from rattlesnake envenomation showed ischemia of the heart, skeletal muscle, urinary bladder, and gastrointestinal tract.<sup>10</sup> Cardiac hypertrophy and myocardial necrosis involving both ventricular free walls and atria was present grossly, and myocytes in both ventricles and the atria were necrotic and degenerative on histopathologic examination.<sup>10</sup> New World camelids dying of rattlesnake envenomation showed severe and hemorrhagic facial swellings, congestion of the lungs and kidneys, ulcerations in the third compartment, and other

systemic manifestations.<sup>7</sup> Postmortem analysis of a cow presumed to have died from the bite of a snake in the Viperidae family showed petechial and ecchymotic hemorrhage to frank hemorrhage in the lung, liver, tracheal lumen, peritoneum, and epicardial and subendocardial surfaces. Pale linear streaks were present in the right ventricular myocardium.<sup>12</sup>

Diagnosis confirmation depends on a positive assay for venom in the patient's blood, urine, and tissues generally. Absolute identification of the snake by a knowledgeable herpetologist can also confirm the species of snake involved with envenomation. In acute cases death has usually occurred by the time the animal is seen. If the actual bite is observed, the diagnosis is made on the history.

### DIFFERENTIAL DIAGNOSIS

#### Differential diagnosis list:

Nervous syndrome:

- Organophosphorus/carbamate toxicosis
- Fluoroacetate toxicosis
- Tick paralysis

Local swelling:

- Anthrax in horses and pigs
- Black widow, redback or brown recluse spider bites
- Blackleg
- Insect stings (wasps, hornets, bees)
- Puncture/trauma wounds versus fang puncture marks
- Scorpion stings

### TREATMENT

In human medicine the application of a tourniquet proximal to a limb bite site has been replaced; for elapid envenomation a firm pressure immobilization bandage (PIB) is applied over the bite to restrict the distribution of the venom via the lymphatics and retain it in the site and prevent systemic effects. The use of PIB for crotalid or viperid envenomation is not recommended because the PIB holds the venom at the application site, and pit viper and viper venoms typically cause significant local tissue damage. As such, use of PIB in these instances may exacerbate local tissue damage. Excision of the bite site is not recommended for the bites of snakes (crotalids and viperids) that are associated with a serious local reaction because the procedure may worsen local tissue damage and enhance the distribution of venom from the bite-site region.

Emergency treatment should include early placement of an intravenous catheter, correction and maintenance of hydration, and establishment of a patent airway. In animals with severe facial or nasal swelling, a tracheotomy may be needed. Systemic treatment should include antivenin (antivenom), antibiotics, antiinflammatories, and antitoxin. Polyvalent antivenin containing antibodies against the venoms of all the

snake species in the geographic region can usually be obtained locally, often in highly purified form.<sup>4,7,8</sup> It is expensive to use but highly effective. Speed is essential, and the IV route is preferred. The dose rate varies widely depending on the degree of envenomation, with the size of the animal and clinical signs determining the dose. In horses and New World camelids this is typically 1 to 5 vials, but the dose may be higher depending on the venom and amount contained in the vial.<sup>5,7,8</sup> The use of antibiotics in human beings is controversial but should be administered to control the local infection at the site of the bite. The occurrence of clostridial infections after snakebite suggests the administration of antitoxins against tetanus and gas gangrene. A nonsteroidal antiinflammatory drug such as flunixin will provide pain relief and assist with local and systemic swelling.<sup>7</sup>

Many other pharmacologic treatments have been used in treating venomous snakebite, including antihistamines and corticosteroids. These drugs have been found to be valuable as a protection against possible anaphylaxis after treatment with antivenin, but in cases where local tissue damage is evident, they are without value and in many cases exert deleterious effects. Adrenaline or epinephrine has little or no value, and calcium salts do not significantly reduce mortality. The application of chemicals to the incised bite area is also of no value and may exacerbate tissue damage. Attention has been drawn to the need to appreciate the mode of action of one's local snake venoms before attempting a general program of treatment—what may be effective in one country may very well be lethal in another.

## CONTROL

Control is difficult because snakes occur in dry lots, paddocks, pastures, and fields where animals live. Vaccination against rattlesnake envenomation in horses is possible, but reported vaccine titers from the commercially available product are not as high as those that develop after natural rattlesnake envenomation.<sup>13</sup>

## BEE AND WASP STINGS (HYMENOPTERA)

Bees (*Apoidea*) and wasps, hornets, and yellow jackets (*Vespoidea*) are stinging insects found in the Hymenoptera family. Their venom is proteinaceous in nature.<sup>1</sup> Bees sting only once and die; wasps, hornets, and yellow jackets are capable of stinging multiple times.

Most single stings are self-limiting, but multiple stings may be associated with severe local swelling up to 6 cm in diameter, similar to those in angioedema. The lips, eyelids, tongue, and vulva are often swollen and painful. Pain may result in pronounced excitement, and in severe cases in horses there may be diarrhea, hemoglobinuria, jaundice, tachycardia, cardiac arrhythmia, rapid breathing, sweating, and prostration. Animals attacked about the head may show dyspnea because of severe local swelling. Horses often show mild to moderate colic. Anaphylaxis is rare and generally occurs within minutes of stinging.<sup>1</sup> In a few cases, the attack may be fatal and nonanaphylactic, usually occurring after a course of 4 to 12 hours.

Treatment depends on the location of the stings, but may include antihistamines, topical hydrocortisone or lidocaine cream or ointment, cool compresses, tracheotomy if swelling and asphyxia threaten, and early recognition and treatment of anaphylaxis. Necropsy lesions vary depending on the number of stings and location but may include hemorrhages and edema of all connective tissues and the bowel wall.

## RED FIRE ANT STINGS (SOLENOPSIS INVICTA)

The red fire ant (*Solenopsis invicta*) is present in most of the southern portion of the United States and many other countries. The venom is a nonproteinaceous alkaloid with a wide range of biocidal activities.<sup>1</sup> Fire ants are aggressive, and an individual attack usually results in a number of stings. Fire ants both bite and sting, but envenomation only occurs with the sting.<sup>2</sup> Stings occur in a circular pattern because the ant first bites the animal with its mandible and then rotates its head around the bite site.

Stings from the aggressive red fire ant have been associated with focal necrotic ulcers of the cornea and conjunctiva of newborn calves. Stings around the nostrils may cause swelling with open mouth breathing, inhalation of more ants, or suffocation. Weak calves, lambs, and deer fawns are most likely to be injured, as are older and weaker animals. In addition, adult animals may develop stress-related anorexia resulting in decreased weight gain or milk production.

Treatment depends on the sting site and severity of signs and may include antihistamines, cool compresses, corticosteroids, tracheotomy, and appropriate therapy for anaphylaxis.<sup>2</sup>

## MOTHS

Insect-generated fiber (e.g., in the cocoons of *Molopo* moths) can be indigestible and, if eaten in large quantities, can be associated with ruminal impaction. The body scales of the brown-tail moth and its larvae have a nettling effect, causing skin irritation on contact and bronchial mucosal irritation on inhalation.

## SWEATING SICKNESS (TICK TOXICOSIS)

SYNOPSIS	
<b>Etiology</b>	Unknown, associated with bites of <i>Hyalomma truncatum</i> .

Continued

**Epidemiology** Reported in Africa, India, and Sri Lanka affecting calves 2 to 6 months of age.

**Clinical findings** Fever, salivation, lacrimation, hyperemia of mucosae, epistaxis, extensive and severe dermatitis, necrosis of oral epithelium.

**Lesions** Dermatitis and necrotic stomatitis, disseminated intravascular coagulopathy.

**Treatment** Symptomatic and use of hyperimmune serum.

**Control** Tick control.

## ETIOLOGY

The cause of sweating sickness in cattle has not been identified, but it behaves as though it were an epitheliotropic or dermatrophic toxin produced by the salivary glands of certain strains of the hard tick *Hyalomma truncatum*. Both male and female ticks of the strains can produce the toxin, but not all strains of *H. truncatum* have the ability to do so.

## EPIDEMIOLOGY

Attempts to transmit the disease between animals by direct contact and by injections of tissue or blood are unsuccessful. The disease occurs in Central, East, and South Africa; Sri Lanka; and probably southern India. Younger animals up to 1.5 years of age are affected as a rule, but rare cases occur in adults. Sheep, pigs, and goats are susceptible, although the disease does not naturally occur in them, and a similar disease has been reported in a dog in Brazil infested with the soft tick *Ornithodoros brasiliensis*, popularly known as the mouro tick.<sup>1</sup>

Sweating sickness occurs at all times of the year but is most prevalent during the wet season when ticks are more plentiful. The morbidity rate varies with the size of the tick population but is usually 10% to 30%. The case-fatality rate is up to 30%.

## PATHOGENESIS

The clinical signs begin 4 to 7 days after the ticks attach, probably 3 days in experimental infestations. The effects are dose specific; if the ticks are removed very early, there is no clinical response, and the animal remains susceptible; with a longer exposure before the ticks are removed, the animal becomes immune but shows no clinical signs. With longer exposure of more than 5 days, the subject develops the full-blown clinical disease and may die. If it recovers, it has a solid and durable immunity. However, there is no passive immunity via colostrum.

## CLINICAL FINDINGS

There is a sudden onset of fever up to 41°C (106°F), anorexia, hyperemia of the mucosae, and hyperesthesia. The animal is lethargic, depressed, and dehydrated and has a serous then mucopurulent oculonasal discharge, an

arched back, and a rough coat. There is an extensive, moist dermatitis commencing in the axilla, groin, perineum, and the base of the ears, and it may extend to cover the entire body in bad cases. "Sweating" refers to this moist dermatitis. The hair is matted together by exudate, and moisture collects in the form of beads on the surface. The eyelids may be stuck together. Subsequently patches of the skin and hair are rubbed off or can be pulled off to leave raw, red areas of subcutaneous tissue exposed. The tips of the ears and tail may slough.

Affected calves seek shade, and their skin is very sensitive to touch. Later it becomes dry and hard, and cracks develop. Secondary bacterial infection and infestation with blowflies or screw-worm larvae are common sequelae. The oral mucosa is hyperemic at first and then becomes necrotic with the formation of ulcers and diphtheritic membranes. The calf salivates profusely, cannot eat or drink, and becomes emaciated and rapidly dehydrated. There are similar mucosal lesions in the vagina and nasal cavities, the latter causing dyspnea. The severity of the mucosal lesions appears to vary with different "strains" of the toxin. There may be abdominal pain and diarrhea in some calves.

The course may be as short as 2 days but is usually 4 or 5 days. In recovered animals the skin may heal and the hair may regrow, but there may be permanent, patchy alopecia, and the calves may remain stunted and unthrifty.

## CLINICAL PATHOLOGY

There is severe neutropenia and eosinopenia and a degenerative left shift;  $\alpha$ -globulin and beta-globulin levels are raised. Urinalysis indicates the existence of nephrosis, but serum creatinine levels are normal. Dermatologic examination fails to reveal the presence of any of the usual infectious causes of dermatitis.

## NECROPSY FINDINGS

The lesions are essentially those seen clinically. There is also evidence of severe toxemia, dehydration, emaciation, and hyperemia of all internal organs and disseminated intravascular coagulation. The necrosis of the oral epithelium extends into the esophagus and may reach the forestomachs.

## DIFFERENTIAL DIAGNOSIS

The combination of extensive dermatitis and mucosal necrosis is unusual. Mucosal disease and bovine malignant catarrh may bear some resemblance, and there could be difficulty in differentiation in areas where the tick *Hyalomma truncatum* occurs.

## TREATMENT

There is no specific treatment; efforts should be directed at relieving the severity of the dermatitis and mucosal loss. Nonsteroidal

antiinflammatory drugs (NSAIDs) and broad-spectrum antibiotic cover is a logical regimen. Hyperimmune serum, produced in sheep and cattle by infesting them with *Hyalomma truncatum* at 6-week intervals for 2 to 5 occasions, is an effective treatment in pigs, sheep, and, to a less extent, calves.

## CONTROL

Control is limited to control of the causative tick. No vaccine is available. Exposure to the strain of ticks for a period of about 72 hours confers a limited degree of immunity.

## 4-AMINOPYRIDINE TOXICOSIS

4-aminopyridine is marketed as an avicide or bird repellent to control the overpopulation of "pest birds" that might destroy crops or damage aircraft, monuments, and other areas. It is a highly toxic, restricted-use pesticide marketed under the tradename Avitrol. Currently, it is available as treated whole corn, treated corn pieces, and mixed grains in 0.5% and 1% concentrations.<sup>1</sup> Interestingly, in 2010 the U.S. Food and Drug Administration (FDA) granted medical approval for the use of 4-aminopyridine in humans with multiple sclerosis.<sup>2</sup>

Poisoning in large animals is rare, with an animal poison center reporting a single cow case in a 10-year retrospective study.<sup>2</sup> In horses, reported clinical signs occurred 6 to 8 hours after ingestion and included signs of fright, profuse sweating, severe convulsions, and fluttering of the third eyelid. Death occurred 2 hours after the onset of signs; the lethal dose was estimated at 2 to 3 mg/kg BW. In cattle, signs include anorexia, frequent passage of small amounts of feces, and tenesmus, with some animals also showing tremor, ataxia, and erratic behavior, especially walking backward, with some sudden deaths.

It is rapidly absorbed from the gastrointestinal tract, metabolized in the liver, and excreted in the urine. 4-aminopyridine blocks specific voltage-gated potassium ion channels and increases the release of acetylcholine at neuromuscular junctions and in the central nervous system.<sup>2,3</sup> In toxic amounts, agitation, hyperactivity, and seizures occur. Death is from cardiac or respiratory arrest.

Treatment is primarily supportive and symptomatic and involves managing the airway and controlling CNS signs with sedatives and/or anticonvulsants.<sup>2,3</sup>

## CADMIUM TOXICOSIS

Cadmium is an environmental pollutant that may accumulate in plants and animals.<sup>1</sup> It contaminates the environment, especially the soil, when sewage sludge and rock phosphate are used as fertilizers. Other sources include industrial pollution from zinc smelters, mining wastes, coal combustion, and water from old zinc- or cadmium-sealed pipes.<sup>2</sup>

There is much interest in cadmium entering the human food chain via animals used as food. The chances of cadmium accumulating in lean meat are not very great because the levels of ingestion required to produce significant levels are so high that they would be associated with observable clinical illness. The kidney and liver accumulate cadmium far more readily than other tissues, and ingestion may be of concern.<sup>2-4</sup>

Accumulation in the kidneys is related to cadmium content in forage and soil ingested.<sup>5</sup> Horses may carry a higher body burden of cadmium than sheep, cattle, and pigs.<sup>6</sup> Concentrations of cadmium in kidneys obtained from animals in rural Croatia showed the highest levels in horses (0.1029–47.4 mg/kg), which exceeded the maximum European Union levels for cadmium in the kidney by 93%. In contrast, cattle exceeded the limit by 14% and sheep by 16%.<sup>6</sup> In Belgium, cattle kidney cadmium levels were much higher (75% cadmium from contaminated areas; 47% from rural areas); no equine kidneys were analyzed.<sup>7</sup>

Ingestion is the most common route of exposure in large animals, with absorption occurring in the intestinal tract. Once absorbed, cadmium is transported to the liver, where it induces and binds to metallothionein, forming an inert complex that decreases the toxic effects of cadmium on the liver.<sup>3,8</sup> The complex decreases biliary excretion of cadmium and increases retention of cadmium in cells, and it ultimately plays a role in the long half-life of cadmium in the body (10 to 25 years in human beings).<sup>2,3,8,9</sup>

Acute ingestion is rare in animals and in most cases result from accidental administrations of farm chemicals (e.g., a cadmium-containing fungicide). The target

organs in acute human ingestions are the lung, liver, kidney, and testes, with nephrotoxicity common.<sup>2,9</sup>

Chronic ingestion in animals is associated with accumulation in tissues such as liver, kidney, lung, bone, testes, intestinal tract, skin, and blood. Chronic poisoning in cattle is associated with inappetence, weakness, loss of weight, poor hoof keratinization, dry brittle horns, matting of the hair, keratosis, and peeling of the skin. At necropsy there is hyperkeratosis of forestomach epithelium and degenerative changes in most organs. In cattle and sheep, cadmium levels in the feed greater than 50 mg/kg DM are associated with toxicity and large accumulations of cadmium in the kidney and liver.<sup>3</sup> Experimental poisoning of sheep is associated with anemia, nephropathy, and bone demineralization at a dose rate of 2.5 mg/kg body weight per day. Abortion, congenital defects, and stillbirths are also potential toxic outcomes. In young pigs, levels in the feed of 50 mg/kg for 6 weeks reduce growth rate and are associated with an iron-responsive anemia. The most signs in horses are lameness and swollen joints with osteoporosis and nephrocalcinosis.

There is currently no accepted treatment.<sup>2</sup> Zinc and iron may play a protective role in liver and kidney accumulation.<sup>3</sup> Selenium in rats has had a protective effect on the liver and kidneys and may be beneficial in individual animals.<sup>10,11</sup> Chelating agents have been suggested in human beings, but there are no documented studies on which particular one is effective.<sup>3</sup>

## CHROMIUM TOXICOSIS

Chromium is most commonly found in two oxidation states: hexavalent and trivalent.

Hexavalent chromium is a strong oxidizing agent that crosses biological membranes and is five times more toxic than trivalent chromium.<sup>1,2</sup> Toxicity from hexavalent chromium occurs primarily from inhalation or industrial contamination and trivalent chromium from ingestion or parenteral administration.

Chromium is absorbed in the gastrointestinal tract and transported in the blood to bone, spleen, liver, and kidney.<sup>1</sup> Excretion is primarily renal, with some biliary elimination.

The use of protein concentrates prepared from tannery waste as an animal feed is not recommended because of the material's high chromium content.<sup>3</sup> Trivalent chromium salts given orally to pigs at the rate of 0.5 to 1.5 and at 3 mg/kg BW are associated with transient diarrhea. With the higher dosage there is also tremor, dyspnea, and anorexia. Toxicity from hexavalent chromium in oil fields has been associated with death in cattle, and dermal absorption of a strong oxidizing solution of chromium has been associated with death in a dairy herd.

## COBALT TOXICOSIS

Cobalt is an essential component of vitamin B<sub>12</sub> (cobalamin).<sup>1,2</sup> Nonruminant animals are unable to synthesize vitamin B<sub>12</sub> and depend on a dietary source of cobalt; ruminants can synthesize it if enough cobalt is provided in the diet.<sup>1</sup> Poisoning from cobalt is unlikely to occur in domestic animals unless there are errors in feed mixing, contamination of feed or water supply, or deliberate overdosing.

Absorption appears to be age dependent, with higher absorption in younger animals. Iron deficiency, in nonruminants, is associated with a higher absorption of cobalt. Cobalt is excreted primarily in the urine, with a small amount of fecal excretion. Tissue concentrations are highest in the liver, followed by the kidney, pancreas, and heart.<sup>2</sup>

Poisoning with cobalt compounds is associated with anorexia, weight loss, rough hair coat, listlessness, and muscular incoordination. Toxic effects appear in calves at dose rates of about 40 to 55 mg of elemental cobalt per 50 kg BW per day. Sheep are much

less susceptible, ingesting 15 mg/kg BW of cobalt without apparent effect. Pigs tolerate up to 200 mg cobalt/kg of diet, but intakes of 400 and 600 mg/kg are associated with growth depression, anorexia, stiffness of the legs, incoordination, and muscle tremors. Supplementation of the diet with methionine, or with additional iron, manganese, and zinc, alleviate the toxic effects.

## PRIMARY COPPER TOXICOSIS

### SYNOPSIS

**Etiology** Acute or chronic intake of copper.

**Epidemiology** Sheep most susceptible, horses least. Significant differences in breed susceptibility. Copper originates from copper-rich soils, industrial contamination of pasture, agricultural chemicals, copper preparations used pharmaceutically, feed, and other sources.

**Pathogenesis** Acute poisoning as a result of ingestion of a single large dose is associated with gastrointestinal tract mucosal necrosis and fatal shock. Acute injectable dosing or chronic oral intake is associated with hepatic necrosis and hemolytic anemia.

**Clinical pathology** Chronic oral poisoning: very high liver copper levels, low packed cell volume (PCV), hemoglobinemia, hemoglobinuria. Liver enzyme activity and blood copper levels may or may not be elevated depending on when they are taken.

#### Necropsy lesions

**Acute oral poisoning:** severe gastroenteritis, bluish-green discoloration of mucosa and ingesta.

**Chronic oral poisoning:** icterus, swollen liver, kidneys, spleen; high tissue levels of copper.

**Diagnostic confirmation** High copper levels in tissues.

**Treatment** Acute poisoning: supportive care; chronic poisoning: various dosages of sodium or ammonium molybdate in combination with thiosulfate; thiomolybdate; chelating agents (penicillamine, dimercaprol, calcium disodium EDTA).

**Control** Removal from source, prophylactic administration of molybdate.

### ETIOLOGY

Acute oral and injectable poisoning is associated with a single large dose of copper. Chronic oral poisonings are associated with the accumulation of small amounts of copper over a long period of time.<sup>1,2</sup> In these instances, the amount of copper may exceed that required by the animal or be related to deficiencies in minerals such as molybdenum and sulfur.<sup>2</sup>

### Causes of Acute Oral Poisoning

- Accidental administration of soluble copper salts
  - Old copper-containing anthelmintics
- Accidental ingestion of copper-containing substances
  - Copper sulfate foot baths, containers of copper algacides or fungicides

### Causes of Acute Injectable Poisoning

- Prophylactic injection of copper salts, especially soluble salts
- Copper (as the diethylamine oxyquinoline sulfonate) at recommended dose rates has been associated with death in sheep.

### Causes of Chronic Oral Poisoning

- Contamination of drinking water
- Contamination of plants with fungicidal sprays<sup>3</sup>
- Copper containing boluses, pastes, needles, or wires placed in the rumen/reticulum<sup>4</sup>
- Feeding seed grain treated with copper-containing antifungal agents
- Feeding mineral or salt licks or mixtures containing excessive amounts of copper
- Grazing pasture contaminated by smelter fumes<sup>5</sup> or by drippings from overhead power cables made of copper but corroded by the constituents of an industrially polluted area
- Grazing pasture growing on soils rich in copper
- Grazing pasture too soon after it has been top-dressed with the following:
  - Copper salts to correct a mineral deficiency in the soil
  - Poultry manure or dried chicken waste when the birds have been fed on a copper-rich diet<sup>6</sup>
  - Pig slurry or dried pig wastes when the pigs have been fed on a copper-enriched ration as a growth supplement<sup>7</sup>
- Mineral or salt mixes containing copper ingested by salt-hungry livestock
- Miscellaneous sources of copper causing poisoning—palm oil cake and lumber treated with arsenic, copper, and chromium
- Overfeeding of copper-enriched concentrate rations

### EPIDEMIOLOGY

#### Occurrence

Sporadic outbreaks of primary copper poisoning occur in many species and in many different countries. Toxicosis occurs far more often in ruminants, especially sheep, than in nonruminants. Poisoning in sheep is commonly reported in countries such as Australia, Brazil, New Zealand, South Africa, and the United States.<sup>1,8</sup> Cattle, buffalo, and goats are also affected, although reports are more sporadic.<sup>2,8-10</sup> The morbidity rate is often low, but the mortality rate is high.<sup>3</sup>

There is a great deal of published anecdotal evidence about the amount of copper fed to specific species that has been associated with illness or deaths but almost no evidence of MD<sub>50</sub> or LD<sub>50</sub>. The following toxic dose rates are provided as a rough guide.

#### Sheep

- Acute: Single oral doses of 9 to 20 mg copper/kg BW;<sup>2</sup> some references provide a range of 20 to 100 mg copper/kg BW.<sup>3</sup>
- Chronic: Daily intakes of 3.5 mg copper/kg BW, 25 ppm being the maximum tolerated concentration in the feed.<sup>3</sup> Even lower concentrations (15 ppm) may poison sheep if adequate molybdenum and sulfate are not present in the diet.

#### Calves (Preruminant)

Toxic doses are similar to those for sheep.<sup>2</sup>

#### Cattle

- Acute: 200 mg copper/kg BW<sup>2</sup> (up to 800 mg/kg BW)
- Chronic: varies considerably depending on the breed

#### Goats

No data are available.

#### Horses

- Acute: 125 mg copper solution/kg BW; signs did not occur when similar amount added to feed.<sup>2</sup>
- Chronic: Relatively resistant; 791 mg copper/kg BW × 6 months resulted in no signs, but a liver copper concentration greater than 3000 mg/kg DM.<sup>2</sup>

#### Swine

- Acute: No data but considered relatively resistant
- Chronic: 200 mg copper/kg BW stimulates growth in weanling pigs; 500 mg copper/kg BW resulted in reduced growth and death.<sup>2</sup>

None of these data on toxic intakes come with information on competing and contributory dietary factors such as sulfate, molybdenum, and zinc, and these are critical in determining the toxic effects of the copper intake.

## Risk Factors

### Animal Risk Factors

Many deaths attributable to copper poisoning are followed by deaths from general debility in sheep in poor condition. Dairy cows, especially those lactating at the time, fail to produce well, and special care is needed to bring them back to full production. Younger animals, especially calves, are more likely to be poisoned as a result of an increase in copper absorption.<sup>2</sup>

### Species Susceptibility

Ruminants, especially young ruminants, are more susceptible than nonruminants. Preruminant calves appear to mirror the susceptibility of sheep. Sheep are the most susceptible species, with some species tolerating as little as 9 mg/kg BW; they are different from other species in the way in which copper is handled. As ingestion increases, sheep are unable to increase the amount of biliary excretion, and copper accumulates in the liver. Goats tolerate higher amounts in their diets than sheep. Goats receiving 36 mg/kg DM for 88 days had higher liver concentrations of copper but no evidence of liver damage. Cattle will usually tolerate 100 ppm,<sup>1</sup> but lethal hemolysis has occurred in cattle fed a low-copper-level mineral supplement (38 mg/kg BW for lactating cows) for 2 years. Swine can tolerate and swine 250 ppm in their diets.<sup>2</sup> Horses are the least susceptible, with a tolerance to levels of 800 ppm in the diet.

### Breed Susceptibility

**Sheep.** Scottish Blackface sheep appeared to be the least susceptible, followed by the Finnish Landrace, with intermediate susceptibility when fed moderate to high amounts of copper.<sup>2</sup> Texel sired lambs followed by Suffolk lambs were the most susceptible.<sup>2</sup> North Ronaldsay sheep are reported to be the most copper sensitive of sheep and mammals in general.<sup>11,12</sup> These sheep normally subsist on seaweed that has a very low content of copper and molybdenum.<sup>12</sup> When the sheep are fed on terrestrial herbage containing normal levels of copper and molybdenum and high levels of zinc, they develop copper poisoning.

**Cattle.** Angus cattle are much more susceptible than Charolais and Simmental. Jerseys may be more sensitive than Holstein cows.<sup>2</sup>

### Environmental Factors

Both acute and chronic copper poisoning occur under field conditions. Acute poisoning usually occurs because of the accidental ingestion or administration of large quantities of soluble copper salts, whereas chronic poisoning occurs principally as a result of ingesting feed containing or contaminated by copper derived from the soil or by its application to the diet as an agricultural chemical or feed supplement.

The toxicity of copper ingested in this manner is governed not only by the absolute amount of copper but also by the interaction of a number of factors, including the amount of molybdenum and sulfate present in the diet, the presence or absence of specific plants in the diet, and the level of protein in the diet.<sup>1,2</sup> In fact, either copper deficiency or copper poisoning can occur on soils with apparently normal copper levels, with the syndrome depending on the particular conditioning factors present. High molybdenum and sulfate levels in the rumen lead to the microbiological synthesis of nonabsorbable thiomolybdates, and a high-sulfate diet also leads to lower retention of copper in tissues.

Other compounding factors exist. There is a competitive relationship between copper and zinc in the internal metabolism of ruminants, with a high level of zinc in the diet reducing the intake of copper. Reduction in rumen protozoa results in an increased susceptibility to copper, as does the use of ionophores such as monensin.<sup>2</sup> Sheep on a selenium-deficient diet and with low blood levels of glutathione peroxidase are more susceptible to chronic copper poisoning. Some sheep are conditioned by inheritance to have low blood glutathione levels in spite of a normal dietary intake of selenium. They also have low glutathione peroxidase blood levels and may be more susceptible for this reason.

### PATHOGENESIS

Toxicokinetics vary depending on the gastrointestinal tract. In nonruminant animals, including preruminant calves and lambs, absorption occurs primarily in the small intestine. Absorption in ruminant animals is low, primarily as a result of the relationship between molybdenum and sulfur in the rumen. In the intestinal mucosa, a portion is bound to metallothionein and eventually excreted in the feces. The remainder is bound to albumin and transcuprin in the blood and transported to the liver. Once in the liver, copper can be stored, incorporated into ceruloplasmin for use, or excreted in the bile.<sup>1,2</sup> Very little renal excretion occurs. The liver has the highest concentration of copper, followed by the kidney and brain.<sup>2,13,14</sup>

Acute exposure to soluble copper salts in high concentrations is associated with intense irritation of the gastrointestinal mucosa, blue-green discoloration of the feces and mucosa, and profound shock. Severe intravascular hemolysis occurs if the animal survives long enough. Free copper acts as a protein coagulant, binding to proteins and forming a reactive oxygen species.<sup>1,2</sup>

When excessive amounts of copper are injected the response is rapid, and animals begin to die the next day, with peak mortality about the third day after dosing.<sup>13</sup> Early deaths appear to be attributable to severe hepatic insufficiency and later deaths to renal tubular necrosis.

Chronic poisoning occurs when ingestion overwhelms biliary excretion. The frequent ingestion of small amounts produces no ill-effects while copper accumulates in the liver and to a less extent, the kidney. This is generally referred to as the "prehemolytic phase."<sup>1,2</sup> When maximum hepatic levels are reached, often after periods of exposure as long as 6 months, copper is released from the liver into the bloodstream, and the animal dies of acute intravascular hemolysis. This phase is generally referred to as the "hemolytic phase."<sup>1,2</sup> The production of superoxide radicals that damage erythrocyte membranes may be responsible for hemolysis. One of the dangers of cumulative copper poisoning is that the animal shows normal health until the hemolytic crisis, when it becomes acutely ill and dies very quickly. Death is ascribed to acute hemolytic anemia and hemoglobinuric nephrosis.

The liberation of the hepatic copper is not well understood, but the favored hypothesis is that the accumulation of copper ions in the liver cells is associated with the accumulation of electron-dense lysozymes in the hepatocytes and hepatic necrosis. Various stresses, including a fall in plane of nutrition, traveling, and lactation, are thought to precipitate the liberation.<sup>2,3</sup> Complex mechanisms relating to disorders of cell membranes; a marked change in hemoglobin composition, including the development of methemoglobinemia; and an increase in the oxidative status of the sheep are described as occurring during the critical stages.<sup>3</sup> Liver-specific enzymes may appear in the serum beginning a few days or weeks before the hemolytic stage. Severe hepatic necrosis occurs at the time of the hemolytic crisis.

### CLINICAL FINDINGS

#### Acute Intoxication

Acute toxicosis from ingestion or injection of large amounts of copper salts is rare. Clinical signs present after ingestion include severe gastroenteritis accompanied by salivation, abdominal pain, dehydration, diarrhea, and vomiting in those species that are able to. The feces and vomitus are mucoid with a characteristic blue-green color. Shock with a fall in body temperature and an increase in heart rate is followed by collapse and death, usually within 24 hours.<sup>1,2</sup> If the animal survives for a longer period, dysentery and jaundice become apparent. Horses receiving an oral solution of copper sulfate (125 mg/kg BW) developed gastroenteritis, hemolysis, and liver and kidney damage, and they died within 2 weeks. Interestingly, horses receiving a similar amount in the feed did not develop any signs of poisoning.<sup>2</sup>

Poisoning associated with the injection of copper salts is manifested by anorexia, depression, and dehydration. Ascites, hydrothorax, hydropericardium, hemoglobinuria, and massive hemorrhages, tachypnea, head-pressing, opisthotonos, aimless wandering,

circling, and ataxia are reported in calves surviving for 3 or more days.<sup>1,13</sup> Lambs similarly poisoned die within 24 hours of injection.

### Chronic Intoxication

In ruminants, anorexia, thirst, hemoglobinuria, pallor, and jaundice appear suddenly. There is no disturbance of alimentary tract function.<sup>1-3,8</sup> Depression is profound, and the animal usually dies 24 to 48 hours after the appearance of signs. A herd of affected lactating dairy goats did not show hemolysis but rather anorexia, recumbency, and neurologic signs, whereas adult Boer goats developed hemolysis and hemoglobinuric nephrosis.<sup>9,10</sup> In pigs, signs of illness are uncommon, with most pigs being found dead without premonitory signs, although dullness, anorexia, poor weight gain, melena, weakness, pallor, hyperesthesia, and muscle tremor may be observed occasionally.

## CLINICAL PATHOLOGY

### Acute Intoxication

In acute intoxications, hepatic enzymes may not rise for a few days. Fecal examination may show large amounts (8000 to 10,000 mg/kg) of copper.

### Chronic Intoxication

Serum enzyme activity (aspartate aminotransferase [AST],  $\gamma$ -glutamyltransferase [GGT], sorbitol dehydrogenase [SDH]) may be increased just before the hemolytic episode. The hepatic enzymes GGT and AST were determined in one experimental study to be the best enzymes to assess copper load in sheep during the prehemolytic phase. GGT activity increases were evident 28 days before the hemolytic crisis, and AST activity increased from 14 days before onset of acute copper toxicosis. In one small study, GGT and AST were predictive indicators of hepatic accumulation in cattle, whereas only GGT was predictive in buffalo.<sup>15</sup>

Other laboratory abnormalities are consistent with hemolysis and renal damage. The packed cell volume decreases sharply with the onset of hemolysis. Hemoglobinemia and hemoglobinuria may be present, and elevations in blood urea nitrogen and creatinine indicate renal compromise.

Levels of copper in the liver are markedly increased in chronic copper poisoning. Liver biopsy is the best diagnostic technique and serves a most useful purpose in the detection of chronic copper poisoning because blood levels do not raise appreciably until the hemolytic crisis occurs before death.<sup>1,6</sup> Because of the greater concentration of copper in the caudate lobe compared with other parts of the liver, an autopsy specimen will give the most reliable results.

Blood levels of copper during the hemolytic crisis are usually of the order of 78 to 114  $\mu\text{mol/L}$  (4.9 to 7.2 ppm), compared with about 15.7  $\mu\text{mol/L}$  (1 ppm) in normal

animals. Normal liver levels of less than 5.5 mmol/kg dry matter (349 ppm) rise to above 15.7 mmol/kg (997 ppm) in the latter stages of chronic copper poisoning in sheep, to 95 mmol/kg in pigs, and to 30 mmol/kg in calves. In sheep, liver values greater than 7.85 mmol/kg and kidney values of greater than 1.25 to 1.57 mmol/kg dry matter are diagnostic. After a massive single dose, it is important to include kidney among specimens submitted for copper assay because levels may be high (more than 25 mg/kg dry matter), whereas liver copper levels have not yet risen. When comparing normal and toxic values, it should be remembered whether results are expressed as dry weight basis or wet weight basis. Assuming approximately 20% dry matter in tissue, a wet weight value of 1.5 ppm copper is actually 7.5 ppm on a dry weight basis, comparable to the toxic range reported previously for blood. Thus a commonly observed toxic value of 200 ppm copper in liver (wet weight basis) would be reported as 1000 ppm copper on a dry weight basis.

## NECROPSY FINDINGS

### Acute Intoxication

Acute copper poisoning via oral exposure is uncommon in ruminants, but gross changes include severe gastroenteritis with erosion and ulceration, particularly in the abomasum. Macroscopic changes in calves poisoned by injected solutions of copper salts include hepatomegaly with an enhanced zonal pattern and massive fluid accumulations in body cavities. Characteristic microscopic findings in such acute copper toxicoses include extensive periportal hepatic necrosis and a variable amount of renal tubular necrosis.

### Chronic Intoxication

In chronic copper poisoning, jaundice and hemoglobinuria are usually but not always present. The liver is swollen and yellow and may contain hemorrhagic foci. The spleen is enlarged, with a soft pulp; the kidneys are swollen and have a dark, gunmetal color. The hemolytic crisis typical of ovine copper toxicosis results in massive acute hepatocellular necrosis, which masks most of the chronic hepatic damage. These changes include hepatocellular vacuolation and degeneration, increased single-cell necrosis of hepatocytes, a variable amount of periportal fibrosis, and proliferation of cholangiolar cells. These chronic lesions are more easily identified in cattle suffering from copper poisoning. Granular casts are often present in the renal tubules, especially in affected sheep. The brain in affected sheep may have focal areas of gliosis in the cerebral cortex and white-matter areas.<sup>14</sup> Hemosiderin deposits are increased in the liver and spleen. Details of the critical copper levels of tissues are provided in the clinical pathology discussion.

Although the lesions described previously do occur in some outbreaks of the disease in pigs, they are not as pronounced as in ruminants, and they are often accompanied by pulmonary edema and by severe hemorrhage from ulcers in the pars esophagea or large intestine.

## Samples for Confirmation of Diagnosis

- **Toxicology**—5 mL blood; 50 g liver, kidney; 100 g stomach content; 500 g suspect feed (ASSAY [Cu])
- **Histology**—formalin-fixed liver, kidney, abomasum, spleen (light microscopy)

**Diagnostic confirmation** is by demonstration of high blood and liver levels of copper plus histologic evidence of liver damage. The history and the examination of feedstuffs and pastures are valuable aids in determining the cause.

## DIFFERENTIAL DIAGNOSIS

### Differential list:

#### Acute Intoxication:

The differential diagnosis list for acute copper poisoning includes other associations with gastroenteritis. Copper poisoning can usually be identified by the bluish-green color of the ingesta or feces.

#### Chronic Intoxication:

Acute hemolytic diseases that may be mistaken for chronic copper poisoning include the following:

- Babesiosis
- Bacillary hemoglobinuria
- Equine infectious anemia
- Leptospirosis
- Nitrate/nitrite poisoning
- Plant poisoning including allium and S-methylcysteine sulphoxide (SMCO) in rape, kale
- Postparturient hemoglobinuria
- Red maple (*Acer rubrum*) toxicosis (horses)

## TREATMENT

In acute poisoning, treatment is primarily symptomatic and supportive. Intravenous fluids, gastrointestinal protectants, and nonsteroidal antiinflammatory drugs may be used for dehydration, gastrointestinal pain, and shock. Blood transfusions may be indicated in individual animals with hemolysis and a rapidly falling packed cell volume.

Chelation may be useful in chronic toxicosis in small herds or individual animals. Common chelating agents used in the treatment of human copper toxicosis include penicillamine, dimercaprol, and calcium disodium EDTA.<sup>16</sup> Penicillamine has been used successfully in goats (50 mg/kg PO q24h  $\times$  7 days), but the cost may limit its use in herd situations.<sup>9</sup> Intravenous calcium disodium edetate (70 mg/kg BW  $\times$  2 days) has been used in calves.

There are a number of dosage recommendations for ammonium molybdate and sodium thiosulfate. For chronic copper poisoning, daily oral treatment of lambs with 100 mg ammonium molybdate and 1 g anhydrous sodium thiosulfate significantly reduced the copper content of tissues and appears to prevent deaths in lambs known to have toxic amounts of copper. In a herd of goats, 300 mg ammonium molybdate (300 mg PO q24h) and sodium thiosulfate (300 mg PO q24h) for 3 weeks has been used.<sup>9</sup> Ammonium tetrathiomolybdate (1.7 mg/kg IV or 3.4 mg/kg SQ every other day for 3 doses) or (2–15 mg/kg IV q24h × 3–6 days) has been recommended for use in food animals and sheep.<sup>17</sup> Different countries may have particular restrictions on the form of molybdenum approved for use, so locally available approved therapy should be determined.

## CONTROL

With chronic intoxication, the provision of additional molybdenum in the diet as described under the control of phyto-genous chronic copper poisoning should be effective as a preventive measure. Ferrous sulfide is effective, but difficulty is usually encountered in getting the animals to eat it. In pigs and sheep, the administration of iron and zinc reduces the risk of copper poisoning in diets supplemented by this element, and a diet high in calcium encourages the development of copper poisoning, probably by creating a secondary zinc deficiency. A lick that contains dicalcium phosphate, sulfur, and zinc sulfate has been used as a prophylactic.

## TOXICOSIS FROM DRIED POULTRY WASTES

Feeding dried poultry wastes to ruminants provides them with a source of nitrogen and gets rid of the chicken farmer's disposal problem. However, deleterious effects include the following:

- Copper poisoning when the chickens are fed on diets supplemented with copper
- Estrogen poisoning when the chickens are fed on estrogen-supplemented diets
- An unidentified problem arises of hepatic necrosis, hypoalbuminemia, and ascites in lambs fed large amounts of poultry waste from hen batteries.
- Litter from broiler houses is associated with renal damage but not to the point of causing mortality.
- Botulism

## TOXICOSIS FROM DEFOLIANTS

Substances used to remove the leaves from plants to facilitate harvesting of seed may represent a toxic hazard if the residual stalks are fed to livestock or if the animals gain access to concentrated product.

- Monochloroacetate sodium (SMCA) is commonly used for this purpose. It is unlikely to cause poisoning unless very large quantities of the stalks are fed or if animals have access to the concentrated defoliants. Toxic signs in cattle include diarrhea, colic, muscular tremor, stiff gait, ataxia, and dyspnea. Terminally there may be convulsions, hyperexcitability, and aggressiveness. The course is short, with most animals dying within a few hours.
- Trialkyl phosphorothioates (Merphos and DEF), organophosphorus compounds used as a defoliant for cotton plants, produce typical signs of organophosphorus poisoning.
- Thidiazuron (TDZ), a cotton defoliant, appears to be nontoxic to animals, but it may enter the human food chain via goat's milk and chicken eggs.

## TOXICOSIS FROM FUNGICIDES

- Zinc ethylene dithiocarbonate (zineb) may be associated with thyroid hyperplasia and hypofunction, degeneration of myocardium and skeletal muscle, testicular weight reduction, and germ cell depletion.
- Thiram (tetramethyl thiuram sulfide) is a widely used agricultural fungicide that is associated with conjunctivitis, rhinitis, and bronchitis on local contact; it is thought to be associated with abortion in ewes on ingestion. It is a known teratogen, but no specific poisoning incidents have been recorded in large animals. In birds, ingestion of contaminated poultry feed caused soft eggshells, depressed growth, and leg abnormalities.<sup>1</sup>

## Fungistatic Agents

- Hexachlorobenzene (HCB) is widely known because of its indestructibility and capacity to pass from grain through cattle and into humans. Legislation against chlorinated hydrocarbons being found in the human food chain is very harsh, and hexachlorobenzene is a prime target for public health veterinarians. Its specific toxicity is not high, although experimental poisoning in pigs is associated with incoordination, paresis, and other disorders of the central nervous system.

## Grain Fumigants

- Grain treated by the fumigant dibromoethane is associated with mortality in sheep. The principal lesions are pulmonary edema, septal fibrosis, alveolar epithelialization, and pleural effusion. Death occurs 48 to 120 hours after exposure.
- Methyl bromide is used for stored grain and as a soil fumigant.

## TOXICOSIS FROM HERBICIDES

Over 200 different substances have been used as herbicides; some of them are historical and no longer manufactured. Herbicides vary widely in their composition, toxicity, associated toxicity, mechanism of action, and use. Associated toxicities include the following:

- Arsenicals herbicides may also cause other signs of arsenic poisoning.
- A hazard of the relatively safe organic compounds described here is their contamination by highly toxic ones as a result of faults in the manufacturing process (e.g., the dioxins that have been found to be significant contaminants of the 2,4,5-T chemical). Today, restrictions on registration and changes in the manufacturing process have drastically reduced contamination by dioxins.
- Sodium chlorate, in addition to other signs, causes methemoglobinemia.
- Some herbicides (e.g., glyphosate) increase the palatability of sprayed pasture more, creating their own toxicity hazard.
- The phenoxy acid herbicides (2,4-D, 2,4,5-T) can increase palatability of some plants after spraying and induce elevated nitrate concentration in plants for several days after spraying.

## BIPYRIDYL DERIVATIVES

Paraquat and diquat, the two common herbicides included in this classification, are poisonous by ingestion, inhalation, and dermal exposure. Paraquat is among the most toxic herbicides currently in use and is restricted in many developed countries; diquat is somewhat less toxic. Poisoning in large animals with a bipyridyl herbicide is unlikely to occur unless it is accidentally or maliciously administered. Cattle and sheep are more sensitive to bipyridyls than other species. The LD<sub>50</sub> of paraquat in cattle is 35 to 50 mg/kg BW; in sheep, the LD<sub>50</sub> is 8 to 10 mg/kg BW; and in pigs, 75 mg/kg BW. The LD<sub>50</sub> of diquat in cattle is 20 to 40 mg/kg BW.<sup>1</sup>

Paraquat accumulates in the lungs, affecting the type I and II alveolar cells and Clara cells and resulting in acute alveolitis and chronic pulmonary fibrosis in many species.<sup>2</sup> Paraquat is associated with fibrosing pneumonitis in pigs, but this does not develop in sheep or cattle with fatal doses. A dose rate of 100 mg/kg BW is uniformly fatal in pigs, with signs of vomiting, diarrhea, and dyspnea. Those animals that survive long

enough may develop acute renal failure. Other lesions include hepatic injury and mucosal damage.<sup>3</sup>

Diquat does not specifically affect the lungs, but rather the gastrointestinal tract, liver, and kidneys. Accidental poisoning of sheep as a result of contamination of pasture by diquat has been associated with widespread illness with signs of diarrhea and significant mortality. In cattle, accidental poisoning with diquat has been associated with fatal abomasitis and enteritis, hepatic and myocardial degeneration, and pulmonary emphysema.

## CARBAMATES, THIOCARBAMATES, DITHIOCARBAMATES

Herbicides in this group include, among others, asulam, barban, di-allate, tri-allate, and metham sodium. In general, these herbicides are safe when used in low concentrations. Repeated small doses are associated with marked alopecia.<sup>4</sup> Barban is toxic at doses of 25 mg/kg BW in cattle. Di-allate is toxic to ruminants, with anorexia, ataxia, and exhaustion reported as common signs.<sup>1</sup> The toxic dose of di-allate in cattle and sheep is 25 mg/kg BW for 5 days or 50 mg/kg BW for 3 days.<sup>1</sup> Tri-allate is associated with severe illness and sporadic death after single oral doses of 300 mg/kg BW in sheep and 800 mg/kg BW in pigs. Salivation, bradycardia, vomiting, muscular weakness, dyspnea, tremor, and convulsions are followed by death in 2 to 3 days. It is also toxic when continuously given in small amounts.

## DINITROPHENOL COMPOUNDS

Dinitrophenol (DNP) and Dinitro-orthocresol (DNOC) are the most common members of this group. Dinoseb, now rarely used, is a highly toxic DNP. Dinitrophenols are hazardous to all species; doses of 25 to 50 mg/kg BW are usually toxic, but much smaller doses produce toxicity when environmental temperatures are high. The toxic dose range in cattle is 2 to 50 mg/kg BW.<sup>1</sup>

Animals can be poisoned accidentally by inhalation, ingestion, or percutaneous absorption of these compounds, which have the effect of uncoupling oxidative phosphorylation and increasing the basal metabolic rate.<sup>5</sup> Poisoning is manifested by an acute onset of restlessness, sweating, deep and rapid respiration, hyperthermia, and collapse. In ruminants, but not in nonruminants, the metabolites of these compounds are associated with intravascular hemolysis, methemoglobinemia, and hypoproteinemia. Death may occur 24 to 48 hours later.

## INORGANIC HERBICIDES

Sodium chlorate, sodium borate or borax, ammonium sulfamate, and several arsenical products have historically been used as herbicides. For the most part they have been replaced by newer preparations. Sodium chlorate, although banned as an herbicide in

several countries,<sup>6</sup> has been studied in sheep, cattle, and pigs as means of decreasing the fecal shedding of *E. coli* and other gastrointestinal pathogens.<sup>7-10</sup>

## Sodium Chlorate

Animals seldom ingest sufficient sprayed plant material to produce clinical illness, and the principal danger is from accidental dosing or permitting salt-hungry cattle to have access to the chemical. The lethal oral dose is 2 to 2.5 g/kg BW for sheep, 0.5 g/kg for cattle, and 3.5 g/kg for dogs. Irritation of the alimentary tract is associated with diarrhea and deep, black erosions of the abomasal and duodenal mucosae. Hemoglobinuria, anemia, and methemoglobinemia result, and somnolence and dyspnea are characteristic. At necropsy, the blood, muscles, and viscera are very dark. No specific treatment is available. Sodium thiosulfate and methylene blue are used in treatment but have little effect; copious blood transfusions have been recommended.

## ORGANOPHOSPHORUS COMPOUNDS

Glyphosate and glufosinate, both organophosphorus compounds, are herbicides regularly used in many countries.<sup>11,12</sup> The acute oral toxicity is low; dermal, ophthalmic, and respiratory irritation can occur from exposure to wet product. Glufosinate is slightly more toxic than glyphosate, and the surfactant used in ammonium formulation has been implicated in human poisonings.<sup>1</sup>

## PHENOXY ACID DERIVATIVES

Substances found in this group are among the most extensively used herbicides, with 2,4-D (2,4-dichlorophenoxyacetic acid) and others commercially available since the mid-1940s. Common phenoxy acid derivatives include 2,4-D, 2,4-DB, 2,4,5-T, dalapon, 2,4-DP (dichloprop), MCPP (mecoprop), MCPA, and silvex. As a group, low doses are relatively safe; ingestion of higher doses results in gastrointestinal and nervous system signs.<sup>1</sup> Silvex, MCPA, 2,4-D, and 2,4,5-T are non-toxic in the concentrations used on crops and pasture, but dosing with 300 to 1000 mg/kg as a single dose is associated with deaths in 50% of cattle. They have also been tentatively linked with the high prevalence of small intestinal carcinomas in sheep.

Ingestion of 2,4-D at doses between 150 and 188 mg/kg BW is fatal to adult cows and at 10 mg/kg BW for sheep. Reversible toxic effects are produced with single doses in calves with doses of 200 mg/kg and in pigs with 100 mg/kg. Repeated administration of 50 mg/kg is toxic to pigs. In adult cows, signs include recumbency, ruminal stasis, salivation, and tachycardia. In calves, the signs are dysphagia, tympanites, anorexia, and muscular weakness; in pigs, additional signs include incoordination, vomiting, and transient diarrhea. Long-term administration to

pigs (500 ppm in the diet for 12 months) is associated with moderate degenerative changes in kidney and liver. Repeated dosing of sheep with silvex for about 30 days at 150 mg/kg BW causes death.

A commonly used mixture of 2,4-D, 2,4,5-T and a brushwood killer, monosodium methyl arsenate, is very toxic by mouth or after application to the skin; signs include anorexia, diarrhea, weight loss, and death in most cases.

### TRIAZINES/TRIAZOLES

Similar to phenoxy acid herbicides, triazine herbicides have been enjoyed widespread use for many years. Common herbicides include atrazine, cyanazine, propazine, prometon, simazine, and terbutryn. Atrazine and prometon appear to be nontoxic at usual levels of ingestion. Accidental poisoning of sheep with atrazine is associated with paralysis, exophthalmos, grinding of the teeth, diarrhea, dyspnea, and tachycardia, and that of cattle is associated with salivation, tenesmus, stiff gait, and weakness. Experimental dosing of heifers with large doses of atrazine is associated with fatalities, but animals treated with activated charcoal have survived. Continuous access to simazine is associated with tremor, tetany and paraplegia, and a prancing gait with the head held against the chest. Death occurs after 2 to 4 days, and mild to moderate myocardiopathy is found at necropsy.

Simazine and aminonitrazole in combination have been associated with death in sheep and horses allowed access to pasture sprayed with the mixture. In sheep the signs are staggering, inappetence, and depression. In horses, colic is the prominent feature.

### UREAS/THIOUREAS

Diuron, isoproturon, linuron, and tebuthiuron are among the many herbicides found in this classification. With the exception of tebuthiuron, most of these herbicides are of low-order toxicity. The toxic dose of diuron in cattle is 100 mg/kg BW for 10 days, and in sheep it is 250 mg/kg BW or 100 mg/kg BW for 2 days.<sup>1</sup> The toxic dose of linuron in cattle is listed as 20 to 40 mg/kg BW.<sup>1</sup> Flumeturon toxicity in sheep results depression and drowsiness, dyspnea, salivation, mydriasis, teeth grinding, chewing movements, and incoordination.<sup>1</sup>

### OTHERS

#### Triclopyr

Triclopyr, a selective postemergence herbicide, is toxic to horses at five times the estimated maximum intake from herbage. It is associated with digestive and respiratory signs, ataxia, stiff gait, and occasional tremors.

#### Delrad

Delrad is an algicide historically used to control the growth of algae on ponds and

other water reservoirs. Cattle and sheep are unharmed by the ingestion of water containing 100 ppm of the compound. Dose rates of 250 g/kg BW in adult cattle, 150 mg/kg BW in calves, and 500 mg/kg BW sheep are associated with toxic effects.

## HYDROCARBON TOXICOSIS

### ETIOLOGY

Crude oil coming directly from wells is usually repellent to animals, but they can consume lethal quantities if they are in salt-deficient and salt-hungry state. A characteristic of crude oil is that it is usually mixed with salty water, which is often left lying in ponds nearby. After extraction most crude oils are temporarily stored in installations where lead paint is available, and thus salt and lead poisoning commonly occur with oil poisoning. Of the natural crude oils, those with the highest content of sulfur ("sour crude") are most unpalatable and most toxic.

Petroleum distillates, including diesel oil, lamp oil, kerosene, and gasoline, are all poisonous to animals. Cattle will drink all of them and appear to have a positive liking for some products, especially used sump oil and liquid paraffin (mineral oil). Among the commercial oil products, those with the highest content of volatile and inflammable components, especially naphtha and petrol (gasoline) fractions, are the most toxic. Gasoline up to the level of 3 ppm in the drinking water does not appear to depress water intake or to interfere with growth performance of pigs.

The additives used with gasoline, especially lead, may also contribute to the poisoning. The introduction of lead-free gasoline has decreased this risk considerably.<sup>1</sup>

Other hydrocarbons or ingredients mixed with them are toxic as well. Toxic agents of all kinds can be encountered when reject sludge oil is available to animals. Chlorinated naphthalenes found in some older lubricants, greases, and oils can cause a severe hyperkeratosis in cattle similar to vitamin A deficiency. Methyl alcohol is used as antifreeze in gasoline engines for pumps working continuously on oilfields in cold regions. Accidental access to the pump enclosure may result in a poisoning incident.

Accurate dose levels are difficult to determine in field outbreaks. In experimental trials, crude oil at the rate of 37 mL/kg BW in a single dose or 123 mL/kg in 5 divided daily doses were poisonous to cattle. Kerosene at 20 mL/kg BW as a single dose and 62 mL/kg BW in 5 equal daily doses was poisonous. Tractor paraffin (kerosene) at a single dose rate of 13 mL/kg BW is associated with severe illness and at 21 mL/kg was fatal to cattle.

### EPIDEMIOLOGY

On farms access to tractor fuel (paraffin, gasoline, kerosene) is the most likely hazard. When highly chlorinated naphthalenes were used as lubricants, access to oil dumps could lead to clinical signs. Kerosene has an unwarranted reputation as a therapeutic agent for bloat and constipation, but it is unlikely to be given in amounts sufficient to be associated with more than slight illness, unless it is given repeatedly.

### PATHOGENESIS

The early signs are thought to be attributable to regurgitation of the oil; aspiration of the oil, causing pneumonia; and absorption of the volatile components through the pulmonary mucosa, causing toxemia. The later signs are thought to be associated with the direct effect of the oil on the alimentary tract.

Local application or ingestion of highly chlorinated naphthalenes to cattle produces hyperkeratosis characterized by thickening

and scaling of the skin, emaciation, and eventual death. The pathogenesis of the skin lesions is attributable to interference with the conversion of carotene to vitamin A, causing a syndrome similar to vitamin A deficiency. When poisoning results from accidental emission from industrial plants, there are additional signs as a result of ocular, nasal, and tracheobronchial irritation; infertility and abortion also occur.

Accidental ingestion of methyl alcohol by cattle is associated with vomiting, recumbency, death, and a high concentration of methyl alcohol in the ruminal contents.

## CLINICAL FINDINGS (OIL INGESTIONS)

### Natural Cases

When large volumes of crude oil are consumed, signs of toxemia and incoordination occur; regurgitation (vomiting) and bloat may or may not occur. In terminal stages mydriasis, tachycardia, hyperpnea, and hyperthermia are evident. Death is rapid. The animals smell of oil, oil is often present on the skin around the mouth and anus, and oil is found in the feces. The feces are usually oily, often soft to semifluid, and frequently black if the crude oil has been ingested. With kerosene the feces are often dry and firm in the later stages, and the regurgitus may be in the form of gelatin-like cuds, smelling strongly of kerosene. Oil persists in the alimentary tract for long periods and may be found in the cud and feces and at postmortem as long as 16 days after ingestion. Animals that survive the acute toxic syndrome eat poorly, lose weight, and die at variable periods from 16 to 36 days later. Recovered animals usually do so poorly after the incident that they are slaughtered after a history as long as 6 months.

### Experimental Cases

Early signs include incoordination, shivering, head-shaking, and mental confusion. Within 24 hours, anorexia, vomiting, and moderate to severe bloating occur. Experimental kerosene inhalation is associated with persistent severe intrapulmonary physiologic shunting, resulting in prolonged hypoxemia and acidemia and may account for the clinical disease in survivors.

## CLINICAL PATHOLOGY

There are no specific clinicopathologic findings, but hypoglycemia, acetonemia, and transient hypomagnesemia are all recorded.

## NECROPSY FINDINGS

In crude oil or kerosene poisoning aspiration pneumonia is recorded constantly in naturally occurring and experimentally produced cases. It is thought to be the result of vomiting and aspiration from the alimentary tract of already swallowed oil. In longstanding cases of bovine kerosene poisoning, the

lungs are colored gray-blue and are enlarged and firm, but there are no significant histopathologic changes, nor are there any in the kidney or liver. Oil is present in the alimentary tract, and there may be thickening and inflammation of the alimentary mucosa. Degenerative changes in liver and kidney are recorded in some cases.

## TREATMENT

No primary treatment is undertaken. Supportive treatment if the animal survives the initial acute phase should include an instillation of fresh rumen contents from a healthy animal.

## IRON TOXICOSIS

Iron poisoning is uncommon in large animals, with sporadic case reports in cattle, goats, horses, and pigs.<sup>1</sup> The occurrence of a genetic iron storage disease is very rare but reported in Saler cattle. Young animals, such as piglets, absorb iron more efficiently than older ones. Toxicity can occur from excessive ingestion or parenteral administration of iron-containing supplements. Poisoning is most severe after intravenous administration followed by intramuscular or subcutaneous use and least with oral administration. Absorption is the rate-limiting factor for oral toxicosis, and intake must be high for systemic poisoning to occur. The toxicity associated with iron occurs from generation of free radicals and peroxidation of lipid membranes.<sup>1,2</sup> Oral toxicity results in damage to the gastric mucosa, whereas systemic toxicity results in accumulation and damage to the liver and other tissues such as the myocardium.

The extent of poisoning also varies with different iron-containing compounds and the presence of dietary substances.<sup>2-4</sup> The most toxic compounds are those that contain a high proportion of their iron in an ionic, and therefore readily absorbable, form. High dietary levels of vitamin E, selenium, or calcium may reduce or modulate iron toxicity; simultaneously low levels of vitamin E or selenium may predispose to toxicity.<sup>1,4</sup> Newborn piglets from vitamin-E-deficient sows showed signs of toxicity when injected with 100 mg or 200 mg iron dextran. In a recent study, day-old piglets with normal vitamin E and selenium levels receiving 100

mg iron dextran injections had normal PCV values and iron liver levels close to normal, whereas those treated with 150 mg and 200 mg had toxic levels of iron.<sup>4</sup>

## Neonatal Pigs

Neonatal pigs frequently receive oral or injected iron supplements after birth to prevent iron-deficiency anemia. Susceptibility in piglets is attributable to low fetal iron stores, insufficient iron concentration in sow's milk, large litter sizes, and rapid growth rate. Recent studies show that the duodenal transporters of iron are almost undetectable at birth, making oral absorption and toxicity less likely to occur.<sup>2</sup>

Two-day-old pigs are much more susceptible to the toxic effects of iron compounds than are 8-day-old pigs. A suggested reason for this age resistance is the older pigs' better renal functional ability to excrete iron. Another possible reason is the greater mobilization of calcium by older pigs in response to iron administration. This mobilization, or calciphylaxis, can be great enough to result in deposition of calcium in damaged tissues or to cause death. This effect appears to be precipitated by simultaneous or immediately preceding (within 24 hours) injection of vitamin D, but the injection is not essential to it. The progeny of vitamin-E-deficient sows are most susceptible; the muscle cell membranes are damaged, and extensive biochemical changes result, including a great increase in extracellular potassium levels causing cardiac arrest and sudden death.

Two different syndromes of poisoning occur. In peracute poisoning, death occurs within several minutes to an hour after injection of an iron salt. Vomiting or diarrhea may occur before death, or piglets may be found dead with no other signs. The mechanism of action, although similar to anaphylaxis, is unknown. In acute or subacute poisoning, death may not occur for 2 to 4 days and is accompanied by gastrointestinal necrosis (if ingested), with vomiting, abdominal pain, depression, and coma. There is an additional possible damaging effect of iron injection in young pigs, the development of asymmetric hindquarters. In this condition there is asymmetry, but the muscles are normal in composition and appear to have asymmetric blood supplies.

## Foals/Horses

Neonatal foals died soon after the oral administration of an oral supplement containing ferrous fumarate (16 mg/kg) or the iron compound alone. Naturally occurring and experimental cases pointed to acute hepatitis as the critical lesion and the iron compound as the cause. Depression, ataxia, recumbency, jaundice, nystagmus, and death occurred 1 to 5 days after administration. Foals were suspected of being more susceptible because of an age-related increase in

intestinal absorption and decreased iron-binding capacity. Postmortem lesions included hepatic cell necrosis with bile duct proliferation and periportal fibrosis.

Deaths have occurred in adult horses within a few minutes of intramuscular injection of iron compounds. Others have shown severe shock but recovered. Death, when it occurs, appears to be attributable to acute heart failure. Chronic iron poisoning may occur in horses receiving large amounts of iron-enriched supplements.<sup>5</sup>

### Cattle

Acute hepatitis and sudden deaths have occurred in 6- to 9-month-old bulls about 24 hours after injection of an organic iron preparation.

## TOXICOSIS FROM FEED ADDITIVES

Many antibiotics, fungistats, vermicides, estrogens, arsenicals, urea, iodinated casein, and copper salts are added to prepared feed mixes to improve food utilization and hasten growth. Many of them are toxic if improperly used. Miscellaneous agents include amprolium, an antithiamine coccidiostat, which is associated with polyencephalomalacia in ruminants, and iodinated casein, which was used experimentally at one time to stimulate milk production in cows but is now associated with cardiac irregularity, dyspnea, restlessness, and diarrhea in hot weather. Toxic additives described elsewhere in this book are arsanilic acid and copper compounds.

### BRONOPOL

Bronopol (2-bromo-2-nitro-1,3-propanediol) is used as a laboratory preservative for milk (e.g., in milk samples used for butterfat estimation). This milk is usually fed to calves or pigs and may be toxic on occasional feedings. Affected calves salivate, are depressed, collapse, and die within 24 hours of feeding. Necropsy lesions include severe necrotizing abomasitis and local peritonitis on the serosal surface of the abomasum. The oral LD<sub>50</sub> values of bronopol in large animals

are not reported, but in male and female rats are 307 and 342 mg/kg body weight, respectively.<sup>1</sup>

### CARBADOX

Carbadox (mecadox, fortigro, getroxel), a member of the quinoxaline-di N oxide family, is used in pig feeds as a growth promoter and in the treatment of swine dysentery and other enteric diseases at the recommended rate of 50 mg/kg of feed/head per day. Toxic effects occur at rates of 150 mg/kg. Two chemically related compounds, cyadox and olaquinox, are also toxic, but carbadox is more harmful than olaquinox, and cyadox is safe in dosages up to 400 ppm. Affected pigs refuse the ration but will eat other rations, are gaunt and emaciated, pass hard fecal pellets, and drink urine, and they have a long and rough coat, pale skin, severe tachycardia, weak hind-quarters, and a swaying walk, followed by knuckling of the hind fetlocks, posterior paralysis, and death in 8 to 9 days.<sup>2</sup> In the early stages the pigs screech frequently. Sows are agalactic and produce stillborn or weak, undersized piglets.

Necropsy lesions are diagnostic, with extensive damage to the zona glomerulosa of the adrenal gland accompanied by renal tubular necrosis. Both carbadox and olaquinox provided to pigs in the feed at 100 mg/kg for 6 weeks caused changes in the zona glomerulosa.<sup>2</sup> The resulting hypoaldosteronism is manifested by low serum sodium levels, elevated serum potassium (8 mmol/L), and elevated blood urea nitrogen levels. The condition is irreversible, and the outcome is severe disability or death.

### PLURONICS

These substances are administered to adult cattle in their feed as prevention against bloat. They are unpalatable and unlikely to be consumed in dangerous amounts unless they are well masked in feed. When they are fed accidentally to calves in their milk, they are associated with dyspnea, ruminal tympany, bellowing, protrusion of the tongue, nystagmus, opisthotonos, recumbency, and convulsions. Death after 24 hours is the usual outcome.

### TIN POISONING

Dibutyltin dilaurate (DBTD) is a coccidiostat fed to chickens in their feed. Errors in mixing may lead to cattle receiving toxic amounts in concentrates or pellets. Calves usually die acutely, with signs of tremors, convulsions, weakness, and diarrhea. Older animals usually suffer a chronic illness characterized by persistent diarrhea, severe weight loss, inappetence, polyuria, and depression, reminiscent of arsenic poisoning. Affected animals may not be suitable for human consumption because of the high content of tin in their tissues.

## TOXICOSIS FROM MISCELLANEOUS FARM CHEMICALS

### FORMALIN

Formalin is used to preserve colostrum for calf feeding and in the preparation of formalin-treated grain. Milk containing too much formalin is associated with severe gastroenteritis and death in some calves that drink it. The clinical signs include salivation, abdominal pain, diarrhea, and recumbency.

### METHYL BROMIDE

Soil fumigants used to prepare fields for planting may be associated with toxicity hazards in animals grazing them or in feed harvested from them. Methyl bromide has been associated with poisoning in horses, cattle, and goats when used in this manner but should soon be historical in nature. Because of depletion of the ozone layer, the use of methyl bromide was phased out in the United States in 2001, in developed countries in 2005, and in developing countries by 2015.<sup>1</sup> Clinical signs in horses, cattle, and goats include ataxia, stumbling, and somnolence.

### POLYBROMINATED BIPHENYLS

Polybrominated biphenyls (PBBs; hexabromobiphenyl, octabromobiphenyl, and decabromobiphenyl) were produced commercially as flame retardants beginning in 1970. They are not especially poisonous, nor are they a greater risk to farm animals, because of degree of exposure, than many other industrial chemicals, but they found their way into the cattle food chain in reported incidents in the United States. In 1973 to 1974, PBBs were accidentally mixed into various animal feeds, and over 9 million people were exposed to contaminated animal products, including eggs, meat, milk, and cheese.<sup>2</sup> Subsequent to that, the production of PBBs in the United States was voluntarily discontinued. Most of the animal losses attributable to contamination with these compounds were a result of destruction of animals because they were

contaminated, and there was concern for adverse effects on humans who consumed them or their products. However, neither animals nor humans exposed to the PBBs showed any signs of illness at the time of exposure.

The excretion of these compounds occurs principally in feces and urine, but as much as 25% of ingested substance may be present in the milk. They are lipotropic and accumulate in fat depots and the liver. These compounds pass into the placenta and are found in fetuses but appear to be associated with no health problems in the offspring. Attempts to hasten excretion have not produced a satisfactory method. Grazing wool sheep on contaminated ground may be an option for utilization of contaminated land.

## CLINICAL SIGNS

### Cattle

Experimental dosing with 67 mg/kg BW daily for long periods is associated with poisoning, but levels of 10 mg/kg BW are not toxic. Clinical signs of illness are anorexia, diarrhea, lacrimation, salivation, emaciation, dehydration, depression, and abortion. Similar signs plus extensive cutaneous hyperkeratosis occur in natural cases. Necropsy lesions include mucoid enteritis, degenerative renal lesions in natural and experimental cases, hyperkeratosis in the glands, and epithelium of the eyelids.

### Pigs

Experimental poisoning in pigs causes no ill-effects in sows, but high concentrations of PBBs develop in the sow's milk, with death of some nursing pigs resulting.

## POLYBROMINATED DIPHENYL ETHERS

Compounds in the polybrominated diphenyl ethers (PBDEs) group (pentaBDE, octaBDE, and decaBDE) are similar to the PBBs in physical and chemical structure and are still produced commercially as flame retardants for use in consumer products.<sup>2</sup> In many countries, the unrestricted production and disposal has resulted in environmental contamination of the water, soil, air, and marine animals.<sup>3</sup> Two of the compounds, pentaBDE and octaBDE, have been voluntarily phased out, restricted, or banned in many countries, including the United States and the European Union. Concentrations of PBDEs have been found in cow's and goat's milk, animal meats, fish, soil, and grass.<sup>3-9</sup>

## POLYCHLORINATED BIPHENYLS

Polychlorinated biphenyls (PCBs) have a number of industrial uses and are common environmental contaminants. They are hydrophobic and lipophilic, accumulate in body fat, have low rates of biotransformation and excretion, and persist in animal tissues for long periods. Concentrations of PCBs,

sometimes with seasonal variation, have been found in cow's milk in countries where no known PCB production occurs.<sup>6,8</sup> Belgium, in 1999, experienced PCB, dioxin, and dibenzofuran contamination of poultry products, resulting in a precipitous drop in egg production, decreased weight gain, and increased chick mortality.<sup>10</sup> At postmortem, degenerative changes were found in the skeletal and cardiac muscle.

The presence of PCBs in animal tissues is likely to cause rejection of meat from the human food chain. Recorded damage refers to unidentified reproductive inefficiency and reduction in efficiency of food conversion and possibly hepatic hypertrophy and gastric erosion, but in the same species a positive growth-stimulating effect has also been recorded. Experimental poisoning of gnotobiotic pigs has been associated with diarrhea, erythema of the nose and anus, distension of the abdomen, growth retardation, and, at doses of more than 25 mg/kg BW, coma and death.

## SODIUM FLUOROSILICATE

Sodium fluorosilicate is white, odorless, and tasteless powder previously used as a poison in baits for crickets, grasshoppers, and other pests. For the past 30 years it has largely been banned, restricted, or otherwise removed from the market in most countries. The preparation as a bran-based pellet made it attractive to all animal species, and poisoning has been recorded in cattle, sheep, and horses, usually because unused baits were not retrieved after baiting programs ended. In sheep, mild illness occurs after doses of 25 to 50 mg/kg BW and death after 200 mg/kg. Clinical signs include drowsiness, anorexia, constipation, ruminal stasis, teeth grinding, abdominal pain, and diarrhea.

## SUPERPHOSPHATE FERTILIZERS

Superphosphate fertilizer is the usual form in which phosphorus-rich fertilizers are applied to the soil and is therefore available to animals in most countries. It is made by a reaction that takes place when rock phosphate is treated by sulfuric acid, and the end product generally contains phosphorus, calcium, sulfur, and fluoride. The fertilizer is also used to prepare "superjuice," which in some countries is administered to cows as a phosphorus supplement.

Higher-than-normal intakes of the fertilizer either by dosing or by pasture application will cause poisoning, largely as a result of the fluoride present.<sup>10</sup> Calcium pyrophosphate, calcium orthophosphate, or calcium sulfate can also contribute to the toxicosis, causing proximal renal tubular nephrosis. It is not highly palatable, but sheep will eat it when it is in "pill" form (small and granular, resembling grain in texture and particle size). Clinical signs of poisoning include anorexia, thirst, diarrhea, weakness, ataxia, and death in about 48 hours. The LD<sub>50</sub>

of superphosphate for sheep is 100 to 300 mg/kg BW.

## TOXICOSIS FROM SEED DRESSINGS

Many poisoning incidents are caused by live-stock gaining access to seed that has been treated in some way. The more common ones are listed here, and each is dealt with under the heading of the toxic agent:

- Grain treated with arsenic used to poison birds
- Grain treated with highly toxic organophosphorus substances used to make baits for market garden pests
- Bran mixed with metaldehyde for use as a snail bait
- Grain to be used as seed that has been treated with a mercury-based fungistatic agent
- Corn treated with 4-aminopyridine for use as a bird repellent

Additional poisonous substances are grain fumigants and other fungistatic agents.

## TOXICOSIS FROM MISCELLANEOUS RODENTICIDES

### BROMETHALIN

Bromethalin is a highly toxic, single-dose, restricted-use rodenticide registered in the

United States but not several other countries, including New Zealand and Europe.<sup>1</sup> Poisoning in large animals is rare and primarily confined to ingestion of bait stations by young animals or accidental mixing in feed. The onset of action is slow, with signs appearing within 10 hours to a few days. Clinical signs are dose dependent and typically occur 1 to 2 days after ingestion.<sup>1,2</sup> Commonly reported signs in small animals are primarily related to the nervous system and include agitation or depression, hyperesthesia, seizures, coma, paresis, paralysis, and death.<sup>2,3</sup>

Bromethalin is a potent neurotoxin that is rapidly absorbed; widely distributed to the liver, fat, and the brain, where it crosses the blood-brain barrier; metabolized in the liver by N-demethylation; and excreted in the bile; it undergoes enterohepatic recirculation.<sup>3</sup> It acts by uncoupling mitochondrial oxidative phosphorylation in the central nervous system, decreasing the synthesis of ATP and the activity of N/K ATPase.<sup>1,2</sup> The end result is an increase in intracellular Na with loss of osmotic control, fluid within the myelin sheathes, increased pressure on nerve axons, increased cerebrospinal fluid pressure, and impairment of nerve conduction.<sup>1,3</sup> Convulsions, paralysis, and death occur.

There is no antidote, and treatment is symptomatic and supportive. Treatment should include therapy for cerebral edema and seizure control.<sup>3</sup> Judicious use of intravenous fluids is advised so cerebral edema does not become worse.

### CHOLECALCIFEROL (VITAMIN D<sub>3</sub>)

Cholecalciferol (vitamin D<sub>3</sub>) is an active ingredient in several rodenticides used worldwide.<sup>1</sup> It is effective when used alone or added to other baits such as coumatetralyl (an anticoagulant rodenticide).<sup>1</sup> Anecdotally, poisoning has occurred in calves that ingested individual baits or in farm animals secondary to mixing errors in their feed. Toxicity and clinical signs vary widely between species, and there are few data available for large animals. In dogs, clinical signs begin about 12 to 36 hours after a toxic ingestion and include vomiting, weakness, lethargy, melena, cardiac irregularities, seizures, and death.<sup>4</sup>

The mechanism of action is similar to other forms of vitamin D<sub>3</sub> poisoning in which cholecalciferol is first hydroxylated in the liver to 25-hydroxycholecalciferol and then modified in the kidney to form the biologically active 1,25-dihydroxycholecalciferol (calcitriol).<sup>1,4</sup> At toxic doses, calcitriol decreases calcium excretion by the kidneys and excessively increases intestinal calcium and phosphorus from the digestive tract, resulting in calcification of the cardiovascular system (vessels), lungs, kidneys, and stomach lining. Renal failure secondary to mineralization generally occurs simultaneously with the onset of clinical signs.<sup>4</sup>

Treatment is directed toward lowering the serum calcium concentrations, preventing

renal compromise, and treating seizures. Intravenous fluids at rates higher than maintenance should be used to increase urine production and promote excretion of calcium. Bisphosphonates are routinely used in small animal medicine to inhibit bone reabsorption and minimize hypercalcemia, but their cost may prohibit use in large animals.<sup>4,5</sup>

### RED SQUILL (SEA ONION)

Poisoning by red squill seldom occurs because the material is extremely unpalatable and when eaten is usually vomited. In all species large doses (100 to 500 mg/kg BW) must be administered to produce toxic effects. Young calves are most susceptible, and goats are least susceptible. Experimental poisoning is associated with convulsions, gastritis, and bradycardia.

### PHOSPHIDES

Zinc phosphide and, to a much lesser extent, aluminum phosphide are commonly used rodenticides; aluminum, calcium, and magnesium phosphides are used primarily as fumigants to protect grain during storage and transportation.<sup>6,7</sup> In large animals, toxicosis occurs primarily from mixing errors or accidental exposure to treated or stored grain. Poisoning is less likely to occur in ruminants because an acidic stomach pH is important for phosphide hydrolysis. Clinical signs occur in most species within 15 minutes to 4 hours of a toxic ingestion.<sup>6</sup> Vomiting and hematemesis (in those species that can vomit), abdominal distension, and abdominal pain occur first and are rapidly followed by tachycardia, tachypnea, agitation, ataxia, and abnormal neurologic behavior. Sixty-six horses accidentally received aluminum phosphide-contaminated grain; of these, 29 showed full body sweating, tachycardia, tachypnea, pyrexia, muscle tremors, seizures, and recumbency.<sup>7</sup> Hypoglycemia was present in all affected horses. The remaining 37 horses were treated aggressively and remained asymptomatic. Signs occurred 14 hours after ingestion of the contaminated grain; despite treatment, death occurred in 27 horses.<sup>7</sup>

The overall toxicity of phosphides is attributable to the generation of phosphine gas. In the stomach, zinc phosphides (or those of other metals) are hydrolyzed to form phosphine gas and zinc hydroxide.<sup>8</sup> Phosphine gas rapidly enters the blood and is widely distributed to the lungs, liver, kidney, and other organs.<sup>1,6,8</sup> Inhaled phosphine gas crosses the respiratory epithelium. The precise mechanism of toxicity from phosphine gas is unknown but was originally thought to be related to inhibition of cytochrome c oxidase.<sup>6</sup> More recent findings suggest that phosphine has an inhibitory effect on oxidative respiration and forms highly reactive free radicals.<sup>6,7</sup> The overall effect is a combination of local corrosive effects in the gastrointestinal tract and circu-

latory collapse. Death occurs from pulmonary edema or cardiac arrest.

There is no antidote, and treatment is symptomatic and supportive. Blood glucose concentrations should be monitored and treated appropriately. In asymptomatic cases, gastric lavage followed by activated charcoal or a di-tri-octahedral smectite has been used successfully.<sup>7</sup>

Necropsy lesions present in a horse ingesting zinc phosphide were congestion and hemorrhages in all organs; pulmonary edema; fatty degeneration of the liver; congestion of the lungs, kidney, and spleen; and hyperemia of the gastrointestinal mucosa. Common lesions in those horses dying from aluminum phosphide-contaminated grain included petechial and ecchymotic hemorrhages in the mesentery, epicardium, spleen, kidneys, lungs, skeletal muscle, and other tissues. Vascular congestion was a consistent finding, and pulmonary edema was present in 3/6 horses.<sup>7</sup>

### SULFUR TOXICOSIS

#### SYNOPSIS

**Etiology** Ingestion of sulfur-containing materials, generally feed and/or water;

*Continued*

inhalation of hydrogen sulfide or sulfur dioxide gas.

**Epidemiology** Sulfur toxicosis is a worldwide problem of ruminants; horses and pigs are rarely affected animals.

**Clinical pathology** Two distinct syndromes occur (acute and subacute). The acute form has a rapid-onset central nervous system (CNS) signs, and death is common; the subacute form has similar signs, but they develop over weeks, and recovery may occur.

**Lesions** Polioencephalomalacia in ruminants; osmotic diarrhea in monogastrics.

**Diagnostic confirmation** The diagnosis is generally made based on postmortem findings and the presence of sulfur in water or feed source. In some cases, hydrogen sulfide concentrations in rumen gas and the presence of sulfhemoglobin in serum may be helpful.

Polioencephalomalacia may not be present in acute cases.

**Treatment** Supportive care, including fluids and electrolytes; thiamine IV or IM.

**Control** Management of sulfur in feed and water; removal of animals near sulfur dioxide or hydrogen sulfide spills.

## ETIOLOGY

Sulfur exists in four different oxidative states: **sulfur (0), sulfide (-2), sulfite (+4), and sulfate (+6)** and all of them are present either naturally (sulfur) or in various biological products (sulfide, sulfite, sulfate). Absorption and metabolism of sulfur-containing compounds depends on the valence state.<sup>1</sup> Ruminants are more susceptible to toxicosis from dietary ingestion of elemental sulfur and sulfate compounds. Water, especially well water high in sulfates; feed products such as sulfate salt, mineral mixes (sulfur containing), protein sources high in sulfur, and dried distiller's grains; and inhaled gases such as eructated hydrogen sulfide gas and sulfur dioxide are all possible sources of sulfur toxicosis.<sup>2-4</sup> Another potential source is the use of elemental sulfur (flowers of sulfur) as an ectoparasiticide<sup>2</sup>

Sulfur and sulfates in the feed and drinking water play a significant role in the etiology of polioencephalomalacia. The feeding of 85 to 450 g per head to cattle has been fatal, as has 45 g of sulfur in feed pellets to ewes, and the minimum lethal dose of a sulfur-protein concentrate for sheep is estimated to be 10 g/kg BW. Continuous feeding of sulfur at the rate of 7 g per day can be fatal to adult sheep. Sulfur given to adult horses at a dose level of 1000 to 1500 mg/kg body weight has been associated with poisoning.

## EPIDEMIOLOGY

### Occurrence

Sulfur toxicosis occurs worldwide and has been reported in beef and dairy cattle, sheep,

goats, and horses.<sup>3,5</sup> It can occur as a single, isolated case or as an outbreak affecting many animals.

## Risk Factors

### Animal Risk Factors

Ruminants are the species most often affected by sulfur poisoning. Rumen microbes reduce sulfates and elemental sulfur to sulfides, which combine with hydrogen to make hydrogen sulfide.<sup>2,3</sup> Systemic absorption of hydrogen sulfide results in interference with cellular energy production and the onset of clinical signs.<sup>1,2</sup> The brain is most often affected because it has the highest energy demands. Inhaled hydrogen sulfide gas not only causes respiratory paralysis but can be absorbed and result in systemic effects.<sup>1</sup>

Horses, lacking a rumen, do not routinely absorb sulfur or sulfates, and they remain in the gastrointestinal tract and act as osmotic agents, pulling water into the intestinal lumen and causing severe, foul-smelling, black diarrhea.<sup>5</sup> Dehydration is severe, and the animals soon become recumbent and dyspneic, develop convulsions, and die after lapsing into a coma.

Pigs exposed to an environment containing 35 mg/kg of sulfur dioxide for long periods show increased salivation accompanied by clinical and histologic evidence of irritation of the conjunctiva and respiratory mucosa.

### Environmental Risk Factors

Animals housed over the slatted floors of a manure pits, exposed to industrial waste pits, or inhaling "sour gas" from crude-oil well explosions are at increased risk for developing respiratory tract irritation and signs of systemic sulfur poisoning.

## Transmission

- Ingestion of sulfur- or sulfate-containing products, either accidental or intentional
- Topical use of sulfur powder (flowers of sulfur) to control external parasites
- Inhalation of sulfur dioxide gas used in the preparation of ensilage or associated with industrial waste pits
- Inhalation of hydrogen sulfide gas from ruminant eructation or as a gas emanating from oil and natural gas wells or manure pits.

## PATHOGENESIS

In small doses the substance is relatively nontoxic, but excessive doses can be associated with fatal gastroenteritis and dehydration. Conversion of the sulfur to hydrogen sulfide by rumen microbes and the absorption of the gas across the rumen can result in the development of polioencephalomalacia in ruminants.<sup>2,6</sup> Hydrogen sulfide blocks ATP production and energy metabolism at a cellular level. Sulfides are potent oxidants, binding both glutathione peroxidase and superoxide dismutase.<sup>1</sup> The brain is most

often affected because of the high energy demands, relative lack of antioxidants, and high lipid concentrations. The amount of hydrogen sulfide produced in the rumen is pH dependent, with more produced as the rumen pH drops.<sup>3</sup> Other metabolism occurs in the rumen, primarily the incorporation of sulfur into amino acids; rumen bacteria can use these amino acids to produce hydrogen sulfide gas. Metabolism occurs in the liver, although much slower for the inhaled gases, and excretion is both renal and biliary.

## CLINICAL FINDINGS

### Ruminants

Two different clinical syndromes exist:<sup>1,2,6</sup>

1. **Acute:** Signs associated with this include central blindness, head pressing, opisthotonus, recumbency, seizures, coma, and death. Other signs include abdominal pain; severe, foul smelling diarrhea; colic; rumen stasis; and the odor of hydrogen sulfide gas. All species, including horses and pigs, are susceptible to this syndrome, which may be associated with the direct irritant effects of hydrogen sulfide and respiratory paralysis.<sup>2</sup> Clinical signs generally occur in 12 to 48 hours, and death is the normal outcome.<sup>6</sup>
2. **Subacute or chronic:** Signs associated with this form include cortical blindness, bruxism, weakness, ataxia, fine muscle tremors of the head, recumbency, and coma. Most signs are related to the development of polioencephalomalacia (cerebrocortical necrosis) and are associated with hydrogen gas production by ruminants. Often these signs do not occur for several weeks after an exposure, and recovery may be complicated by persistent neurologic deficits.<sup>6</sup>

## NECROPSY FINDINGS

The lungs are congested and edematous, the liver is pale, the kidneys are congested and black in color, there is severe gastroenteritis with peritoneal effusion, and petechial hemorrhages occur extensively in all organs and in musculature. Polioencephalomalacia may occur in a high proportion of cases.

## DIFFERENTIAL DIAGNOSIS

Water and feed analyses are helpful in making a diagnosis. Elevated hydrogen sulfide concentrations in the rumen and the presence of sulfhemoglobin in the systemic circulation may also be used.

### Monogastrics

- Carbohydrate overload
- Gastrointestinal parasites
- Infectious causes of diarrhea (*Salmonella*, *Clostridium perfringens*, *Neorickettsia risticii*)
- Nonsteroidal inflammatory toxicosis

- Organophosphorus/carbamate toxicosis
- Osmotic laxatives

#### Ruminants

- Amprolium administration
- Cyanobacteria (blue-green algae) toxicosis
- Lead toxicosis
- Listeria
- Rabies
- Sodium chloride (salt) poisoning/water deprivation
- Thiamine deficiency
- Thromboembolic meningoencephalitis

## TREATMENT

### TREATMENT

Thiamine (10 mg/kg slow IV, IM every 12h for 3 days) (R-2)

All sources of sulfur supplementation should be removed from the diet and environment. Treatment is primarily supportive with attention to fluid and electrolyte replacement. Glucose supplementation may be helpful.<sup>2</sup> Other adjunct therapies include a broad-spectrum antibiotic and corticosteroids.<sup>1,2</sup> Thiamine, even though polioencephalomalacia is not related to a thiamine deficiency, has been effective in several cases.<sup>1,2</sup>

## CONTROL

Management is the most effective way to prevent and control sulfur poisoning. Water sources and all dietary material should be tested to identify sources high in sulfur. Animals living close to oil wells and industrial waste pits should be monitored closely and moved if necessary.

## VANADIUM TOXICOSIS

Vanadium is used extensively in industry and high amounts may occur in the air, soil, ash, and soot in areas surrounding smelters, burners, and other processing plants. Experimental and natural poisoning of adult cattle, calves, and sheep are recorded. Signs include anorexia, diarrhea, dehydration, oliguria, difficulty in standing, and incoordination. Postmortem findings include ruminal ulcers, hemorrhage in the gastrointestinal tract and surrounding the heart and kidney, and

congestion of the liver and lungs. Field cases are only likely to be encountered when industrial contamination of pasture occurs. Liver is considered the best tissue for assessing chronic vanadium toxicosis in cattle grazing vanadium-contaminated pastures.<sup>1</sup> Careful plowing of the pasture, especially when the vanadium is contained in a fertilizer such as basic slag, reduces the toxic risk.

## TOXICOSIS FROM WOOD PRESERVATIVES

### Chromated Copper Arsenate

Chromated copper arsenate (CCA) is composed of chromium trioxide, copper oxide, and arsenic and was at one time the most widely used wood preservative in the United States. In 2003 the U.S. Environmental Protection Agency restricted CCA to industrial use because it poses an unreasonable human health risk. Several industrial uses remain, however, and it can still be used in animal production facilities, on utility poles, and in other cases.<sup>1</sup>

It is recorded that animals would need to eat at least 28 g of the treated wood daily for a month before a chronic poisoning occurred. Horses that crib or chew could eat more than that and could theoretically become poisoned. The risk to animals, however, is not ingested treated wood but ingestion of ashes left from burning treated lumber.<sup>1</sup> Burning concentrates arsenic in the ashes, and cattle, in particular, have been poisoned in this manner.

### Pentachlorophenol

Agricultural and residential use of pentachlorophenol (PCP; penta) in the United States was prohibited in 1986, but the treated lumber may still be found in older buildings, water and feed troughs, fence posts, and other animal areas. PCP is extremely toxic in humans by inhalation and ingestion and is irritating to the skin, respiratory tract, and mucous membranes.<sup>2</sup> Feeding pigs in PCP-treated wood troughs resulted in salivation and irritation to mucous membranes.<sup>1</sup> Inhalation of PCP by animals in an enclosed area caused death.<sup>1</sup> Acute signs include agitation, pyrexia, tachycardia, tachypnea, muscle tremors, seizures, and death.<sup>1,3</sup> Chronic

intoxication causes weight loss, fatty liver, and nephrosis. In high doses, PCP is embryotoxic and fetotoxic.<sup>3</sup>

Horses bedded on shavings from pentachlorophenol-treated wood, prepared wrongly by treating the rough lumber and then dressing it instead of applying the preservative to the dressed lumber, may have been poisoned by dioxin, a common contaminant in the preservative. Clinical signs include depression of appetite; severe weight loss; ventral and limb edema; hair loss; anemia; and a crusty, scaly dermatitis around the eyes, muzzle, axilla, and inguinal region, and on the neck. Exudation through cracks in the skin is a feature of the lesion. Lesions in liver biopsies include necrosis and severe vacuolar changes in the hepatocytes.

Pentachlorophenol is rapidly absorbed from the skin, lungs, and gastrointestinal tract; metabolized in the liver; and excreted primarily in the urine.<sup>2</sup> It acts to uncouple oxidative phosphorylation, increasing oxygen consumption and decreasing ATP production.<sup>1-3</sup> Acute fatal doses range from 27 to 350 mg/kg BW.<sup>1</sup>

There is no treatment other than removal from the source and supportive care. Intravenous fluids at doses higher than maintenance may be useful in promoting excretion.<sup>2</sup> Strict attention must be paid to the potential for milk and meat residues.

### Creosote (Coal Tar Creosote)

Creosote is produced as a by-product of high-temperature distillation of coal tar, and it contains hundreds of different compounds, including phenols, cresols, toluene, naphthols, and tar acids and bases.<sup>1,4</sup> Among these, phenol and phenolic compounds are among the most toxic. It is no longer registered in the United States for residential use but is used on utility poles, railroad ties, and other industrial lumbers. There are no human or animal studies clearly demonstrating the toxicokinetics of coal tar creosote.

Large animals are generally exposed to creosote by licking the material from treated lumber such as railroad ties or intentional topical misuse. A high mortality may be encountered in newborn pigs, and there may be a greater than normal incidence of stillbirths when sows are farrowed in treated crates. Weaned pigs may show depression, skin irritation, and, occasionally, death. Creosote applied as a treatment for ringworm has shown marked toxic effects in cattle. Fatal doses for coal tar creosote are 4 to 6 g/kg BW as a single dose or 0.5 g/kg BW daily.

Experimentally, a sheep dosed with 8000 mg/kg BW died in 4 days after dosing and a calf dosed with 4000 mg/kg BW survived but lost weight. There were no specific clinical signs in the sheep before death. At postmortem, excess fluid was present in the pleural cavity, and the urine was dark, with a tarry odor.<sup>4</sup>

Three sheep were dosed with varying amounts of creosote and monitored on a daily basis. A sheep receiving 500 mg/kg BW for 32 days showed no clinical signs; both other sheep, one receiving 1000 mg/kg BW and the other receiving 2000 mg/kg BW, died at 8 and 16 days, respectively.<sup>4</sup> Clinical signs included rapid weight loss, anorexia, and weakness. Postmortem findings included excess peritoneal fluid, epicardial petechiation, inflammation of the colon and duodenal mucous membranes, and thyroid enlargement. A calf dosed with 500 mg/kg BW for 11 days lost weight, as did a second calf dosed with 1000 mg/kg BW for 11 days.<sup>4</sup> Weight loss in the second calf continued for 3 weeks after the dosing was discontinued.

There is no treatment other than removing the animals from the source, bathing with a degreasing shampoo if applied topically, and providing supportive care.

## ZINC TOXICOSIS

### SYNOPSIS

**Etiology** Ingestion of excess amounts of zinc from a variety of sources.

**Epidemiology** Rare occurrence in large animals.

**Clinical pathology** Elevated serum and tissue levels of zinc.

### Clinical findings

Pigs: lameness as a result of degenerative arthritis

Cattle: lethargy and anorexia, diarrhea or constipation, reduced milk yield

Horses: lameness, stiff gait, joint effusion

### Necropsy lesions

Pigs: degenerative arthritis

Cattle: degenerative lesions in all organs, especially pancreas

**Diagnostic confirmation** Elevated serum and tissue levels of zinc.

**Treatment** Find and remove source; supportive care.

**Control** Rinse galvanized pipes and utensils after each carriage of milk or milk products. Supplement diet with additional calcium.

### ETIOLOGY

Zinc is an essential element in most mammals, serving as a component in enzyme systems and structural and regulatory processes in the body. It plays a major role in the regulation of immune function, appetite, and growth.<sup>1</sup> It is found in feed supplements, medicines (zinc oxide), industry (steel and other alloys), wood preservatives, and a variety of other commercial and industrial products. Contamination of soil may lead to an increase in water and plants.<sup>2</sup> Zinc phosphide is a commonly used rodenticide, but it in cases of overdose, poisoning occurs from the generation of phosphine gas and not the amount of zinc ingested.<sup>3</sup>

Toxic doses are not well defined,<sup>4</sup> but drinking water containing 6 to 8 mg/kg of zinc is associated with constipation in cattle, and 200 g of zinc as lactate fed over a period of 2 months as a 0.1% solution is associated with arthritis in pigs. The maximum amount tolerated by pigs is 0.1% zinc (as zinc carbonate) in the diet. Experimental zinc poisoning in sheep and cattle is associated with reduced weight gains and feed efficiency when zinc is fed at the rate of 1 g/kg BW. At 1.5 to 1.7 g/kg BW there is reduced feed consumption in both species and depraved appetite in cattle.

### EPIDEMIOLOGY

#### Occurrence

Zinc poisoning in large animals is a rare occurrence and poorly documented. Case reports, when present, usually indicate the presence of another heavy metal.

Dietary levels of zinc associated with poisoning in different species have been summarized. Pigs develop abnormal articular cartilage at 500 ppm dietary zinc, whereas 2000 ppm zinc in the ration is associated with copper deficiency, anorexia, and subcutaneous hematoma. For horses, approximately 3600 ppm in the diet or 90 mg/kg body weight reduces growth rate. Sheep and cattle generally are adversely affected by 900 ppm zinc in their diet.

### Risk Factors

#### Animal Risk Factors

The accidental oral administration of large doses of zinc oxide may be associated with

hypocalcemia and a syndrome comparable to milk fever.

The addition of zinc to pig rations as a preventive against parakeratosis is unlikely to be associated with poisoning because of the unpalatability of rations containing excessive amounts.

Careless use of zinc sulfate as a prophylactic and treatment for the following should be avoided:

- Poisoning by fungi, especially *Pithomyces chartarum*
- Ovine foot rot
- Lupinosis—it is apparent that daily doses of 50 to 100 mg zinc/kg BW in these circumstances can be associated with severe abomasal lesions, pancreatic damage, and death in sheep, provided the material is administered with a drenching gun. The same dose administered by ruminal intubation is nontoxic, because the zinc triggers a closure of the reticular groove, resulting in its immediate deposition in the abomasum.

### Farm Risk Factors

Industry-related zinc dust settling on crops and pastures is a hazard; dose rates up to 45 mg/kg BW have no effect on cattle, 50 mg/kg is associated with anemia, and daily dose rates of 110 mg/kg BW are associated with deaths.

An outbreak of poisoning occurred in pigs fed buttermilk from a dairy factory. The buttermilk was piped to the pig pens each day through a long galvanized iron pipe. The buttermilk sat in pools in the pipe after each batch was run through; souring occurred, and the lactic acid produced was associated with the formation of zinc lactate, which was passed to the pigs in the next batch of buttermilk. The concentration of zinc in the milk (0.066%) was slightly higher than the minimum toxic strength (0.05%).

### Transmission

Common sources of zinc include:

- Zinc released from galvanized surfaces in the following circumstances:
  - When subjected to electrolysis when galvanized and copper pipes are joined
  - Galvanized bins flake zinc when used for storage of pig swill.
- Zinc chromate used as a paste in joining electrical cables
- Fumes from a nearby galvanizing factory
- Zinc, often associated with cadmium, is a common pollutant from industrial plants handling a variety of ores; nearby pasture may contain more than 500 mg/kg of zinc.
- Zinc-based paints, with a 50% to 55% zinc content when cattle lick freshly painted ironwork

- Zinc added to calf-grower rations as a nonspecific dietary supplement
- Accidental inclusion of zinc oxide in a prepared dairy cow ration

## PATHOGENESIS

Ingested zinc is absorbed primarily from the proximal small intestine, and approximately one-third of absorbed zinc is protein bound in the plasma. Phytic acid content of plant proteins interferes with absorption of zinc in monogastric diets. Other nutrients or elements that reduce zinc absorption include calcium, cadmium, and copper. Once absorbed, zinc accumulates rapidly in liver and pancreas, with slower accumulation in muscle and bone. Excretion is primarily in feces contributed from bile and from secretion via intestinal mucosa and bile.

The pathogenesis of zinc poisoning has not been determined, but it is likely that the arthritic lesions observed will be a result of faulty calcium absorption. The lesion in equines may be related to interactions of zinc and copper with interference in collagen metabolism. The development of anemia in some animals is poorly understood, but it may be a result of interactions of zinc, copper, and calcium.

## CLINICAL FINDINGS

### Acute Poisoning

#### Cattle

Large doses are associated with light-green-colored diarrhea and drastic reduction in milk yield. Severe cases show additional signs, including somnolence and paresis.

#### Pigs

Large doses are associated with decreased food intake, arthritis, hemorrhages in the axillae, gastritis, and enteritis. Death may occur within 21 days.

### Chronic Poisoning

#### Dairy Cattle

Dairy cattle show chronic constipation and a fall in milk yield. Other reported signs include inappetence, loss of condition, diarrhea with dehydration or subcutaneous edema, profound weakness, and jaundice.<sup>4</sup>

#### Pigs

Pigs fed buttermilk containing zinc show anorexia; lethargy; unthriftiness; rough coat; subcutaneous hematomas; stiffness; lameness, progressive weakness with enlargement of the joints, particularly the shoulder joint; and, finally, recumbency.

#### Horses

Chronic poisoning is associated with a nonspecific, degenerative arthritis, especially at the distal end of the tibia. The lesion is accompanied by an effusion into the joint capsule and the obvious enlargement of the hock joint. There may also be a generalized osteoporosis, lameness, and ill-thrift.

Affected foals may be reluctant to rise and have a joint effusion with a stiff gait.

Zinc fed experimentally to foals is associated with pharyngeal and laryngeal paralysis, stiffness, and lameness resulting from swelling of the epiphyses of long bones.

## CLINICAL PATHOLOGY

After experimental feeding, elevated levels of zinc are detectable in tissues, especially the liver, pancreas, and kidney, and liver (and serum) levels of copper are reduced. Serum zinc levels in affected cattle may be as high as 500 µg/mL, in contrast with the normal levels of about 140 µg/mL in normal cattle. Estimated as zinc protoporphyrin, the levels in poisoned donkeys and mules reach 900 to 1900 µg/mL. Fecal levels of zinc are likely to be elevated from an average of 220 mg/kg in normal animals to 8740 mg/kg in affected ones.

## NECROPSY FINDINGS

Severe, acute poisoning in sheep is associated with an abomasitis and duodenitis, in which the mucosa may appear green in color. In survivors, a severe, fibrosing pancreatitis may develop.

Acute poisoning in cattle has been accompanied by generalized pulmonary emphysema, a pale flabby myocardium, renal hemorrhages, and severe hepatic degeneration. Chronic poisoning in this species may result in lesions in many organs but the **most consistent damage** is in the pancreas. Atrophy of exocrine pancreatic acini with extensive interstitial fibrosis have also been described in piglets receiving a total parenteral nutrition diet.

In chronic zinc poisoning in pigs there is a nonspecific, degenerative arthritis affecting particularly the head of the humerus, with the articular cartilage being separated from the underlying osteoporotic bone. In foals, similar joint lesions and nephrosclerosis may be seen.

The hepatic zinc content in normal animals is high (30 to 150 mg/kg wet matter in calves) and may reach levels of 400 to 600 mg/kg wet matter after continued ingestion of zinc chromate paste without being accompanied by signs of zinc poisoning. In acute poisoning by zinc oxide in cattle, levels of 2000 mg/kg dry matter in the liver and 300 to 700 mg/kg dry matter in the kidney may be achieved; tissue copper levels in these animals may be reduced to 10 to 20 mg/kg. Tissue levels in calves dying of experimental zinc poisoning are much lower: 200 to 400 mg/kg.

## Samples for Confirmation of Diagnosis

- **Toxicology**—50 g liver, kidney; 500 g suspect feed or ingesta (ASSAY [Zn])
- **Histology**—formalin-fixed pancreas (light microscopy)

## Tissue Assay

The zinc Content of liver in normal animals is high (30 to 150 mg/kg wet matter in calves) and may reach levels of 400 to 600 mg/kg wet matter after continued ingestion of zinc chromate paste without being accompanied by signs of zinc poisoning. In acute poisoning by zinc oxide in cattle, levels of 2000 mg/kg dry matter in the liver and 300 to 700 mg/kg dry matter in the kidney may be achieved; tissue copper levels in these animals may be reduced to 10 to 20 mg/kg. Tissue levels in calves dying of experimental zinc poisoning are much lower at 200 to 400 mg/kg.

Diagnostic confirmation of zinc poisoning depends on identification of elevated levels of zinc in fluids or tissues.

## DIFFERENTIAL DIAGNOSIS

### Differential diagnosis list:

- Erysipelas
- Lead toxicosis
- Naphthalene toxicosis
- Osteochondrosis/degenerative joint disease
- Rickets limited in occurrence to young pigs

## TREATMENT

Removal of the source and supportive care are the most effective means of treatment. In foals, serum copper concentrations should be evaluated because copper may need to be added to the diet. Chelating agents, especially calcium disodium EDTA, have been used successfully in small animals and human beings.<sup>5</sup>

## CONTROL

Galvanized utensils and piping should be rinsed after each use in carrying milk. The addition of extra amounts of calcium to the diet of pigs is capable of preventing the toxic effects of zinc if the calcium supplementation is heavy and the zinc intake is not too high.

## DIITERPENOID ALKALOID TOXICOSIS

### SYNOPSIS

**Etiology** Toxic plants in *Aconitum* spp. (monkshood), *Delphinium* spp. (larkspur), and *Erythrophleum* spp. (Cooktown ironwood). Toxins include aconitine, MSAL-type alkaloids (methyllycaconitine [MLA], nudicauline [NUD], 14-deacetylnudicauline [DAN], and MDL-type alkaloids (deltaline, 14-O-acetyl dictyocarpine [14-OAD]).

**Epidemiology** *Aconitum* spp. are present in North America and Europe. Toxic *Delphinium* spp. are rangeland plants found throughout the western United States. *Erythrophleum* spp. are trees in northern Australia, Asia, Africa. Poisoning is most often in cattle, but all species may be affected.

**Clinical pathology** Toxic alkaloids in blood, urine, or ingesta.

**Lesions** Nonspecific.

**Diagnostic confirmation** Toxic alkaloids in blood, urine, ingesta, tissues, or plant.

**Treatment** Physostigmine/neostigmine (*Delphinium* spp.). Supportive care.

**Control** Avoid all consumption of *Aconitum* spp. or *Erythrophleum* spp. plants. Graze cattle before or after "toxic window" for *Delphinium* spp.

### ETIOLOGY

Diterpenoid alkaloids occur in *Delphinium* spp. (larkspur), *Erythrophleum* spp., and *Aconitum* spp. and are associated with poisoning in grazing animals. Diterpenoid alkaloids in toxic larkspur are divided into three different groups: norditerpenoid alkaloids, C-20 diterpenoid alkaloids, and bis-diterpenoid alkaloids.<sup>1,2</sup> Of these, norditerpenoid alkaloids are the most toxic, and they are further divided into two primary groups: MSAL-type norditerpenoid alkaloids (important toxins include methyllycaconitine [MLA], nudicauline [NUD], 14-deacetylnudicauline [DAN]) and MDL-type norditerpenoid alkaloids (important toxins include deltaline, 14-O-acetyl dictyocarpine [14-OAD]).<sup>2,3</sup> At least 18 different toxic alkaloids are produced by poisonous species of larkspur.<sup>4</sup> Methyllycaconitine and deltaline are present in many toxic larkspurs. MSAL type alkaloids are approximately 20 times as toxic as the MDL type,<sup>5</sup> but MDL types are more abundant and may potentiate the toxicity of MSAL-type alkaloids.<sup>4</sup> Plants in the *Erythrophleum* spp. contain a number of different toxic alkaloids;

among them are diterpene ester alkaloids. Aconitine is the toxin found in monkshood or wolfsbane (*Aconitum napellus*).<sup>6,7</sup>

There are over 100 species of these plants, but a full alkaloid content profile has been completed in only a few. Larkspur is often divided into low, tall, and plains larkspur based on their mature height and geographic distribution. The species known to contain toxic diterpenoid alkaloids and to be associated with disease in livestock are as follows:

- *Aconitum napellus* (monkshood, wolfsbane)
- *Delphinium andersonii* (low; Anderson's larkspur)
- *D. barbeyi* (tall; subalpine larkspur)
- *D. bicolor* (low; little larkspur)
- *D. geyeri* (plains; Geyer's larkspur)
- *D. glaucescens* (tall; smooth larkspur)
- *D. glaucum* (tall; sierra larkspur)
- *D. nuttallianum* (low; twolobe larkspur)
- *D. occidentale* tall; duncecap or subalpine larkspur)
- *Erythrophleum* spp., e.g. *E. chlorostachys* (Cooktown ironwood)

Some of the species assumed to contain the alkaloids because of their known association with the disease are as follows:

- *Delphinium ajacis*
- *D. consolida*
- *D. elatum*
- *D. hybridum*
- *D. nelsonii*
- *D. parryi*
- *D. ramosum*
- *D. robustum*
- *D. tricornis*
- *D. trollifolium*
- *D. virescens*

### EPIDEMIOLOGY

#### Occurrence

North America, especially the western United States, and Europe are the principal locations of *Delphinium* spp. and *Aconitum* spp. poisonings. Rangeland larkspurs (*Delphinium* spp.) are important pasture plants in North America, and many of them are associated with heavy losses (2% to 15%) in grazing livestock.<sup>4</sup> The incidence of poisoning varies widely with season and climate because of variations in the concentration and chemical composition of specific alkaloids in the specific larkspur plants. Plants in the *Erythrophleum* spp. are found in Africa, Asia, and northern Australia and have been associated with death in cattle and horses.<sup>8</sup> *Aconitum* spp. grow in the United States and Europe, but poisoning rarely occurs in large animals.

#### Risk Factors

##### Animal Risk Factors

All animal species are susceptible, but most cases are seen in cattle, less often in sheep, and rarely in horses. Sheep are 5 times less susceptible than cattle, and little is reported

about horses.<sup>9</sup> The rate of consumption and amount consumed are known risk factors for grazing cattle. The toxicity of tall larkspur is seasonal, being much more toxic early in the season and less so as it matures.<sup>3</sup> A "toxic window" has been established for grazing cattle that begins just before the flowering stage and ends with shattering of the pod.<sup>4</sup> During this time period, grazing cattle are at the highest risk for developing toxicosis.

### PATHOGENESIS

The principal action of diterpenoid alkaloids is neuromuscular paralysis secondary to blockade at the postsynaptic neuromuscular junction.<sup>3,4</sup> The toxins are competitive postsynaptic inhibitors of acetylcholine; MLA is a potent competitive blocker at nicotinic acetylcholine receptors (nAChRs) in the striated muscles and autonomic nervous system.<sup>3</sup> Interference with the other parts of the neuromuscular arc is also possible. Signs peak 18 to 24 hours after first ingestion, but the effects may be cumulative.<sup>10,11</sup> The signs in the herd disappear 6 to 7 days after the plant is withdrawn from the diet.<sup>10,11</sup>

Aconitine and other alkaloids present in *Aconitum* spp. are potent neurotoxins and cardiotoxins with actions on cell-membrane voltage-sensitive sodium channels.<sup>7</sup> Nerves, muscles, and myocardium are affected, becoming refractory to excitation. The alkaloids in *Erythrophleum chlorostachys* have a cardiac glycoside-like action.

### CLINICAL FINDINGS

Clinical signs in terminally poisoned cattle include tachycardia, muscle weakness, tremors, sternal recumbency leading to lateral recumbency, and death.<sup>3,4</sup> Other signs include constipation, bloating, and dyspnea.<sup>4</sup> Many animals are simply found dead. Those animals ingesting lower amounts may show dyspnea, an irregular heart rate, and collapse, but not death.

Diarrhea is reported in *Aconitum* spp. poisoning, possibly as a result of the presence of additional toxins. In large ingestions, rapid death from paralytic respiratory failure or ventricular arrhythmias may occur.<sup>7</sup> Aspiration of ruminal contents after regurgitation also causes some deaths. In the terminal stages, the pupils are dilated, and the pulse and respiration may be barely perceptible. Some animals are found dead without evidence of clinical signs.

*Erythrophleum chlorostachys* (ironwood) and *E. guineense* are both poisonous to all animal species. Clinical signs include anorexia, a staring expression, partial blindness, tremor, ataxia, contraction of abdominal muscle, increased heart sounds, mucosal pallor, and terminal dyspnea. Horses poisoned by *E. chlorostachys* have loud and often irregular heart sounds, dyspnea, and sporadic contraction of abdominal muscles, and they die rapidly.

## CLINICAL PATHOLOGY

There are no specific findings other than identification of toxic alkaloids in blood, urine, ingesta, and tissues.

## NECROPSY FINDINGS

There are no specific postmortem lesions. Aspiration pneumonia may be an incidental finding in some cases.

Diagnostic confirmation of larkspur poisoning depends on chemical identification of the causative alkaloids in the blood, urine, rumen contents, or plants. Normal and reverse-phase high-performance liquid chromatography (HPLC) has been used to successfully identify toxic alkaloids in several *Delphinium* spp.<sup>12</sup> Aconitine has been confirmed in urine and blood using liquid-chromatography tandem mass spectrometry (LC-MS/MS).<sup>13</sup>

### DIFFERENTIAL DIAGNOSIS

Differentiation from other plant poisonings causing incoordination, recumbency, and death in cattle on extensive grazing is usually based on botanical identifications.

#### Differential diagnosis list:

- *Clavibacter toxicus* (tunicamyluracil poisoning)
- Lead poisoning
- Organophosphorus compounds.
- *Paspalum* spp., infested with *Claviceps paspali* (paspalitreum poisoning)
- *Phalaris* spp. (tyramine poisoning)

## TREATMENT

### TREATMENT AND CONTROL

Physostigmine (0.04–0.08 mg/kg BW IV, repeat prn) (R-2)

Neostigmine (0.02–0.04 mg/kg BW, IM or IV, repeat prn) (R-2)

Physostigmine and neostigmine have been used as effective antidotes for *Delphinium* spp. poisoning, but they may have limited practical value in a herd situation. Physostigmine, a cholinergic drug, given IV at 0.08 mg/kg BW, has been used successfully in experimental and field conditions;<sup>4</sup> alternate dosages in recumbent cattle include IV, SC, or IP administration at 0.04 to 0.08 mg/kg BW.<sup>14,15</sup> Intravenous neostigmine (0.04 mg/kg BW) has reversed clinical signs in cattle,<sup>14</sup> and IM administration at 0.02 mg/kg BW has been used in cattle as a “rescue” drug.<sup>3,4</sup> Neostigmine may be more effective in reversing tachycardia and physostigmine in reversing muscle weakness.<sup>14</sup> The duration of action is less than 2 hours, and repeat doses will need to be administered.

No specific treatment has been identified for *Aconitum* spp. or *Erythrophleum* spp. poisoning. Treatment is supportive, with

particular attention paid to the cardiovascular and respiratory systems.

## CONTROL

Control of *Delphinium* spp. poisoning is only possible by careful management of pasture and preventing access to heavily infested areas. Prevention of grazing during the “toxic window” decreases toxicity, but the quality of the forage declines substantially.<sup>4</sup> Sheep are more resistant to the poisoning than cattle, but they are fond of the plant and may have to be restricted to areas where it does not occur.<sup>9</sup> Attempts to create and maintain a long-standing aversion to the plants to prevent ingestion of them and allow grazing of infested pastures have not always been successful.<sup>4,16</sup> Herbicides may be effective in reducing heavy growths of larkspur, but application timing is critical to success, and some herbicides may actually make plants more palatable.<sup>4</sup>

## ERGOT ALKALOID TOXICOSIS

Ergot alkaloids are mycotoxins produced by fungi found primarily in the *Claviceps* and *Neotyphodium* genus.<sup>1,2</sup> The presence of rich, fertile soil in addition to warm temperatures, elevated humidity, and high rainfall increase the production of ergot alkaloids. Many of the fungi occur naturally in plants and produce similar clinical syndromes, however, their presence in a feedstuff does not necessarily indicate toxicity. Rather, determination of the specific ergot alkaloid should be pursued.

Ergot alkaloids in the genus *Claviceps* produce external spores, infecting the flowers of grasses and cereal grains such as rye, barley, wheat, millet, and oats, and ultimately forming an ergot alkaloid packed sclerotium.<sup>2</sup> The sclerotia in cereal grains are generally large and easily visible; those in grass seeds often quite small and difficult to see. Several fungi in the *Neotyphodium*, *Balansia*, and *Epichloe* genera found in grasses produce ergot alkaloids.<sup>1</sup> These endophytic fungi do not sporulate and grow within plants in a variety of symbiotic relationships ranging from antagonistic (*Epichloe*) to mutualistic (*Neotyphodium*).<sup>1</sup>

The individual toxins, and the plants they parasitize, are only partially identified. A list of the fungi, the toxins they contain and the syndromes attributed to them is as follows:

- *Claviceps africana*<sup>3,4</sup>—sorghum ergot; contains dihydroergosine (DHES) and related alkaloids; agalactia, hyperthermia, decreased production
- *C. cinerea*—gait incoordination
- *C. cynodontis*<sup>5</sup>—paspalitreum B, ergonovine, ergine; muscle tremors
- *C. cyperi*—ergocryptine; hyperthermia and decreased milk production
- *C. fusiformis*—agalactia
- *C. paspali*<sup>6</sup>—paspalitreum A, paspalitreum B, paspalitreum C, paspalinine; gait incoordination, muscle tremors
- *C. purpurea*<sup>1,2</sup>—ergometrine, ergotamine, ergocornine, ergocristine, ergosine, ergocryptine; peripheral gangrene, hyperthermia and decreased production, reproductive failure, rare nervous signs
- *C. sorghi*<sup>7</sup>—sorghum ergot
- *C. sorghicola*<sup>7</sup>—sorghum ergot
- *Balansia epichloe*—gait incoordination, peripheral gangrene
- *Neotyphodium* spp.<sup>1,2</sup>—ergonovine and lysergic acid amide; gait incoordination
- *Neotyphodium (Acremonium) coenophialum*<sup>1,2</sup>—ergopeptine alkaloids, ergovaline, ergotamine; hyperthermia, milk yield drop, peripheral gangrene

## ERGOTISM

Alkaloids produced by fungi in the *Claviceps* genus are generally referred to as ergots, and ergotism is loosely defined as the toxicity or physical manifestations that occur when a toxic amount of ergot is ingested.<sup>2</sup> *Claviceps purpurea*, with an ability to infect over 600 plants worldwide,<sup>1</sup> is often used to describe the clinical syndromes associated with ergotism.

### SYNOPSIS

**Etiology** Ingestion of large quantities of cereal grains or grasses containing ergots produced by *Claviceps purpurea*.

**Epidemiology** Warmth, high humidity, fertile soil; worldwide distribution in temperate climates.

**Clinical pathology** No specific abnormalities.

**Lesions** Gangrene of the extremities; hyperthermia in cattle; reproductive issues (abortion, poor mammary development, early neonatal deaths in mares and sows), poorly documented nervous syndrome.

**Diagnosis confirmation** Assay for specific ergot alkaloid in feed and/or body tissues.

**Treatment** Remove from source.

**Control** Avoid exposure or dilute feed with nontoxic material.

## ETIOLOGY

*Claviceps purpurea* is a fungus that under natural conditions infects rye and triticale and, less commonly, other cereals and many grasses, including the rye grasses, tall fescue grass, *Phleum pratense* (timothy, cocksfoot, Yorkshire fog), *Cynosurus cristatus* (crested dogtail, tall oat grasses, the brome grasses), *Brachiaria decumbens*, *Brachiaria humidicola*, and *Pennisetum typhoides* (bulrush millet). Ingestion of large quantities of seed heads infested with the fungal sclerotia is associated with ergotism in cattle, sheep, pigs, horses, dogs, and birds.

There is some evidence that corn smut may have pharmacologic activity similar to that of *C. purpurea*. *Claviceps cynocontis* infected *Cynodon dactylon* (Bermuda or couch grass, “kweek”) may be related to the tremor syndrome that occurs occasionally in cattle grazing this grass.<sup>5</sup>

## EPIDEMIOLOGY

*Claviceps purpurea* is widespread in distribution, but it is seldom ingested in large enough amounts during its toxic stage to be associated with poisoning. Poisoning is most likely to occur during or after a warm, wet season, which favors the growth of the fungus. Ergotism occurs commonly in cattle and usually in stall-fed animals feeding on heavily contaminated grain over

a considerable period of time. Other species are not usually exposed to the infected grain.

Ergot-infected pasture may be associated with the clinical syndrome, and the toxicity is preserved through the ensiling process. Cows may show early signs of lameness in as short a period as 10 days after going onto an infected pasture, but most animals do not become affected until 2 to 4 weeks after exposure. Peripheral gangrene occurs in the cooler months; hyperthermia in warmer weather.

## PATHOGENESIS

The ergots contain a number of alkaloids and amines with pharmacologic activity, and these vary in concentration with the maturity of the ergot. Clavine alkaloids, lysergic acid and lysergic acid derivatives (e.g., ergometrine or ergonovine), ergopeptine alkaloids (e.g., ergotamine, ergocornine), and lactam ergot alkaloids (e.g., ergocristine) are the four main groups of naturally occurring ergot alkaloids.<sup>1,2</sup> Ergometrine, ergotamine, ergocornine, ergocristine, ergosine, and ergocryptine are the most common alkaloids produced by *Claviceps purpurea*.<sup>1,2</sup> Structurally, the ergot alkaloids are similar to serotonin, dopamine, norepinephrine, and epinephrine, and they are able to bind to biogenic amine receptors and elicit an effect.<sup>1</sup> The pharmacologically active compounds in the group stimulate (constrict) the smooth muscle of arterioles, intestines, and the uterus and decrease serum prolactin. The peptide alkaloids of ergot, particularly ergotamine, are associated with arteriolar spasm and capillary endothelial damage, with restriction of the circulation and gangrene of the extremities, when small amounts are ingested over long periods.

## CLINICAL FINDINGS

Four different clinical syndromes have been described. Classical ergotism is characterized by gangrene of the extremities, the hyperthermic syndrome results in elevated body temperatures and decreased production, and the reproductive syndrome presents with agalactia, lack of mammary gland development, low birth weight, and stillborn animals.<sup>1,9</sup> In spite of the known abortifacient action of *Claviceps purpurea*, abortion does not usually occur in poisoned animals. The fourth syndrome is a rare, ill-defined nervous form that may be associated with a single, acute ingestion of large amounts of sclerotia.

### Peripheral Gangrene (Classical Ergotism)

The extremities, particularly the lower part of the hindlimbs, tail, and ears, are affected. There is reddening, swelling, coldness, loss of hair or wool, and lack of sensation of the parts initially, followed by the development of a blue–black color and dryness of the skin.

Gangrene usually affects all local tissues, and after the lapse of some days, the affected part becomes obviously separated and may eventually slough. The lesions are not painful, but some lameness is evident even in the early stages, and the animal may remain recumbent most of the time. Severe diarrhea is often an accompanying sign. In sheep, gangrene of the limbs does not occur under experimental conditions, but there is ulceration and necrosis on the tongue and mucosa of the pharynx, rumen, abomasum, and small intestine.

The experimental feeding of ergots (1%–2% of ration) is associated with severe reduction in feed intake and growth rate in young pigs without producing overt signs of ergotism.

### Hyperthermia Form

Affected cows have temperatures of 41° to 42° C (105–107° F), dyspnea, and hypersalivation. Milk production and growth rate are depressed, and morbidity is about 100%. The syndrome occurs in hot weather conditions when affected animals seek water or shade, but exposure to sunlight under normal conditions of air temperature and humidity can be enough to be associated with clinical signs. Affected animals stressed by exercise in ambient temperatures over 30° C (86° F) commonly die. Long-term, low-level feeding of ergot to fattening beef cattle can result in reduced feed intake and weight gain, increased water intake and urination, failure to shed winter coat, and increased susceptibility to heat stress.

### Reproductive Form

The manifestation varies depending on the species. Although rare in cattle, a brief exposure to a heavily ergotized pasture caused abortion in late pregnant cows. It also occurs as a single outbreak of agalactia, lack of mammary gland development, abortions, prolonged gestations, and early foal deaths in mares fed oats containing *Lolium multiflorum* seeds heavily infested with *C. purpurea*. In sheep, the feeding of ergot reduces the chance of fetal survival, and thus relative infertility occurs, and feeding pregnant ewes on ergotized grain is not recommended.

In pigs, ergotism is manifested by lack of udder development and agalactia in sows, and the birth of small pigs that suffer a heavy neonatal mortality. Some of the piglets survive and subsequently suffer gangrene of the ear edges and tail tip. In sows, the chronic feeding of *C. purpurea* may not disturb existing pregnancies, but premature births, mummified fetuses, and low litter size are recorded. Levels up to 0.2% in the diet appear to be safe. A specific ergot, *Claviceps fusiformis*, which grows on *Pennisetum typhoides* (bulrush millet), is known to be associated with agalactia in sows in Zimbabwe. *Claviceps africana*, the ergot of

sorghum, has been associated with agalactia in sows and perinatal mortality of piglets in Australia.

## CLINICAL PATHOLOGY

There are no specific abnormalities. Samples of fungus-infested material, either animal tissues or feed, may be submitted for assay. High-performance liquid chromatography (HPLC) and liquid chromatography/mass spectrometry (LC/MS) techniques can be used to identify the presence of many ergot alkaloids.<sup>1,2,10</sup>

## NECROPSY FINDINGS

In cattle, gangrene of the extremities is the principal gross lesion. There may be evidence of congestion, arteriolar spasm, and capillary endothelial degeneration in the vicinity of the gross lesions and in the central nervous system. Ulceration and necrosis of the oral, pharyngeal, ruminal, and intestinal mucosae are recorded in sheep.

Diagnosis confirmation depends on a positive assay of ergot alkaloids in feed or tissues.

## DIFFERENTIAL DIAGNOSIS

### Differential diagnosis list:

- Classical ergotism
- Poisoning by *Neotyphodium coenophialum*
- Arterial thrombosis and embolism
- Trauma causing obstruction of circulation to the part
- Bacteremia (e.g., in salmonellosis)
- Hyperthermia/poor production
- Heat stroke
- Water deprivation

## TREATMENT

The infected grain should be withdrawn from the ration immediately. Further treatment is not usually attempted, although vasodilator drugs may have some beneficial effect.

## CONTROL

Heavily ergotized grain or pasture fields containing ergotized grasses should not be used for animal feeding. They may be grazed if they are first mowed with the mower blade set high to remove the seed heads. Feed should not contain more than 0.1% of ergot-infested heads. It is best not to feed ergot-infested feed to pregnant females.

## NEOTYPHODIUM (ACREMONIUM) SPP. TOXICOSIS

Infestation of the grasses *Achnatherum inebrians* (drunken horse grass) in China and *Stipa robusta* (sleepy grass) in North America by endophytes is associated with a syndrome of incoordination in horses and sheep grazing on the grass. Identification of the fungi is not complete but they contain ergonovine and lysergic acid amide. Low levels of

paxillene and lolitrem B (indo-terpenoids) are also present.

## FESCUE TOXICOSIS

### CLINICAL FINDINGS

Four clinical syndromes are associated with ingestion of *Neotyphodium (Acremonium) coenophialum*, an endophyte present in the tissues of the tall fescue grass *Lolium arundinaceum* (formerly *Festuca arundinacea*). The toxic hyphae are invisible without microscopy and produce no fruiting bodies. There is no visible effect on the growth of the grass, and spread of the endophyte is via infected seeds.<sup>1</sup> The fungus produces ergopeptine alkaloids, principally ergovaline, and many other pharmacologically active compounds, including peramine and ergine (lysergic acid amine). There is a great deal of variation in the toxicity of different varieties of the tall fescue grass: KY-31 is most toxic; Kenhy, Mo-96, and Kenmont are intermediate; and Fawn is least toxic.

Several clinical syndromes are associated with ingestion of pasture grass or hay made from infected tall fescue grass. In cattle and sheep, fescue summer toxicosis, fescue foot, and fat necrosis are reported; in mares, reproductive abnormalities occur most often.<sup>1</sup> All of these syndromes could theoretically occur on the same pasture, but summer toxicosis occurs only in the summer and fescue foot in the winter.

In Australia, horses grazing on a pasture seeded with novel Mediterranean (Max P or Max Q) fescue varieties known not produce ergovaline developed a fescue-associated edema syndrome.<sup>11</sup> Clinical signs included depression, inappetence, and dependent subcutaneous edema affecting the head, neck, chest, and abdomen. Analysis of the serum showed a low total protein, in particular a low albumin concentration.<sup>11</sup> Ruminants grazed on the same pasture were unaffected. It was proposed that *N*-acetyl norlooline, a pyrrolizidine alkaloid produced by the Max P endophyte, was responsible for the clinical signs.

### Fescue Summer Toxicosis (Summer Slump, Epidemic Hyperthermia)

Fescue summer toxicosis has caused significant economic losses in the US, New Zealand, and Australia dairy industries because of the high rate of use of tall fescue as a pasture grass. It is also the most common of the clinical syndromes associated with fescue toxicosis.<sup>1,12</sup>

The syndrome occurs in cattle at pasture in the summer and consists of a period of poor production manifested by a fall in milk production or a failure to grow adequately in fat cattle, both in the presence of what appears to be an optimum amount of nutritious pasture. The same poor weight gain is experienced by steers fed on fescue seed and in sheep. In cattle grazing at pasture the

depressing effect on production is made worse by environmental temperatures above 31°C (87°F). Affected cattle show hyperthermia with temperatures as high as 40.5°C (104.5°F), dyspnea, hypersalivation, inappetence, and rough coat, and they may compulsively seek out water or tree shade in which to stand. Hyperthermia may not recede until about 6 weeks after the cattle are moved from the pasture.

The mycotoxin responsible is ergovaline, an ergopeptide similar to, but more powerful than, ergotamine. The lowered milk yield is accompanied by low blood levels of prolactin, resulting in an indifferent prolactin surge when the premilking stimuli are applied. Prolactin levels may be significantly increased by the administration of metoclopramide, a dopamine antagonist, but side effects and cost may preclude use.

### Fescue Foot

Fescue foot occurs in cattle grazing pasture dominated by tall fescue, usually within 10 to 14 days of being turned onto the pasture during cold weather. Cattle permanently pastured on the field do not appear to be affected, and horses seem to be able to graze with impunity. The lesions and clinical signs include severe lameness followed in 2 or more weeks by gangrene and sloughing of the extremities, especially the digits and, to a lesser extent, the tail. The incidence in a herd may be as high as 10%. The lesions are associated with the vasoconstrictive agent ergovaline produced by *N. coenophialum*. In freezing temperatures, frostbite may be a complicating factor. New cases may continue to appear for up to 1 week after removal from the affected pasture. Broad-spectrum antibiotics may be useful early in the syndrome to prevent secondary infections.

There is a close similarity to the disease associated with the ingestion of *Claviceps purpurea*, and *Claviceps* ergot alkaloids are also present in fescue; thus identifying the specific cause of gangrene of the extremities may not be possible. Grass heads are commonly infested by *C. purpurea*, but the disease occurs in their absence.

### Fat Necrosis (Lipomatosis)

Abdominal fat stores in cattle are affected in the syndrome of fat necrosis. Clinical signs vary depending on the location of fat, but in general fat stores become hardened and necrotic. Dystocia may result if this occurs in the pelvic canal. Necrotic fat in the mesentery may cause an obstruction or bloat. Generally, the presence of fat necrosis is an incidental finding at postmortem.

### Reproductive Abnormalities in Mares

Pregnant mares grazing on pastures infected with *Neotyphodium (Acremonium) coenophialum* can experience a much higher incidence of dystocia, prolonged gestation,

low foal survival, small udder development, and poor milk yield compared with mares on unaffected pastures.<sup>8</sup> “Fescue” foals may be small and dysmature or large and overly mature. The delivery of an overly mature foal may result in dystocia or the birth of a “red bag” foal. This occurs when a prematurely detached chorioallantois enters the birth canal before the foal.<sup>8</sup> Prolongation of luteal function, an increase in cycles bred per pregnancy rate, and early embryonic death significantly reduce reproductive efficiency. Pregnant mares are most susceptible to toxicity after day 300 of gestation and should be removed from infected pasture before that time.

Domperidone, a D-2 dopamine antagonist, is an FDA-approved drug marketed for the prevention of fescue toxicosis in mares.<sup>8,13</sup> The drug is best used for those mares that cannot be removed from infected pasture. A dosage of 1.1 mg/kg BW/day is recommended, but it should be given no sooner than 15 days before the expected foaling date.<sup>13</sup> If the mare is agalactic after foaling, domperidone may be administered at the same dosage rate for an additional 5 days.<sup>13</sup>

## CONTROL

Planting endophyte-resistant varieties of tall fescue, rotating cattle through fescue and other grass and clover varieties, and diluting infected hay with nonfescue varieties are among the most effective means of control. Newer, novel endophyte-infected varieties of fescue should be planted with caution until complete information is available.<sup>11</sup> Ammonization of the affected hay will degrade ergovaline so it is safe to feed, but the procedure is expensive, labor intensive, and time consuming. Cattle on summer pastures with fescue-infected hay should have adequate shade and access to water; those on similar pasture in cooler weather should have shelter or windbreaks. If possible, mares should be removed from fescue-infected hay or pasture before 300 days of gestation; if this is not possible, domperidone should be administered as described previously.

## FUMONISIN TOXICOSIS

### SYNOPSIS

**Etiology** Corn or corn products contaminated with fumonisins B<sub>1</sub> (FB<sub>1</sub>) and B<sub>2</sub> (FB<sub>2</sub>).

**Epidemiology** Sporadic occurrences worldwide in those countries where corn is grown. Equine leukoencephalomalacia (ELEM) and porcine pulmonary edema (PPE) are the two most widely recognized syndromes.

**Clinical pathology** Nonspecific increases in hepatic enzyme activities; increased serum or tissue concentrations of sphinganine (Sa) and sphingosine (So) and increase in Sa:So ratio.

**Lesions** ELEM: Fatal neurologic or hepatic syndrome; PPE: pulmonary edema, left-sided heart failure, hepatic syndrome.

**Diagnostic confirmation** Presence of FB<sub>1</sub> or FB<sub>2</sub> in corn or corn product.

**Treatment** None.

**Control** Remove animals from source, test corn or corn product; feed contaminated product to slaughter cattle.

## ETIOLOGY

Fumonisin B<sub>1</sub> and B<sub>2</sub> are mycotoxins produced by *Fusarium verticillioides* (synonym *F. moniliforme*, *Gibberella fujikuroi*) and *F. proliferatum* growing on moldy corn (maize) grain.<sup>1,2,3</sup> More than 25 fumonisins have been isolated and grouped (A, B, C, and P); however, the most important and well studied is fumonisin B<sub>1</sub> (FB<sub>1</sub>).<sup>4,5,6</sup> Fumonisin B<sub>2</sub> (FB<sub>2</sub>) and B<sub>3</sub> (FB<sub>3</sub>) occur in lower concentrations than FB<sub>1</sub> and don't appear to play an important role in the development of toxicity.<sup>4</sup> *Aspergillus niger* and other species of *Fusarium* also produce fumonisins;<sup>4,5</sup> there is some controversy as to whether *Alternaria alternata* f. sp. *lycopersici* produces fumonisins.<sup>5</sup>

## EPIDEMIOLOGY

Equine leukoencephalomalacia (ELEM) and porcine pulmonary edema (PPE) are the two most widely recognized syndromes associated with ingestion of FB<sub>1</sub> and FB<sub>2</sub> in corn.<sup>1,2,7</sup> Of the known toxic fumonisins, FB<sub>1</sub> is the most common cause of animal disease and is a known carcinogen in humans (esophagus) and rats (liver).<sup>4,5</sup>

## Occurrence

Outbreaks of ELEM and PPE associated with fumonisin-contaminated corn have occurred worldwide.<sup>4,8,9</sup> Historically, there have been reports of poisoning associated with FB<sub>1</sub>- and FB<sub>2</sub>-contaminated oats and New Zealand forage grass,<sup>3</sup> but the majority of problems occur with contaminated corn and corn products.<sup>1-3</sup>

## Risk Factors

### Animal Risk Factors

Horses and pigs are much more susceptible to the poisoning than cattle and poultry.<sup>1,7,10</sup> The recommended concentration of fumonisins in animal feed varies depending on the species; both the U.S. FDA and the European Union Commission have published guidelines.<sup>1,7</sup> In the United States, the total fumonisins (FB<sub>1</sub>, FB<sub>2</sub>, and FB<sub>3</sub>) present in maize or maize by-product in formulated feed should not exceed 5 ppm for horses.<sup>1,7</sup> Fumonisin are not excreted in the milk of cows or sows ingesting the toxin, so nursing animals should not be at risk for development of toxicity.<sup>1</sup>

### Environmental Risk Factors

The fungus is commonly found growing on moldy corn (maize) grain that has been affected by rain while on the stalk or stored wet. All forms of corn, including pelleted feeds, are susceptible to contamination, and visible mold may not necessarily be present on the corn. Infection by *F. verticillioides* may occur more often when a drought is followed by cool, damp weather during the pollination period.<sup>9</sup>

## PATHOGENESIS

The mechanism of action has not been clearly defined but may be related to interruption in sphingolipid metabolism.<sup>1,8</sup> The molecular structure of FB<sub>1</sub> and FB<sub>2</sub> is very close to that of sphinganine and sphingosine, sphingolipids found in lipid substances such as cellular membranes. Both FB<sub>1</sub> and FB<sub>2</sub> inhibit ceramide synthase (sphingosine and sphinganine *N*-acyl-transferase), effectively blocking sphingolipid metabolism and interfering with cellular differentiation, growth, communication, and transformation.<sup>1,9</sup> Serum and tissue concentrations of sphinganine and sphingosine increase and may be used as a biological marker of exposure to fumonisins.<sup>1</sup> An elevation in the serum, tissue, or urine ratio of sphinganine to sphingosine (Sa:So) may have promise as a biomarker.<sup>1,11</sup>

## EQUINE TOXICOSIS

### Equine Leukoencephalomalacia (Moldy Corn Disease)

The most common clinical entity is equine leukoencephalomalacia (ELEM), a disease of horses, mules, and donkeys associated with the ingestion of fumonisin-contaminated corn.<sup>4,9,12</sup> Of the known fumonisins, FB<sub>1</sub> and FB<sub>2</sub> are the most important, and FB<sub>1</sub> has been shown to be the specific cause of ELEM. Poisoning occurs in stored moldy corn, but it also occurs in horses fed commercial feeds, including pelleted feed; the disease incidence is usually in the form of an outbreak, with some of them being large-scale outbreaks.<sup>4,9,13</sup> Most feeds associated with ELEM contain a minimum of 15 to 22 ppm FB<sub>1</sub>, although risk is increased with ingestions of feeds containing 10 ppm FB<sub>1</sub>.<sup>4,8,13</sup>

### CLINICAL FINDINGS

Classically, the disease is described as either a neurotoxic or hepatotoxic syndrome, although it is likely a single syndrome with the spectrum of signs related more to the actual concentration of fumonisins present in the feed, prior exposure, individual susceptibility, and total amount ingested.<sup>13</sup> Cardiovascular dysfunction may play an important role in the development of ELEM.<sup>1,4</sup>

Clinical signs occur 14 to 21 days after introduction of contaminated feed; occasionally animals present with signs at 7 days and on rare occasions, not for 90 days.<sup>1</sup> Reported early neurologic signs (neurotoxic syndrome) include proprioceptive deficits and decreased tongue tone, followed by a wide variety of other signs.<sup>13</sup> Anorexia, hypersensitivity and agitation, sweating, muscle tremor and weakness, hypermetria, staggering, circling, inability to swallow, lower lip paralysis, protrusion of a flaccid tongue, apparent blindness, circling, head pressing, and dementia have all been reported.<sup>1,8,9,13</sup> Most animals die 4 to 24 hours after the onset of signs, although some horses are found dead without signs having been observed.<sup>1,9</sup> Hepatic signs (hepatotoxic syndrome) are edematous swelling of the lips, nose, supraorbital fossa, and lower limbs. Icterus, mucosal petechiae, and dyspnea are common signs. The time period from the onset of clinical signs to death is 5 to 10 days.<sup>1</sup>

### CLINICAL PATHOLOGY

Sphinganine and sphingosine concentrations and Sa:So ratio may be elevated. Serum chemistry analysis in horses with hepatic signs shows elevations in liver enzyme activities, including gamma-glutamyl transferase (GGT) and aspartate aminotransferase (AST).<sup>1,4</sup> Total bilirubin and bile acids may also be elevated. The cerebrospinal fluid in horses with ELEM often shows elevations in protein concentration.<sup>13</sup>

## NECROPSY FINDINGS

The classical lesion associated with ELEM is liquefaction necrosis of the white matter. There are macroscopic areas of softening, especially in the cerebrum, accompanied by hemorrhages in the white matter of the cerebral hemisphere and brown to yellow areas of discoloration. Histologically, there are swollen astrocytes or oligodendrites (previously referred to as clasmotodendritic astroglia) containing eosinophilic intracytoplasmic globules and eccentric hyperchromatic nuclei.<sup>8,9</sup> Grossly, the liver is firm and small with an increased lobular pattern. Hepatic periportal fibrosis and hepatocyte vacuolization or necrosis are present on histopathology.<sup>1,9,12</sup>

## SWINE TOXICOSIS

The lungs, liver, and heart are the primary target organs for FB<sub>1</sub> and FB<sub>2</sub> toxicosis in swine.<sup>1,4,10</sup> A reduction in cardiac and vascular efficiency is seen with chronic fumonisin intoxication. Alterations in immune function and intestinal colonization by pathogens may be present.<sup>2,14</sup> Fusaric acid, a mycotoxin also produced by *E. moniliforme*, is associated with depression and vomiting in pigs.

## PORCINE PULMONARY EDEMA

Ingestion of fumonisin-contaminated corn in levels as low as 16 ppm is associated with the development of fatal pulmonary edema (PPE).<sup>1,4,13</sup> Fumonisin B<sub>1</sub> blocks L-type calcium channels, resulting in left-sided heart failure and pulmonary edema.<sup>1,4</sup> Heart rate, contractility, and cardiac output are decreased, and pulmonary artery wedge pressure is increased.<sup>1</sup>

### Clinical Signs

Clinical signs occur 2 to 7 days after ingestion of feeds containing large concentrations of FB<sub>1</sub>.<sup>1,4</sup> There is an acute onset of respiratory distress characterized by a rapid respiratory rate, dyspnea, and open-mouth breathing. Decreased feed consumption, weakness, and cyanosis have been reported.<sup>13</sup> Death from pulmonary edema and hydrothorax occurs in a matter of hours following the onset of clinical signs.<sup>1,4</sup>

### Necropsy Findings

Grossly, the apical and cardiac lobes are firm and consolidated, with evidence of edema.<sup>15</sup> Alveolar edema, interstitial edema surrounding airways and vessels, and dilated lymphatics are present histologically.<sup>1,13</sup>

### Hepatositis/Hepatic Effects

Hepatic toxicity precedes the development of PPE and occurs when ingested amounts are less than those associated with PPE or, less often, in chronic exposures without development of PPE.<sup>1,10</sup> Common clinical signs include anorexia, weight loss, and icterus. More chronic cases of the hepatosis

syndrome are accompanied by hyperkeratosis and parakeratosis of the distal esophageal mucosa.<sup>10</sup>

### Clinical Pathology

Elevations in liver enzyme activities (GGT, alkaline phosphatase [ALP], and AST) and increases in total bilirubin and bile acids occur as early as a day or so after exposure to fumonisins.<sup>1,2,15</sup> Experimentally, serum total protein and albumin were lower and AST and ALT activity higher in swine chronically fed diets containing more than 10 ppm FB<sub>1</sub>.<sup>2</sup>

### Necropsy Findings

The liver is large, yellow, and friable. Hepatic fibrosis and nodular hyperplasia are present in chronic cases.<sup>1</sup>

## RUMINANT TOXICOSIS

Ruminants are relatively resistant to the fumonisins, likely from minimal rumen absorption.<sup>1</sup> Beef calves fed 148 ppm fumonisins for 31 days developed only anorexia, but serum analysis showed evidence of hepatic damage.<sup>1,16</sup> Dairy cattle seem to be more susceptible compared with beef cattle. Lower milk production and decreased feed intake occurred when fed 100 ppm fumonisins for 7 days before and 70 days after parturition.<sup>10</sup> Lambs receiving high concentrations of fumonisins developed acute hepatic and renal toxicity and died.<sup>1,16</sup>

## DIAGNOSIS

The diagnosis depends on the species, clinical signs, and pathologic findings, but must include detection of the specific toxin (FB<sub>1</sub> or FB<sub>2</sub>) in the feed. The presence of *Fusarium* spp. in the feed does not confirm a diagnosis. High-performance liquid chromatography (HPLC) and enzyme-linked immunosorbent assay (ELISA) are available in many areas to assay corn and feed products for FB<sub>1</sub> and FB<sub>2</sub>.<sup>7</sup> Experimentally, liquid chromatography high-resolution mass spectrometry (LC-HRMS) has been used to identify hydrolyzed fumonisins in corn,<sup>17</sup> and a liquid chromatography-tandem mass spectrometry (LC-MS/MS) method has been developed and validated to identify FB<sub>1</sub> and FB<sub>2</sub> in swine liver.<sup>18</sup>

## TREATMENT

The onset of signs is so rapid that no specific treatment, other than supportive, has been effective. All suspect contaminated feed should be removed as soon as possible.

## CONTROL

Corn and corn-based products, including pellets, should be tested for the presence of FB<sub>1</sub> and FB<sub>2</sub> and compared with published guidelines for maximum tolerable levels for individual species.<sup>1</sup> Contaminated corn should be disposed of or diluted and fed to feeder cows.

## GLUCOSINOLATE TOXICOSIS

### SYNOPSIS

**Etiology** Glucosinolates in *Brassica* spp. and related plants used as feed.

**Epidemiology** Outbreaks in grazing cattle or in cattle fed crop by-products, especially cake or meal made from residues of seed oil extraction.

**Clinical pathology** Assay of blood levels of glucosinolate or metabolic end products.

**Lesions** Nonspecific goiter, enteritis, pulmonary emphysema, and interstitial pneumonia.

**Diagnostic confirmation** Positive blood assay of glucosinolate.

**Treatment** Supportive care only.

**Control** Avoid toxic plants and meals.

## ETIOLOGY

Glucosinolates, sometimes referred to as “mustard oil glycosides” or “thioglucosides” are organic substances containing a sulfonated oxime group, combined with glucose

**Table 21-12** Plants causing glucosinolate poisoning

### Goitrogenic effect

Pasture and forage plants:

Rape (syn. canola)

*Brassica napus*

Kale, kohlrabi, chou moellier

*Brassica oleracea*

Cabbage, cauliflower, broccoli

Brussels sprouts, calabrese

Chinese cabbage

*Brassica chinensis*

Turnip rape, cole

*Brassica campestris*

Swede, rutabaga

*Brassica napobrassica*

Turnip

*Brassica rapa*

Radish

*Raphanus sativus*

Plant by-products:

Rapeseed oil cake

Weeds:

Turnip weed

*Rapistrum rugosum*

### Diarrhea, unpalatability, taint effects (caused by mustard oil glucosinolates)

Culinary plants:

Horse radish

*Armoracia rusticana*

Cress, mustard greens

*Lepidium*, *Nasturtium*, *Tropaeolum* spp.

Wild radish

*Raphanus raphanistrum*

White mustard

*Sinapis alba*

Black mustard

*Sinapis nigra*

Oriental mustard

*Brassica juncea*

Weeds:

Fanweed

*Thlaspi arvense*

Charlock

*Sinapis arvensis*

Wormseed or treacle mustard

*Erysimum cheiranthoides*

Note: The taxonomy of the *Brassica* spp. varies between countries.

in the form of glycosides. More than 120 compounds have been identified and characterized.<sup>1,2</sup> The metabolic by-products include isothiocyanates, nitriles, oxazolidinethiones, and carbinols. These plants also contain thioglucosidase (myrosinase), the enzyme needed to hydrolyze the glucosinolate to glucose and the toxic radical.<sup>1,2</sup>

A special group, mustard oil glucosinolates, occurs in the foliage of some plants and is concentrated in their seeds and the seeds of some others. Plant sources of glucosinolates are mostly from the family Brassicaceae (Cruciferae), as listed in Table 21-12.

## EPIDEMIOLOGY

### Occurrence

Outbreaks of glucosinolate poisoning are common wherever intensive animal husbandry is practiced, especially where plant wastes from the food industries are fed to livestock in feedlots.

### Risk Factors

#### Animal Risk Factors

Pigs are the most sensitive to glucosinolate poisoning followed by ruminants.<sup>2</sup> There is

one equine report of toxicity associated with rapeseed oil.

### Human Risk Factors

The toxic substances may be excreted in cows' milk, but the observed goitrogenic effect when the milk is fed may be attributable to the low iodine content of the milk.

Tainting of milk occurs in cows fed plants, more commonly plant seed by-products, containing glucosinolates. The odor and off-flavor are attributable to volatile thiocyanates and not to isothiocyanates. Treatment of the feed with caustic soda prevents the tainting.

### Plant Factors

Plants in several uncommon botanical families contain glucosinolates, but animal poisoning is largely limited to the agriculturally important members of the Brassicaceae (Cruciferae) family, all members of which contain these substances. The common fodder plants and commercial vegetables listed in Table 21-12 have all been associated with poisoning. Seed oil crops, such as seed rape and mustard seed, may be fed as roughage after

the seed has been harvested and represent a possible source of poison. Large quantities of seed also become available for animal feed, and because of the large quantity fed they may be associated with the enteric form of the disease. Glucosinolates are present in the vegetative parts of these plants but are in much higher concentration in the seeds. The glucosinolate concentration varies widely between species of plants (e.g. *Brassica napus* is much more goitrogenic than *B. campestris*), and even between cultivars of the same species at different times of the year and under different conditions of growth. Including the rapeseed in ensilage does not reduce its goitrogenicity. Plant stress, including drought and overcrowding of plants, and the feeding of high-3.sulfate diets are known to increase the concentration of the toxin, and small young leaves may contain as much as 5 times more glucosinolate than large, mature leaves. The high content of sulfate and glucosinolates in cabbage makes it a damaging feed. The most common and serious cases of poisoning occur in animals fed rapeseed or rapeseed meal. Diets containing as low as 3% of rapeseed meal may be associated with goiter and reduced weight gain in pigs. The meal is often fed in amounts up to 20% of the diet. An extensive plant-breeding program has produced varieties of seed rape that have very low concentrations of glucosinolate.

### **PATHOGENESIS**

Glucosinolate metabolites and the relative proportions of them produced by enzymatic breakdown of the glucosinolates depend largely on the composition of the glucosinolate present, but factors such as pH also have an effect. There are three groups of glucosinolates, each producing a particular metabolite:

- Glucosinolates producing principally isothiocyanates—some of these (e.g., allyl-isothiocyanate, 3-butenyl isothiocyanate) are the irritant components of mustard oils, contained in plant seeds, and are irritant to alimentary tract mucosa causing gastroenteritis, diarrhea, and dysentery. Others, present in the leaves of the plants, are hydrolyzed further to form thiocyanate ion.
- Glucosinolates producing principally thiocyanate ion—which, when taken in small amounts over long periods, is a goitrogen. It is likely to be associated with goiter only when the iodine status of the diet is low. This substance reduces iodine capture by the thyroid gland, and the condition can be alleviated by the administration of iodine.
- Thiones (e.g., 5-vinyloxazolidine-2-thione or goitrin), produced by the hydrolysis of glucosinolates present in the seeds of cruciferous plants, are more potent goitrogens than thiocyanate ion.

They interfere with the synthesis of thyroxine, and iodine is ineffective in the treatment of the poisoning. Clinically, the effects of low-level intakes of isothiocyanate and thiones include goiter and a related reduction of the growth rate in the young, and possibly an indirect, depressing effect on reproduction in adults. The reduction in growth rate may be attributable to the observed hypothyroidism, but there is, in addition, a reduction in palatability with diets containing high levels of glucosinolates. This effect is most noticeable in young pigs but may also be evident in high-producing cows.<sup>2</sup>

There is a positive correlation between cruciferous plants (*Brassica* spp.) and polioencephalomalacia in ruminants (e.g., in rape blindness), but the brain lesion is likely associated with the high sulfur content of the plant.<sup>3</sup> Mustard oil glucosinolates are associated with violent diarrhea, sometimes dysentery, and abdominal pain in animals eating large amounts of seeds.<sup>2</sup> No identifiable pathogenesis is advanced as being associated with acute pulmonary emphysema and interstitial pneumonia, or the ill-defined “digestive disturbance” seen in some outbreaks of poisoning with these plants.

### **CLINICAL FINDINGS**

#### **Goiter**

Enlargement of the thyroid may occur at any age, including the newborn of dams fed the plants during pregnancy. Deaths as a result of hypothyroidism, after a period of hypothermia, weakness, recumbency, and coma, are more likely in the latter age group. In older animals the accompanying syndrome will be weight loss or failure to gain weight.<sup>2</sup> In serious outbreaks the thyroid is enlarged by 50% in most lambs, with more than 10% showing gross enlargement. Affected flocks have longer-than-usual gestation periods, and lamb mortality is increased threefold because of the poor vigor of the lambs.

#### **Enteritis**

Abdominal pain, salivation, vomiting in some cases, diarrhea, dysentery, and a short course with a fatal outcome are common after animals have access to large amounts of reject seeds of these plants.

#### **Acute Pulmonary Emphysema and Interstitial Pneumonia**

The condition of acute pulmonary emphysema and interstitial pneumonia has been observed only in cattle. Affected animals show severe dyspnea, with stertorous rapid respiration, mouth breathing, and subcutaneous emphysema. The temperature may or may not be elevated. Affected animals may survive but often remain chronically affected and do poorly.

### **Polioencephalomalacia (Rape Blindness)**

Polioencephalomalacia, characterized by blindness, head pressing, aimless walking, ataxia, and recumbency, occurs in cattle, and rape blindness is manifested by the sudden appearance of blindness in cattle and sheep grazing these crops.<sup>3</sup> The eyes are normal on ophthalmoscopic examination; the pupils show some response to light and may or may not be dilated. Complete recovery usually occurs but may take several weeks.

### **Other Unrelated Diseases**

- Digestive disturbances in steers on rape are usually accompanied by anorexia, the passage of small amounts of feces, absence of ruminal sounds, and the presence of a solid, doughy mass in the rumen. Only a small quantity of sticky, black material is present on rectal examination.
- Photosensitization and bloat are also encountered in cattle grazing rape.

### **CLINICAL PATHOLOGY**

Assays of blood levels of glucosinolates and their metabolic products are available. The diet and the pastoral environment should be examined for the presence of the plants and plant by-products known to contain glucosinolates.

### **NECROPSY FINDINGS**

Goiter, enteritis, pulmonary emphysema, and interstitial pneumonia are nonspecific and dealt with at other points in the text. In *Thlaspi arvense* poisoning there may be massive edema of the forestomach walls.

Diagnostic confirmation is detection of glucosinolates in the blood of animals with access to relevant plants or feedstuffs made from them.

### **DIFFERENTIAL DIAGNOSIS**

#### **Differential diagnosis list:**

##### **Goiter:**

- Inherited goiter
- Low, continuous intake of cyanogenetic glucosides in, for example, pasture plants such as *Cynodon aethiopicus*, *C. nlemfuensis* (couch grasses), and *Trifolium repens* (white clover)
- Nutritional deficiency of iodine

##### **Diarrhea with or without dysentery:**

- Arsenic poisoning
- Infectious gastroenteritis
- Other poisonous plants in which the toxin has not been identified
- Salmonellosis

### **TREATMENT**

Treatment is symptomatic and supportive.

### **CONTROL**

Avoidance of losses can be best achieved by avoiding the use of the poisonous substance

or the grazing of the affected area. Some of the goiters can be relieved by the administration of iodine, and avoidance of high-sulfate diets reduces the level of glucosinolate production. Plant by-products containing glucosinolate derivatives can be treated with alkali solutions to destroy their toxicity.

## MISCELLANEOUS MYCOTOXINS

### CYCLOPIAZONIC ACID

Cyclopiazonic acid (CPA), an indole-tetramic acid, is a secondary metabolite produced by several genera of *Aspergillus* and *Penicillium* growing on stored grain, including sunflower seeds.<sup>1</sup> It has been found in human and animal foods and food sources, including milk, eggs, and poultry.<sup>1,2</sup>

Toxicity associated with CPA is considered low, based on an LD<sub>50</sub> in rats of 30 to 70 mg/kg BW, and reports of animal poisonings are rare.<sup>1</sup> Ingestion of CPA-contaminated feed in sows is associated with feed refusal and conception problems in sows. Isolated from *A. flavus*, cyclopiazonic acid is associated with weakness, anorexia, loss of body weight, and diarrhea in pigs. Necropsy lesions include gastric ulceration and hemorrhages throughout the alimentary tract.

### PATULIN

Patulin, an important toxin in human medicine, is produced by *Aspergillus clavatus* and other fungi, including *Byssoschlamys nivea*, *Penicillium urticae*, *P. claviforme*, and *P. patulum*.<sup>3,4</sup> Toxicity is most commonly associated with rotting apples or apple juice, and poisoning may occur in pigs fed food waste containing rotten fruit.<sup>3</sup>

Cattle and sheep poisoned by patulin producing fungi develop brain hemorrhage, pulmonary edema, or liver and kidney damage with abomasal hemorrhage. When fed to piglets, it is associated with vomiting, salivation, anorexia, polypnea, weight loss, leukocytosis, and anemia. Patulin may be the toxin associated with neurologic problems in cattle ingesting malting by-products and

sprouted grains.<sup>4,6</sup> Affected cattle develop neuromuscular signs, including salivation, ataxia, hind limb weakness, muscle tremors, recumbency, and death.<sup>4-6</sup>

### STERIGMATOCYSTIN

Sterigmatocystin (STC) is a hepatotoxin and potential carcinogen in humans.<sup>7</sup> Carcinogenesis in farm animals is not reported. It has been isolated from *Aspergillus* spp., *Bipolaris* spp., *Penicillium luteum*, and other species of fungi.<sup>7,8</sup> It is a precursor of aflatoxin synthesis.<sup>7</sup> Contaminated foods include grains, soybeans, nuts, animal feeds, and silage.<sup>8</sup>

## MUSHROOM TOXICOSIS

Reports of poisoning associated with mushrooms in large animals are rare. Grazing animals may have access to poisonous mushrooms and develop clinical signs, but a specific mushroom is rarely identified, and diagnostic tests are often limited.

### AMATOXINS

Mushrooms in the genera *Amanita*, *Galerina*, and *Lepiota* contain amanitins (cyclopeptides) that are toxic to the gastrointestinal tract, kidney, and liver.<sup>1</sup> *Amanita phalloides* (dead cap) and *Amanita ocreata* (Western North American destroying angel), both found in the coastal western and southwestern United States and parts of Mexico, have been associated with poisonings in calves,<sup>1</sup> cattle,<sup>2</sup> dogs,<sup>3</sup> and human beings<sup>4-5</sup> and perhaps horses.<sup>1,4</sup> As a group, amatoxins include several amantins, amanin, amanullin, and proamanullin, but amanitins are the most commonly reported toxins. *A. phalloides* and *A. ocreata* contain high concentrations of  $\alpha$ -amanitin and  $\beta$ -amanitin.<sup>1</sup> Ingestions of small amounts have resulted in poisoning in humans and dogs; the toxic amount in large animals is unknown.

In monogastric animals, amanitins are absorbed in the gastrointestinal tract and transported to the liver, where they are taken

up by OATP1B3, an organic acid hepatic transporter.<sup>5</sup> Protein binding does not occur. Metabolism has not been recorded, and 80% to 90% of an ingested dose is eliminated in the urine and 7% in the bile.<sup>1</sup> Bioavailability, serum half-life, and plasma detection time vary with the species.<sup>1,2</sup> Similar information is not available for ruminants.

Clinical signs occur from inhibition of nuclear RNA polymerase II, which causes a decrease in messenger RNA and ultimately protein synthesis.<sup>1,2</sup> Hepatocytes, crypts cells, and those in the proximal convoluted tubules of the kidney are most commonly affected. Other cellular effects are at work as well.<sup>1,2</sup> The earliest signs identified in animals are gastrointestinal and include severe pain, vomiting, and bloody diarrhea.<sup>2</sup> These are followed by a latent period of hours to a few days and a final stage with acute necrotizing hepatic failure and renal failure.<sup>1,2</sup> Coagulation defects, hypoglycemia, elevations in liver enzymes, and encephalopathy may occur.

Several different modalities, including a liver transplant in humans, are used to treat toxicosis in humans and dogs, but large animals are generally found dead or die before treatment can be provided.

Postmortem examination shows a friable liver with diffuse centrilobular to panlobular necrosis.<sup>1</sup> Other organs, such as the kidney, and the gastrointestinal tract are also affected. Liquid chromatography/mass spectrometry is available in some laboratories to analyze serum, urine, liver, kidney, and gastric contents, including rumen, for amanitins.<sup>6</sup>

### RAMARIA FLAVO-BRUNNESCENS

The *Ramaria flavo-brunnescens* mushroom is found only in the eucalyptus woods of North America, Australia, China, Brazil, and Uruguay.<sup>7-9</sup> The toxin is unknown, but toxicity may be related to interference with sulfur-containing amino acids (cysteine) in keratinized structures.<sup>9</sup>

Clinical signs of "eucalyptus poisoning" have been recorded in sheep and cattle. Jersey calves experimentally poisoned with 20 mg/kg BW *R. flavo-brunnescens* mushrooms developed anorexia, hyperemia of the oral mucosa, and loosening of hair shafts at the tip of the tail.<sup>8</sup> Other recorded signs include salivation; lingual and esophageal ulcers; loss of hair, especially of the tail brush; recumbency; and pain in, and loss of, hooves.

### SCLEDERMA CITRINUM

*Scleroderma citrinum* (common earth ball) fed to a miniature Chinese pot-bellied pig has been associated with vomiting, depression, recumbency, and death.<sup>4</sup> The pupillary light reflex was lost, but the eye preservation reflex remained. Pain on abdominal palpation, hyperthermia, tachycardia, and mucoid feces passed with some straining were present; death occurred in about 5 hours. The toxin has not yet been identified.

## CORTINARIUS SPECIOCISSIMUS

*Cortinarius speciocissimus* has been associated with deaths in sheep in Norway with renal tubular necrosis and terminal uremia.

## INO CYBE AND CLITOCYBE SPP.

Muscarine, a mycotoxic alkaloid found in the macrofungi, is associated with excessive salivation, bradycardia, diarrhea, and vomiting. Atropine is an effective antidote.

## PHALARIS SPP. (CANARY GRASS) TOXICOSIS

### SYNOPSIS

**Etiology** Associated with the ingestion of the *Phalaris* spp. grasses containing dimethyltryptamine (causing an incoordination syndrome) or unknown substances (causing a sudden death/cardiac syndrome and a sudden death/polioencephalomalacia-like syndrome).

**Epidemiology** Outbreaks on lush, rapidly growing pasture; sheep most commonly affected.

**Clinical pathology** Isolation of tryptamines in plants and affected animals.

**Lesions** Green-gray discoloration of renal medulla, medulla oblongata, brainstem.

**Diagnostic confirmation** By detection of tryptamines in body fluids or cadaver.

**Treatment** None.

**Control** Limitation of access to causative plants.

## ETIOLOGY

Dimethyltryptamines associated with incoordination syndrome include the following:

- *Phalaris aquatica* (synonym *P. tuberosa*)
- *P. angusta*, timothy canary grass
- *P. arundinacea*, reed canary grass
- *P. caroliniana*, Maygrass, Southern canary grass
- *P. brachystachys*

- *P. canariensis*, annual canary grass, commercial canary grass
- *P. minor*, littleseed canary grass, wild canary grass
- *P. paradoxa*, hooded canary grass

The cause of acute death from cardiac arrest, originally ascribed to the methylated tryptamines, is unknown, but may be related phenylethylamines, other alkaloids (indoles/oxindoles), or other factors.<sup>1</sup> The cause of death associated with polioencephalomalacia, once thought to be related to thiamine analogs produced by the ruminal flora, is also unknown.<sup>1</sup>

## EPIDEMIOLOGY

### Occurrence

The disease has been recorded in many parts of Australia, New Zealand, South Africa, Spain, California, and South America where the phalaris grasses are in common use as pasture plants.<sup>1-3</sup> Heavy losses occur on individual farms as a result of sudden deaths, but careful management relieves the burden of the incoordination syndrome.

The individual tryptamine alkaloids associated with the disease vary significantly in their toxicity, and thus plants in a pasture can vary greatly in the danger they present. The concentration of tryptamines in the grass is increased by high environmental temperature and their growing in the shade, and toxicity is greatest when the plants are young and growing rapidly, especially after a break in a dry season. Provision of cobalt appears to stimulate the proliferation of microorganisms in the rumen that are capable of destroying the causative agent, but sheep affected with phalaris staggers do not usually show any signs of cobalt deficiency. Under some circumstances, plants with low tryptamine content will be associated with the syndrome.

## Risk Factors

### Animal Factors

Sheep, followed by cattle, are most commonly affected, although alpacas have developed the incoordination syndrome and horses the sudden death/cardiac syndrome.<sup>1,4,5</sup>

Up to 30% of a flock may be affected when *P. aquatica* dominates the pasture or is preferentially grazed. On lightly stocked pastures the sudden death syndrome, with signs appearing within 4 hours but usually between 12 and 72 hours after going onto the pasture, is most likely to occur. Deaths are most common in hungry sheep in the early morning or in foggy or cloudy weather. This syndrome is also recorded in cattle on irrigated *Phalaris* spp. pasture in hot, humid weather.

The incoordination syndrome occurs in similar circumstances but in sheep that have protracted or repeated exposure. In this case clinical signs appear 2 to 3 weeks after sheep are put onto pasture showing new growth, usually in the autumn or early winter. Both

forms may occur in a single flock of sheep and also in feedlots. Sheep of all ages are affected, and mild cases may occur among cattle.

The variability in the numbers affected and the severity of the disability in sheep flocks from day to day appear to be attributable to the variation in the amount of toxin absorbed, possibly affected by the degree of detoxification of the tryptamines in the rumen. The reduction in severity of an outbreak associated with dietary supplementation with cobalt is thought to be effected in this way.

## PATHOGENESIS

Tryptamine alkaloids, structurally similar to serotonin, are present in the grass under certain conditions and are associated with the incoordination syndrome by a direct agonist action on serotonergic receptors in specific brain and spinal cord nuclei.<sup>1,4</sup> Clinical signs mimic those of the serotonin syndrome and include repetitive head movements tremors, rigidity, and hyperreactivity. The nervous disturbance appears to be functional in contrast to that associated with  $\beta$ -carbolines, which is accompanied by axonal degeneration and is an irreversible syndrome.

A characteristic of the disease is a greenish-gray discoloration of the brainstem, diencephalon, dorsal root ganglia, and kidneys.<sup>4</sup> The pigmentation is a result of the accumulation of indole-like pigments at the locations where the causative alkaloids act, but the pigments themselves do not have any effect on the signs.

## CLINICAL FINDINGS

The sudden cardiac death syndrome, the most rare of the three syndromes, is manifested by sudden collapse, especially when excited, a short period of respiratory distress with cyanosis, and then death or rapid recovery.<sup>1</sup> During the stage of collapse there is arrhythmic tachycardia followed by ventricular fibrillation and cardiac arrest. Consciousness is retained.

The sudden death polioencephalomalacia syndrome cases are rarely observed alive, but occur commonly after short periods of feed deprivation. This occurs most often in sheep, although cattle have been affected as well.

In the initial stages of the incoordination syndrome in sheep, signs appear only when the animals are disturbed. Hyperexcitability and generalized muscle tremor, including nodding and bobbing of the head, occur first. On moving, the limb movements are stiff, and the hocks are not bent, causing dragging of the hindfeet. Incoordination and swaying of the hindquarters follow. Some animals walk on their knees, others bound or hop, and others knuckle at the fetlocks; some show splaying of the digits. In the most severe cases collapse into lateral recumbency is accompanied by paddling movements of the legs and irregular involuntary

movements of the eyeballs. There is rapid respiration and irregular tachycardia. The sheep may die at this stage, but if left undisturbed they may recover and walk away apparently unaffected. If the sheep are left on the pasture, the condition worsens in individual cases, with the animal becoming recumbent and manifesting repeated convulsive episodes until death supervenes.

There is a great deal of variation from day to day in the number of sheep showing signs and in the severity of the signs observed. Even after sheep are removed from the pasture the clinical state may deteriorate, and although some appear to recover, clinical signs can usually be elicited by forcing them to exercise. Deaths are reported to continue for 1 week after removal of sheep from toxic pasture, and clinical signs of the nervous form of the disease may persist for as long as 2 months. The extraordinary situation is recorded where new cases continue to occur for as long as 12 weeks after sheep are moved onto pasture that contains no *Phalaris* spp.

In cattle, the signs may be restricted to stiffness of the hocks and dragging of the hind toes, but severe cases similar to the common syndrome in sheep also occur.<sup>3,4</sup> Additional, and more common, signs observed in some, but not all, cattle include an extraordinary incoordination of the tongue and lips in prehension; thus, the hungry animal, trying desperately to eat, can onlyprehend a few stalks of grass at a time.<sup>4</sup> The jaw movements are quite strong, but the tongue stabs and darts, and it lacks the sinuous curling movements normally present. There may also be an inability to put the muzzle to the ground, and thus prehension can only occur from a raised manger or hayrack. Affected cattle are often hyperexcitable and difficult to handle.

### CLINICAL PATHOLOGY

Laboratory tests on antemortem material can detect the presence of the causative tryptamines in plant material but are unlikely to be generally available.

### NECROPSY FINDINGS

Other than the characteristic green–gray pigmentation of tissues in the renal medulla, brainstem, midbrain, and dorsal root ganglia, gross lesions are absent. Degeneration of spinal cord tracts and of the ventral portion of the cerebellum has been observed in terminal cases of the incoordination syndrome, but is not a consistent finding. In the sudden death or cardiac syndrome sheep are usually found dead on their sides with their heads strongly dorsiflexed and legs rigidly extended. Some sheep have blood-stained nasal discharge, and many froth at the mouth. Abdominal visceral congestion and epicardial and duodenal hemorrhages are present and indicate acute heart failure. Polioencephalomalacia is characteristic of the sudden death–polioencephalomalacia syndrome.

The association between the nervous disease and the plants should suggest the diagnosis. The appearance of these signs only on exercise is significant, suggesting a functional rather than a physical lesion. Diagnostic confirmation rests on the identification of the causative tryptamines in the feed materials and the tissues and fluids on antemortem or postmortem examination.

### TREATMENT

Flocks of affected sheep should be removed immediately from the pasture. There is no specific antidotal treatment.

### CONTROL

No preventive measures are available against the sudden death syndrome, but the nervous form may be prevented by the oral administration of cobalt.<sup>1,4</sup> Affected pastures may be grazed if sheep are dosed with cobalt (at least 28 mg per week) at intervals of not more than 1 week, or if alternative grazing is provided in rotation. Dosing at too long intervals or with inadequate amounts may account for some failures in prevention. The parenteral administration of cobalt or vitamin B<sub>12</sub> is not effective. The additional cobalt can be provided by drenching the sheep individually or spreading it on the pasture mixed with fertilizer as described under cobalt deficiency. Unfortunately, the genetic selection of *P. aquatica* cultivars with low contents of methylated tryptamines favors a significant increase in toxic  $\beta$ -carbolines.

## TOXICOSIS FROM PLANT PHENOLS (GOSSYPOL AND TANNINS)

Two important groups of plant polyphenols (hydroxyl derivatives of benzene) are **gossypol** and the **tannins**.

### GOSSYPOL

#### ETIOLOGY

Gossypol is found primarily in oil glands (gossypol glands) of the seed but also in some other portions of the plant. It is present in variable amounts in cottonseed cake made

from the seeds of *Gossypium* spp. and hybrids (commercial cotton) and in the seeds and their hulls, and poisoning occurs primarily from ingestion of seed meal or other seed products. Seed meal usually contains 300 to 400 ppm but may contain as much as 18,000 ppm of free gossypol in a 17% protein ration.

### EPIDEMIOLOGY

Swine and preruminant animals are more susceptible to poisoning than mature ruminants. Levels of 200 to 300 ppm are toxic to swine, and preruminant calves' diets containing 100 to 200 mg/kg BW resulted in gossypol mortality. Horses appear to be resistant to gossypol toxicity, with no natural cases being on record.<sup>1</sup>

Most recorded outbreaks of gossypol poisoning refer to pigs. Cottonseed cake should not be fed to pigs at all, especially young pigs. Adults may tolerate up to 60 ppm gossypol in the feed, although other sources suggest 100 ppm may be safe.<sup>1</sup>

Animals with a functioning rumen are able to tolerate higher levels of free gossypol than preruminant animals. Goats are more susceptible than others, with daily intakes of 350 to 400 mg gossypol being fatal after 3 months. Calves die of heart failure if fed 800 to 1000 g cottonseed meal/day. Illness and mortality have also been produced by feeding gossypol to adult dairy cows. Adverse effects on spermatogenesis with an increase in sperm morphologic abnormalities occurs in bulls on low intakes and without clinical signs. Sheep are susceptible if the toxin is injected but appear to be unaffected when it is fed. In rams, feeding free gossypol in concentrations greater than 9 mg/kg BW resulted in reproductive toxicity.<sup>2</sup>

### PATHOGENESIS

Cottonseed oil is extracted at high temperatures, and during this process gossypol is released from the oil glands. Some binds to proteins and is considered nontoxic; the remainder is referred to as "free gossypol" and is the toxic form. In swine, free gossypol is absorbed from the gastrointestinal tract, conjugated in the liver, and excreted in the feces.<sup>1</sup> Little is excreted in the urine or milk. The mechanism of action is that of a reactive species, forming free radicals and damaging various tissues, especially the heart.<sup>1,2</sup> Other mechanisms are likely at work as well. Myocardial necrosis with congestive heart failure and hepatic changes are commonly associated with ingestion of toxic amounts of gossypol.<sup>1</sup>

### CLINICAL FINDINGS

Clinical signs are abrupt but don't usually appear until animals have been fed on rations containing cottonseed meal for 1 to 2 months. Pigs poisoned by gossypol are thin, are exercise intolerant, cough, and are severely dyspneic, with a "thumping" type of respiration.

Death from cardiac insufficiency occurs in a few days, often preceded by cyanosis and seizures. Feeding cottonseed meal to pregnant sows at the rate of 20% to 40% of the ration is associated with shortening of the gestation length, and in some cases 40% of piglets are born prematurely and die. Poisoned calves show anorexia, dyspnea, cough, brisket edema, ascites, distension of the jugular vein, and weakness; hematuria occurs occasionally, and death follows an illness of several days. Sublethal rates of ingestion are associated with stunting of growth and reduction of fertility in bulls. Feeding cottonseed meal to young bulls and rams is not recommended because of the risk of permanent damage to spermatogenic tissues, but the risk is considered to be negligible.

### CLINICAL PATHOLOGY

There are no specific clinical pathology tests that are specific for gossypol. In later stages, hepatic enzyme activities may be elevated; Thoracic radiographs may demonstrate the presence of fluid, which can be examined for protein content after collection via thoracocentesis.

### NECROPSY FINDINGS

There is generalized edema, including high-protein fluid in all the serous cavities, and hepatomegaly as a result of congestive heart failure, and histologically there is degeneration of the myocardium and skeletal musculature. Centrilobular necrosis in the liver is also a characteristic lesion, and the liver will contain as much as 42 µg/g gossypol.

### CONTROL

Cottonseed cake may be fed with safety to adult cattle if the daily intake of meal is less than 2.5 to 3 kg/head per day, and it may be fed to pigs if it constitutes less than 9% of the ration.<sup>1</sup> Cooking of the cake or the addition of 1% calcium hydroxide or 0.1% ferrous sulfate to it are efficient methods of detoxification. In experimental trials the addition of iron in equal proportions to gossypol up to 600 mg/kg of the ration will protect pigs. Significant quantities of cations (particularly calcium and iron) in water supplies or rations appear to be protective. Providing calcium carbonate at a rate of 12 g/kg of whole cotton seed (WCS) for every 0.5% of free gossypol in the WCS prevents reproductive effects in cattle. Selenium (sodium selenite) supplementation in rams at 1 mg/ram per day has been used experimentally to counteract the adverse effects on semen characteristics.<sup>2</sup>

### TANNINS

Tannins include the condensed tannins (proanthocyanidins), which are insoluble and nontoxic, except that they may be associated with oral mucosal lesions, and the hydrolyzable tannins, which are soluble and

potentially toxic.<sup>3</sup> Pyrogallol, a degradation product of hydrolyzable tannins, is a gastrointestinal (GI) and renal toxin. Oaks (*Quercus* spp.) and yellow-wood tree (*Terminalia oblongata* ssp. *oblongata*) are important in this group. Miscellaneous other toxic plants in this group include the following:

- *Acacia melanoxylon*—black wattle
- *Acacia salicina*—black sally wattle
- *Clidemia hirtia*—harendong
- *Elephantorrhiza elephantina*—elephant's root; elan's bean
- *Stryphnodendron* spp.
- *Thilsea glaucocarpa*—sipaua, vaqueta
- *Ventilago viminalis*—supple jack

### OAK (*QUERCUS* spp.)

The leaves and acorns of many varieties of oak trees can be browsed by animals and are associated with no illness when they form only a small part of the diet.<sup>3</sup> When ingested in large quantities, all *Quercus* spp. are associated with toxicity, including the following:

- *Q. agrifolia*—coast live oak
- *Q. garryana*—Oregon white oak
- *Q. havardii*—sand shin oak
- *Q. marilandica*—blackjack oak
- *Q. robur* (synonym *Q. pedunculata*)—European oak
- *Q. rubra*—Northern red oak
- *Q. velutina*—black oak

The toxic principles are hydrolyzable tannins and simple phenols in the leaves, especially the **young buds**, and **green acorns**. All species of animals are affected, with losses in sheep and cattle being reported most commonly and occasional cases occurring in horses.<sup>4-8</sup> Goats are thought to be capable of surviving much greater intakes of tannin than cattle because of greater concentrations of tannase enzymes in their ruminal mucosa.<sup>4</sup> Experimental administration of tannic acids to goats has produced anemia, but there is no record of the natural occurrence of the disease.

Oak toxicosis involves the gastrointestinal tract and kidneys.<sup>4-7</sup> Cattle and sheep tend to show both GI and renal disease, whereas horses are more likely to develop gastroenteritis and fewer renal issues. If little else is eaten, oak foliage and acorns ingested for 3 to 4 days may be associated with nephrosis, which is manifested by polyuria, ventral edema, abdominal pain, and constipation followed by the passage of feces containing mucus and blood. Blood urea nitrogen (BUN) and creatinine levels are elevated; serum electrolytes are altered (increased potassium, decreased sodium); urine specific gravity is low, and proteinuria, glucosuria, and hematuria may occur.<sup>4,6</sup> Hepatic enzymes, indicative of liver damage, may be elevated, depending on the animal and/or oak species. At necropsy in ruminants there is edema of the gastrointestinal wall and mesentery, a characteristic nephrosis, and hepatic damage. Ulcerations of the mucosa consistent with uremia may be present.

Survivors of an initial attack of nephrosis make compensatory weight gains and perform well in feedlot situations.

Extensive areas of oak-brush range in the United States can be utilized for cattle grazing, but this requires careful management if losses are to be avoided. The phenol content varies between species, and thus stands of *Q. alba* can be much less toxic than those of *Q. rubra* or *Q. velutina*. Calcium hydroxide (15% of the ration) is an effective preventive under experimental conditions.

### YELLOW-WOOD TREE (*TERMINALIA OBLONGATA* spp.)

The foliage of the Yellow-Wood Tree contains a hepatotoxic tannin punicalagin and an unidentified nephrotoxin, and it is associated with losses in cattle. Acute poisoning of cattle is manifested by a sudden onset of hepatopathy, jaundice, and photosensitization, with some nephrosis and signs of abdominal pain and dehydration. Necropsy reveals a swollen congested liver, swollen gray-green kidneys, and gray-green pigmentation of the gastrointestinal mucosa, with multiple small hemorrhagic erosions of the abomasal mucosa. Chronic poisoning of cattle is dominated by severe nephrosis with pigment accumulation and fibrosis in the kidney cortex, polyuria, and wasting of the body. Yellow-wood poisoning of sheep is a nervous derangement, manifested by seizures if sheep are excited by handling, from which they recover spontaneously.

### MISCELLANEOUS PLANT TOXICOSIS

#### AESCULIN

The glycoside aesculin (7-hydroxycoumarin-6-glucoside) occurs in *Aesculus* spp. plants,

including *A. californica*, *A. glabra*, *A. hippocastanum*, *A. octandra*, and *A. pavia* (buckeyes or horse chestnuts), with *A. pavia* being the most toxic.<sup>1</sup> Ingestion of the seeds and nuts is usually reported, but toxicity also occurs after eating bark and foliage.<sup>1</sup> In monogastric animals the glycoside is associated with gastroenteritis with vomiting, but its digestion in ruminants to a soluble aglycone results in the more common syndrome of depression, straddled posture, stiff and uncoordinated gait, tremor, easy falling, recumbency, and convulsions with opisthotonos. Signs are exacerbated by handling or harassment. No necropsy lesions are reported.

### ALCOHOL (COMPLEX PLANT)

Included in alcohol toxins are cicutoxin, occurring in *Cicuta* spp. (water hemlock); oenanthotoxin, isomeric with cicutoxin, in *Oenanthe* spp. (water hemlock dropwort); and tremetol in *Ageratina altissima* (formerly *Eupatorium rugosum* [white snakeroot]) and *Isocoma pluriflora* (rayless goldenrod).

Cicutoxin and oenanthotoxin are C17 conjugated polyacetylenes and act as  $\delta$ -aminobutyric acid antagonists in the CNS;<sup>2</sup> tremetol is composed of complex mixtures of alcohols and ketones that may act to impair the tricarboxylic acid cycle.<sup>3,4</sup>

- **Cicutoxin** poisoning in all species is characterized by early tremor, restlessness, and stumbling gait, followed by violent clonic convulsions with bellowing, opisthotonos, and frothing at the mouth.<sup>5</sup> Between convulsions there is ruminal tympany, dyspnea, profuse salivation, teeth grinding and chewing movements, frequent urination and defecation, tachycardia, hyperthermia, and pupillary dilation. Most affected animals die of respiratory failure after a course of a few minutes, but more usually several hours. Serum levels of muscle enzymes are elevated as a result of the muscle activity. Necropsy lesions are comprised of skeletal and cardiac myodegeneration. The characteristic roots may be found in the forestomachs, more commonly lodged in the esophageal groove than in the rumen proper. In experimentally produced cases, IV sodium pentobarbital administered at the onset of the first convulsion prevents further convulsions and the myodegeneration, but no practicable remedy is available for natural cases. Green seed heads and tubers are toxic.<sup>6</sup> Prevention depends on keeping animals away from the plant, including the roots, which may be exposed during excavation or after flooding
- **Oenanthotoxin** poisoning is associated with an identical syndrome, most commonly in cattle. The roots of the plant are the common source of the poison.

- **Tremetol** is associated with stiffness and incoordination of gait, severe tremor, salivation, depression, recumbency, and coma preceding death in ruminants. In goats, skeletal muscle degeneration and necrosis is extensive.<sup>3,7</sup> In horses, there is heavy sweating, regurgitation of food through the nostrils, and the passage of dark, hard feces; there may be congestive right-heart failure with electrocardiographic abnormalities and extensive myocardial damage.<sup>4</sup> Cardiac troponin I may be a useful diagnostic tool for horses suspected of tremetol toxicosis.<sup>4</sup> The alcohol is excreted in the milk of animals that ingest the plant and may be associated with clinical illness and even death in humans drinking the milk.<sup>7</sup> Liver damage and skeletal muscle and myocardial swelling and pallor are gross lesions at necropsy.

### ALIPHATIC ACETOGENIN (MONOGLYCERIDE)

The toxin responsible for poisoning by *Persea americana* (avocado, alligator pear) is a biologically active aliphatic acetogenin, persin, with the form of a monoglyceride. Only varieties of Guatemalan origin are toxic; Mexican varieties are not. All parts of the plants can be toxic. Horses, ruminants, and ostriches have been affected. In lactating females, poisoning produces sterile mastitis and agalactia, with necrosis of secretory epithelium of mammary glands. Horses are affected by a heart failure syndrome, usually nonfatal, with severe subcutaneous edematous swelling of the head and dyspnea. In some cases, there is ischemic necrosis of masseter and tongue muscles. Fatal cases have myocardial necrosis. Colic and diarrhea have been reported in foals. Poisoned ostriches have paresis of neck muscles, edema of the neck, pulmonary edema, and necrosis of cardiac muscle.

### AMINE TOXICITY

Tyramine (*N*-methyl-phenylethyl-amine) is found in *Acacia berlandieri* (guajillo) and two mistletoes, *Phoradendron villosum* and *Viscosum album*. Clinical signs in poisoning by the acacia include gait incoordination, limb weakness, and recumbency, all exacerbated by exercise or harassment, and all of which disappear if the patient is removed from contact with the plant. No signs are attributed to poisoning by mistletoe; in the only event recorded, the patient was found dead.

### AMINO ACID TOXICITY

The best-known toxic amino acids are as follows:

- Indospicine in *Indigofera hendecaphylla* (formerly *I. spicata*, creeping or trailing indigo)
- Indospicine in *Indigofera linnaei* (*I. dominii*, *I. enneaphylla*, Birdsville indigo)

- Canavanine in *Canavalia* spp., *Indigofera linnaei*
- Mimosine in *Leucaena leucocephala* (lead tree) and *Mimosa pudica* (sensitive plant)

### Indospicine/Canavanine

Poisoning by *Indigofera linnaei* has generally been ascribed to indospicine, an arginine analog, and, to a lesser extent, canavanine, also an arginine analog, but a nitrocompound may also be involved. The mechanism of action is an inhibition of nitrous oxide synthesis, decreased glutathione levels, and increased superoxides in hepatocytes.

Indospicine transmitted to dogs fed on meat from poisoned horses is associated with fatal liver damage in the dogs. *Canavalia* spp. and *I. hendecaphylla* in sheep and cattle are associated with a similar syndrome that includes anorexia, icterus, weakness, gait incoordination, and, less commonly, abortion. Horses show anorexia, depression, ataxia, and seizures.

### Mimosine

The nonprotein amino acid mimosine occurs in *Mimosa pudica* (sensitive plant) and *Leucaena leucocephala*, a leguminous fodder shrub.<sup>8,9</sup> Mimosine plus an enzyme in plant tissue produces 3,4-dihydropyridone (3,4-DHP), a potent goitrogen, which on mastication yields 2,3-DHP through the action of rumen flora. Mimosine, 3,4-DHP, and 2,3-DHP are all toxic.<sup>10</sup> Both plants are associated with alopecia, but *Leucaena* spp. is associated with the disease known as “jumbay” (Bahamas) or “lamtoro” (Indonesia). Some varieties of the tree contain more mimosine than others. Safe daily intakes of mimosine are 0.18 g/kg BW for cattle, 0.14 g/kg BW for sheep, and 0.18 g/kg BW for goats. There is a great deal of variation in the effects of poisoning with *L. leucocephala*, depending on the variety of the tree, the amount of other fodder available, and the selection of the feed by the animal.<sup>11</sup> Horses, sheep, cattle, and goats are all affected.

Cattle and goats in Indonesia, Hawaii, and the Virgin Islands, where the tree is indigenous, eat very large amounts of the plant without ill-effect. This immunity is attributable to the adaptation of ruminal microflora to degrade the mimosine, with the degree of degradation varying with the diet and being much greater on a concentrate diet than on a roughage one. A transfer of rumen contents from resistant to susceptible cattle is a successful preventive veterinary procedure. The bacterium capable of degrading the toxins is *Synergistes jonesii*.<sup>10,12</sup> In some areas, if ruminants are introduced to the plant gradually enough, the ruminal microflora may develop the capacity of metabolizing mimosine, and thus poisoning is not a problem. Animals in the areas of concern can be given a *Synergistes*

*jonesii* ruminal inoculum and successfully graze on leucaena pastures without issues.<sup>10</sup>

Loss of wool and hair is the most common sign. Other less frequent signs are anorexia, weakness, thyroid gland enlargement, gingival atrophy, lingual epithelial ulceration, infertility, and low birth weight. In experimental animals, hepatic injury is one of the most marked effects, but this is not recorded in field cases.

In horses the loss of hair is most marked in the mane and tail and around the hocks and knees. Ring formation in the hooves and emaciation also occur. In cattle and sheep, shedding of hair or wool occurs soon (7–14 days) after the first exposure to the plant, when very large amounts are fed. The alopecia is not necessarily general but is symmetric and includes the tail, ears, face, and sheath. Experimental feeding of large amounts of the plant to steers has been associated with hair loss, especially on the tail, pizzle, and escutcheon. Cattle fed on the plant for long periods develop other chronic syndromes, including incoordination, temporary blindness, and hyperactivity to the point of severely interfering with normal handling procedures. A secondary phase of poisoning is associated with the formation of DHP recorded in some countries, but not others. It is characterized by enlarged thyroid glands, poor breeding performance, and goitrous, weak calves. The goitrogenic effect is limited to ruminants, associated with 3,4-DHP, and unresponsive to iodine administration. A further complication, seen in goats on low-level feeding over a long period, is fibrous osteodystrophy of the mandible, causing salivation, slow eating, and weight loss. The long bones are normal.

In pigs, the feeding of diets containing up to 15% of dried *L. leucocephala* to pregnant gilts is associated with a high proportion of fetuses being resorbed and some having limb deformities. Feeding 1% ferrous sulfate in the diet reduces these effects.

Toxic effects are quickly reversible by removing animals from access to the plants, so the case-fatality rate is usually low. Taste aversion conditioning has been successful in an experimental setting and may be in useful in reducing toxicity in those animals that must graze on leucaena pastures.<sup>13</sup> Supplementation of the diet of ruminants with iron, copper, and zinc is also claimed to reduce the toxic effects.

Animals grazing heavily on *L. leucocephala* may have low blood levels of thyroxine and are likely to have high blood and urine levels of DHPs.<sup>9,11</sup> Necropsy lesions are limited to alopecia, oral and esophageal ulcers, and thyroid enlargement.

### ARISTOLOCHINE

Aristolochine, an alkaloid, occurs in the following *Aristolochia* spp.:

- *A. bractea*
- *A. clematitis*—birthwort
- *A. densivena*
- *A. elegans*

In goats, poisoning takes the form of diarrhea, dyspnea, alopecia, and hindlimb weakness. In horses, signs include straining to urinate, passing small amounts of urine frequently, polyuria, and tachycardia.

### CREPENYNIC ACID

Necrosis of cardiac and skeletal muscle, manifested clinically by staggering and recumbency, or sudden death during exercise, is the significant lesion in poisoning of sheep by crepenynic acid, which is found in mature seed heads of *Ixiolaena brevicompta* (button weed).

### CYCAD GLYCOSIDES

All cycads that have been investigated contain one or more glycosides of methylazoxymethanol (MAM) and a neurotoxic amino acid ( $\beta$ -N-methylamino-L-alanine or BMAA). The two common glycosides are cycasin and macrozamin. These include species of the following:

- *Bowenia*
- *Cycas*
- *Dioon*
- *Encephalartos*
- *Lepidozamia*
- *Macrozamia*
- *Stangeria*
- *Zamia*

These robust cone-bearing plants grow in greatest numbers in poor soil in hot climates, and their young leaves and seeds are eaten eagerly by ruminants when other feed is short. Methylazoxymethanol glycosides are more concentrated in seeds than in leaves and roots.<sup>14</sup> The MAM glycosides are hydrolyzed in the rumen to aglycones and sugars. The MAM aglycone is the toxic portion, alkylating DNA and RNA and causing hepatotoxicosis with periacinal hepatocyte necrosis and damage to blood vessels leading to hepatic veno-occlusion. Long-term intake results in liver cirrhosis. The liver lesions result in anorexia, weight loss, jaundice, and photosensitization. In addition, acute poisoning is associated with hemorrhagic necrosis of the abomasum and small intestine in sheep and cattle, causing severe diarrhea. Sheep are more likely than cattle to consume seeds and develop hepato/gastrointestinal MAM poisoning.<sup>14,15</sup> Pigs and horses have been experimentally poisoned with seeds. MAM is mutagenic and carcinogenic in laboratory animals, but this effect has not been described under natural conditions.

The role  $\beta$ -N-methylamino-L-alanine (BMAA) plays in animal toxicosis has not been well established. It is a potent neurotoxin that concentrates in the roots of several *Cycas* spp. and may be associated with or produced by cyanobacteria.<sup>16,17</sup> It has

also been linked to the development of amyotrophic lateral sclerosis/parkinsonism dementia complex present in the Chamorro people in Guam.<sup>16</sup>

An unidentified neurotoxin in *Bowenia*, *Cycas*, *Macrozamia*, and *Zamia* produces posterior ataxia in cattle, a syndrome recognized in Australia, where it is called zamia staggers; some Japanese islands; and in the Caribbean region.<sup>18</sup> This is the most likely result of cattle consuming these plants under natural conditions; however, affected cattle often have some degree of chronic liver damage. This ataxia syndrome in sheep has been produced experimentally but is rare under natural conditions. Clinically, the condition is a proprioceptive defect affecting the hindlimbs causing an irregular, stiff overextension (“goose-stepping”) and knuckling over at the fetlocks. Atrophy of hindlimb muscles and posterior paralysis may follow. There are degenerative lesions of the fasciculus gracilis, dorsal spinocerebellar tracts, and corticospinal tracts of the spinal cord. Affected cattle do not recover.

### GRAYANOTOXINS

Grayanotoxins (synonyms acetylandromedol, andromedotoxins, rhodotoxins) are resinoid substances, members of the diterpenoid group of substances, and found in plants of the Ericaceae (heath), family including:

- *Agauria salifolia*
- *Clethra arborea*—heathers
- *Kalmia* spp.—mountain laurels
- *Ledum* spp.—labrador tea
- *Leucothoe* spp.—sierra laurel, hanahiri
- *Lyonia ligustrina*—staggerbush
- *Menziesia ferruginea*—mock azalea
- *Pieris* spp.—apanese pieris
- *Rhododendron* spp.—azaleas and rhododendrons

Grayanotoxins concentrate in the leaves but are found in all plant parts including the flowers and nectar. The toxins present in nectar are transferred to honey made from these plants and have been associated with poisoning in humans.<sup>19,20</sup> The toxins bind to voltage-dependent sodium channels, slowing their opening and closing, resulting in persistent activation and an increase in axon sodium ion permeability of almost 100-fold.<sup>19,21</sup> At higher doses, calcium channels may be affected as well.

The toxins are very poisonous, with deaths often occurring after plant clippings are thrown into pastures or fed individually by unsuspecting individuals.<sup>20,21</sup> The toxic dose of *Rhododendron* spp. in cattle is 0.2% of their body weight and for *Kalmia* spp. is 0.4% of body weight.<sup>19,21</sup> Cholinergic type signs begin 3 to 14 hours after the plant is eaten and include depression, salivation, projectile vomiting, bloat, repeated swallowing or belching, tenesmus, abdominal pain, and diarrhea.<sup>19–21</sup> Other signs include irregular respirations, blindness, weakness,

recumbency, convulsions, and cardiac arrhythmias (bradycardia, tachycardia, others). Diarrhea is rare. Aspiration pneumonia is a common sequela and is the only common gross necropsy finding.<sup>19,21</sup> Typically the acute signs last for about 24 hours, with 2 to 3 days required for resolution of the neurologic effects.<sup>19</sup>

### ISOQUINOLINE ALKALOIDS

**Berberine**, a pyridine alkaloid, a subgroup of the isoquinoline alkaloids, occurs in the following weeds:

- *Argemone mexicana*—Mexican prickly poppy
- *A. ochroleuca*
- *A. subfusiformis*
- *Berberis* spp.
- *Mahonia* spp.

The clinical syndrome in cattle and pigs includes weight loss, dyspnea, and subcutaneous edema. Diarrhea, abdominal pain, and recumbency are also recorded. At necropsy the principal lesion is cardiomyopathy accompanied by fluid in body cavities and pulmonary edema, and gastroenteritis in some cases. The toxic effect of *A. mexicana* seeds may be attributable to their total content of isoquinoline alkaloids rather than to their berberine content.

**Bulbocapnine** is an isoquinoline alkaloid found in *Corydalis flavula* (fitweed, fumatory) and *Dicentra spectabilis* (bleeding heart) and is associated with a transient syndrome of tremor, tetanic convulsions, frenzy and biting at surrounding objects, opisthotonos, drooling of saliva, and vomiting in grazing ruminants.

**Chelidonine**, a toxic isoquinoline alkaloid found in *Chelidonium majus* (greater celandine or celandine poppy), is associated with a syndrome of gait incoordination, dribbling urine, drooling saliva, and convulsions in cattle, especially if they are harassed.

**Corydaline** is an isoquinoline alkaloid found in *Corydalis caseana* (fitweed) and is associated with acute diarrhea, frenzy and excitement exacerbated by harassment, clonic convulsions, and a quick death in grazing animals. The same toxin in *Dicentra cucullaria* is associated with a similar syndrome, except that vomiting occurs and diarrhea does not. Gastroenteritis is present at necropsy.

### JUNIPERINE

An alkaloid, juniperine occurs in *Juniperus* spp. trees and is reputed to be associated with nephrosis, cystitis, and rumenitis when eaten. Signs include abdominal pain, diarrhea, proteinuria, elevation of blood urea nitrogen (BUN) levels, and abortion.

### RHOEADINE

Rhoeadine is an alkaloid found in the seed capsules of *Papaver rhoeas* (field poppy), and probably *P. nudicaule* and *P. somniferum*, and is associated with restlessness,

hypersensitivity, ataxia, ruminal stasis, dyspnea, and convulsions, but no significant necropsy lesions.

### SAPONIN POISONING

Saponins are naturally occurring glycosides with the physical properties of soaps; that is, they produce a stable froth in water. They have a bitter taste. They also lyse erythrocytes in vitro. There are two classes of saponins, those with a triterpene aglycone radical and those in which the nonsugar radical is a steroid.

#### Triterpene Saponins

In plants, almost all saponins are triterpene saponins. The compounds are concentrated in the rapidly growing shoots, the bark, and the roots, and they are thought to have an insect-repellent role in these sensitive areas of the plant. They are absorbed very slowly, if at all, from the alimentary tract, and it seems unlikely that they will exert any systemic effect unless there is preexisting damage to the intestinal mucosa.

Information regarding the toxicity of triterpene saponins for animals is scarce. The principal pathogenic effect is enteritis and gastroenteritis, manifested by diarrhea and dysentery. Other less common signs include abdominal pain, vomiting, and salivation. The following plants are known to have this effect:

- *Aleurites fordii*
- *Dialopsis africana*
- *Gutierrezia microcephala*
- *Hedera helix*
- *Jatropha curcas*
- *J. hyssopifolia*
- *Phytolacca americana*
- *Phytolacca dioica*—packalacca
- *Phytolacca dodecandra*
- *Saponaria officinalis*
- *Sesbania* spp.

*Bulnesia sarmientii* (Palo santo tree) seed pods and foliage contain an unspecified toxic saponin that is associated with convulsions, licking of forelimbs, geophagia, chewing movements, ruminal atony, bradycardia, and frequent urination and defecation. The bitter taste of saponins may result in a decrease in feed intake and a reduction in growth rate in monogastric animals.

#### Steroidal Saponins

Steroidal saponins are associated with Scandinavian (Norway) photosensitization disease (alveld or “elf fire”) and occasionally nephrosis in ruminants; they occur in the following plants:

- *Agave lecheguilla*
- *Agrostemma githago*
- *Brachiaria decumbens* grass
- *Kochia scoparia*—summer cypress
- *Narthecium ossifragum*—also associated with alveld
- *Panicum* spp. grasses
- *Panicum schinzii*

- *Panicum miliaceum*—French millet
- *Panicum coloratum*—kleingrass
- *Panicum. dichotomiflorum*—smooth witch grass
- *Tribulus terrestris*.

Other *Panicum* spp. grasses that should now be on the suspicious list for this kind of poisoning are as follows:

- *P. decompositum*
- *P. effusum*
- *P. maximum*
- *P. queenslandicum*
- *P. whitei*

Birefringent crystals composed of the glucuronides of epismilagenin and episarsasapogenin formed from an ingested saponin accumulate in the biliary system, blocking it and causing damage to it and surrounding hepatocytes. Jaundice, photosensitization, and hepatitis result. Blockage of the bile canaliculi and bile ducts and filling of hepatocytes, Kupffer, and renal tubules cells by acicular crystals are characteristic. Necrosis of the distal renal tubules, papillary muscles of the heart, and adrenal cortex are accompanying lesions. Other steroidal saponins are present in *Tribulus terrestris*, but they appear to be nonlithogenic.

### SESQUITERPENES

Sesquiterpenes are common plant poisons. Subgroups of them, described elsewhere in this chapter, are as follows:

- Furanoid sesquiterpenes
- Ipomeanols
- Ngaiones
- Sesquiterpene lactones
- Sporidesmin

Unspecified sesquiterpenes are also listed as being associated with other poisonings. For example, *Flourensia cernua* and *Vernonia* spp. are associated with heavy losses in South America and Africa as a result of hepatic necrosis in grazing ruminants. Affected animals show nonspecific signs of anorexia, ruminal atony, hypothermia, staggering gait, recumbency, and convulsions. Serum levels of liver enzymes are elevated, accompanying a massive liver necrosis.

### FURANOID SESQUITERPENES (FURANOSSESQUITERPENOID) POISONING

Furanosessquiterpenoids, including ngaione and myodesmone, are essential oils in the following plants:

- *Lasiospermum bipinnatum*—ganskweed
- *Myoporum* spp.—boobialla, Ellangowan poison bush, and others

Ingestion of these plants usually is associated with jaundice, photosensitization, ruminal stasis, constipation, tenesmus, and abdominal pain. Necropsy findings are limited to hepatic necrosis, jaundice, and photosensitive dermatitis. Ingestion of *L. bipinnatum* by lambs also is associated with the same hepatic insufficiency syndrome, but

the same plant from a different part of a farm may be associated with pulmonary and mediastinal emphysema and interstitial pneumonia reminiscent of the ipomeanols. The fungi *Ceratocystis* spp. is associated with the same problems as *L. bipinnatum*. The following are associated with acute hepatic injury and deaths in ruminants:

- *Myoporum laetum*—ngaio tree
- *Eremophila deserti* (= *M. deserti*)—Ellangowan poison bush
- *M. tetrandrum*—Australian boobialla

### Ipomeanol

Ipomeanols are produced in sweet potatoes in response to infection by the *Fusarium* fungi, *F. solani*, *F. oxysporum*, and *F. javanicum*, and *Ceratostomella fimbriata* and are associated with pulmonary emphysema and edema and interstitial pneumonia when fed to animals.<sup>22-24</sup> Ipomeanols are also suspected of being associated with the poisoning of *Perilla frutescens* (purple mint weed)<sup>25</sup> and *Zieria arborescens* (stinkwood tree). *P. frutescens* is toxic only after the plant has flowered and then loses its toxicity once it has been wilted by frost. Cases appear in calves 3 to 12 days after they begin eating the plant. Pulmonary edema develops because of damage to endothelial cells and young pneumocytes.

*Zieria arborescens*, a small tree in Tasmania and eastern Australia, is associated with interstitial pneumonia in cattle, and the disease is reproducible by feeding the foliage. Clinical signs appear as tachypnea, abdominal, grunting respiration with extension of the head, mouth breathing, and a nasal discharge. In severe cases the temperature and pulse are elevated. Most cases die after an illness of 1 to 21 days. Necropsy lesions include massive pulmonary edema and emphysema.

### Sesquiterpene Lactones

There are very many plant lactones suspected of being poisonous. Plant genera known to owe their toxicity to their content of sesquiterpene lactones include *Centaurea* spp. (especially *C. repens*, *C. solstitialis*), *Chrysanthemum* spp. (associated with contact dermatitis), *Geigeria* spp., *Helenium* spp., *Hymenoxys* spp., *Iphiona aucheri*, and *Parthenium hysterophorus* (parthenium weed).

### Vomiting Syndrome

*Geigeria*, *Helenium*, and *Hymenoxys* spp. poisonings in cattle are associated with a syndrome of regurgitation (spewing sickness, vermeersiekte), salivation, dysphagia, and coughing. An ELISA is available for the quantitative detection of the sesquiterpene lactone dihydrogriesenin in *Geigeria* spp. Contrast radiography of the esophagus and biopsy of skeletal and esophageal muscle are helpful in diagnosis. Dietary supplements used to prevent poisoning by sesquiterpene

lactones, including a soybean meal–sodium sulfate combination, are useful if thiol groups are added to the ration. Urea potentiates the poisoning.

### Encephalomalacia Syndrome

*Centaurea solstitialis* (yellow star thistle) and *C. repens* (Russian knapweed) poisoning in horses is associated with a well-known syndrome of severe depression, constant chewing movements, salivation, tongue flicking, dysphagia, intestinal bloat, paralysis, recumbency, and death.<sup>26</sup> Yawning and somnolence are evident, but the horse is easily aroused. Some horses show aimless, slow walking, and, in the early stages, transient circling. The gait is not grossly abnormal, with a slight stiffness in the walk being the only abnormality except for weakness in the terminal stages. A fixed facial expression is common, with the mouth being held half open or the lips drawn into a straight line. Wrinkling of the skin of the lips and muzzle and protrusion of the tongue are present in many cases. Signs fluctuate in severity for 2 to 3 days and then remain static until the animal dies or is destroyed. Nigropallidal encephalomalacia and fluid accumulations in body cavities are characteristic necropsy lesions. Areas of necrosis or softening are visible macroscopically in the brain, with lesions within the substantia nigra pars reticulata (sparing the dopaminergic cell bodies in the pars compacta) and in the rostral portion of the globus pallidus.<sup>26</sup>

The plants do not appear to be toxic to ruminants, rodents, or monkeys, and sheep do well on sole diets of the plants.

### SELENOCOMPOUNDS

Organic selenocompounds occur in two classes of plants that preferentially accumulate selenium: primary converter or indicator plants that grow only in soils with abnormally high selenium content and secondary converters that grow anywhere but accumulate selenium if it is available. Primary converters are more toxic, attaining levels of greater than 1000 and up to 10,000 ppm.<sup>27</sup> Secondary converters reach levels of about 1000 ppm.

Primary converters include the following:

- *Astragalus* spp.—milk vetch, poison vetch
- *A. bisulcatus*—two grooved milk vetch<sup>27</sup>
- *A. pattersonii*—Patterson's milk vetch
- *A. praelongus*—sinking milk vetch
- *A. pectinatus*—narrow leaf milk vetch
- *A. racemosus*—alkali milk vetch, creamy locoweed
- *Oenopsis condensata*—goldenweed
- *Stanleya pinnata*—prince's plume<sup>27</sup>
- *Xylorrhiza* spp.—woody aster

Secondary converters include the following:

- *Acacia cana*
- *Aster* spp.—woody aster

- *Astragalus* spp.
- *Atriplex canescens*—saltbush
- *Castilleja* spp.
- *Comandra pallidai*
- *Grindelia squarrosai*
- *Machaeranthera ramosa*
- *Morinda reticulata*
- *Neptunia amplexicaulis*
- *Penstemon* spp.
- *Sideranthus* spp.—ironweed

Clinical findings include the common acute form with signs of aimless wandering, circling, apparent blindness, head-pressing, dyspnea, lameness and recumbency, teeth grinding, and salivation. The chronic form is characterized by alopecia, weight loss, coronitis, hoof deformity, and hoof shedding in all species, including pigs. Assay of selenium in the feed is usually necessary to confirm the diagnosis. Daily intakes of more than 30 ppm are usual in the subacute form. In chronic cases the intake is usually below this level and has been maintained for some months.

Necropsy findings are nonspecific and include hepatic, myocardial, and renal injury and erosion of joint cartilage.

### STEROIDAL ALKALOIDS (SOLANUM SPP.)

*Solanum* spp. plants contain many poisonous glycosidic steroidal alkaloids, including solanidine, soladulcidine, solasodine, tomatidine, and others. The most well-known poisonous plants in the group include the following *Solanum* spp.:

- *S. bonariensis*<sup>28</sup>
- *S. dulcamara*—bitter nightshade, bittersweet
- *S. elaeagnifolium*—silver leaf nightshade, white horse nettle
- *S. esuriale*
- *S. fastigiatum*
- *S. kwebense*<sup>29</sup>
- *S. lycopersicum*—tomato
- *S. nigrum*—black nightshade
- *S. pseudocapsicum*—Jerusalem cherry
- *S. triflorum*—cut leaf nightshade<sup>30</sup>
- *S. tuberosum*—potato

The other important members of the genus are *S. malacoxylon* and *S. glaucophyllum*, with the principal association being enzootic calcinosis.<sup>31</sup> *Lycium halimifolium* is also listed as containing these alkaloids.

Acute poisoning with steroidal alkaloids, associated with large doses, appears in experimental animals as a syndrome of gastroenteritis, with diarrhea and necropsy lesions of mucosal necrosis in the stomach and intestines. Subacute poisoning with smaller doses, which are not associated with an enteric lesion but are absorbed, is associated with nervous signs of exercise-induced gait incoordination, easy falling, a straddled gait, nystagmus, and convulsions with opisthotonos, complemented in some cases by cardiac irregularity, hemolysis, and sometimes diarrhea. Records of necropsy lesions include

only occasional references to the presence of encephalomalacia and cerebellar agangliosis associated with the incoordination syndromes. *Solanum esuriale* has been suggested as being associated with humpy back, a common disease in sheep in Australia, but the association is unproven. After forced exercise, affected sheep show gait stiffness in the hindlimbs with shortness of steps. This is followed by an inability to keep walking and the adoption of a peculiar hump-backed stance. The disease occurs only in summer in fully woolled sheep. At necropsy, there is degeneration of spinal cord tracts. In the United States, *S. dimidiatum* is associated with a "crazy cow syndrome" of staggering and incoordination, with a selective loss of Purkinje cells from the cerebellum. A similar syndrome is associated with *S. kwebense* in South Africa (mad drunk disease),<sup>29</sup> one by *S. bonariense* (naranjillo) in cattle in Uruguay,<sup>28</sup> one by *S. cinereum* in goats in Australia, and one by *S. fastigiatum* var. *fastigiatum* in Brazil. The latter appears to be an acquired gangliosis. It is characterized by cytoplasmic membranous bodies in the Purkinje cells and a syndrome identical to that described previously for subacute poisoning with steroidal (*Solanum* spp.) alkaloids. After an attack lasting up to 60 seconds, the animal returns to normal. Affected animals do not recover but do not die unless by misadventure. The animals can be provoked to have an attack by raising their heads or by holding them in lateral recumbency and then letting go.<sup>28,29</sup> It is probable that these are not true "convulsive" diseases but cerebellar incoordination in which frantic efforts by a seriously ataxic animal give a superficial resemblance to convulsive episodes. It is also probable that the lesions in this disease are not associated with steroidal alkaloids but with perhaps with  $\beta$ -carbolines.

Potatoes are toxic only if they are green and sprouted, and the toxic alkaloid solanine is concentrated in those parts; potatoes must constitute more than 50% of the diet before toxicity occurs. Pigs are most commonly affected, but all species are susceptible. In pigs there is dullness, copious diarrhea, anorexia, hypothermia, and coma in the terminal stages. The mortality rate may be high. In horses, the signs include depression and prostration, but usually there are no signs of alimentary tract irritation. In cattle, dermatitis, comprised of vesicles and scabs on the legs, is a more common syndrome. At necropsy in all species there is a moderate hyperemia of the alimentary mucosa. Sprouted or diseased potatoes can be fed safely if they are boiled and the amount fed is restricted to less than 25% of the diet.

There are several anecdotal reports that tomatoes are toxic to horses and ruminants if they are fed green vines and foliage from tomato plants. This was not shown to be the case, at least in beef cattle; they did not

develop any clinical signs other than weight loss after being fed large amounts of tomato foliage for 42 days.

Some of these plants also contain specific teratogenic steroidal alkaloids that contain  $\alpha$ -piperidine moiety. The plants, in decreasing order of toxicity in terms of producing craniofacial deformities in laboratory animals, are as follows:

- *S. elaeagnifolium*
- *S. saccharoides*
- *S. dulcamara*
- *S. melongena*
- *S. tuberosum*

### VELLEIN

The toxin vellein, found in the plant *Velleia discophora*, is associated with hyposensitivity, dyspnea, tachycardia, and recumbency but no specific necropsy lesions.

### VERATRINE

The mixture of alkaloids found in *Veratrum californicum* is associated with a syndrome of salivation, dyspnea, vomiting, diarrhea, frequent urination, cardiac irregularity, and convulsions. The plant also contains the teratogen cyclopamine.

### ZIGADINE (ZIGADENINE)

The phytotoxin zigadine occurs in the plants *Zigadenus* spp. (death camas), especially the bulb, and is associated with a syndrome of salivation, vomiting, tremor, ataxia, and dyspnea. The toxin has been identified in the rumen of dead cattle by electron impact mass spectrometry, avoiding the necessity of identifying the plant botanically.

## TOXICOSIS FROM BREWER'S RESIDUES

Diseases associated with the feeding of by-products of brewing and distilling include the following:

- Carbohydrate engorgement in cattle fed wet brewer's grains
- Possibly spinal cord degeneration in adult cattle fed sorghum beer residues contaminated by *Aspergillus flavus* and containing aflatoxin
- Excess sulfur (>0.45% in the diet) from some methods of processing, which can lead to polioencephalomalacia

## TRICHOTHECENE TOXICOSIS

Trichothecenes (TCT) are the largest group of mycotoxins and are among the most toxic.<sup>1,2</sup> They may produce toxic effects in the liver, kidney, gastrointestinal tract, central nervous system, immune system, or hematopoietic system or adversely affect productivity in many animals.<sup>3-5</sup> Trichothecenes exert these effects through several mechanisms, including inhibition of protein synthesis, inhibition of RNA and DNA synthesis, activation of cytokines, increased lipid peroxidation, dysfunction of mitochondria, and apoptosis.<sup>6,7</sup>

More than 180 TCT mycotoxins have been identified, all containing an epoxy group at the C12 to C13 portion of their chemical structure that is necessary for toxicity.<sup>7,8</sup> This epoxy group is necessary for toxicity.<sup>1,9</sup> They are divided into two different categories, the macrocyclic and the nonmacrocyclic trichothecenes, on the basis of their molecular structure. Chemically, they are divided into four types (A, B, C, D) based on substitutions at five different sites on the TCT molecule.<sup>1,2</sup> Type A contains T-2 toxin, HT-2 toxin, and 4,15-diacetoxyscirpenol (DAS); type B contains deoxynivalenol (DON) and nivalenol (NIV); type C contains crotoxin and baccharin; and type D contains the macrocyclic mycotoxins such as verrucarins, roridin, and satratoxins.<sup>1,2,6</sup>

## MACROCYCLIC TRICHOTHECENES

Trichothecene mycotoxins in this group include satratoxin, verrucarins, roridin and others.

The standard nomenclature for toxicity associated with this group of mycotoxins is retained, stachybotryotoxicosis and myrotheciotoxicosis.

### Stachybotryotoxicosis

Toxins in the fungus *Stachybotrys chartarum* (*S. atra*, *S. alternans*), which is associated with stachybotryotoxicosis, are the macrocyclic trichothecenes, satratoxins G and H, roridin E, and verrucarins J. These mycotoxins are found worldwide as contaminants of wet and decaying straw and hay.<sup>10,11</sup> Horses, cattle, sheep, and pigs may be affected, and the disease is characterized by fever, ruminal atony, diarrhea, dysentery, necrotic ulceration, hemorrhages of the nasal and oral mucosae causing epistaxis and purulent nasal discharge, and conjunctivitis causing lacrimation.<sup>3</sup> Drying and cracking of the skin are visible, especially peri-orbitally and on

the face. At necropsy there are hemorrhages into all tissues and under all serous membranes. An important abnormality is the depression of leukocyte formation, causing agranulocytosis and producing a disease not unlike that associated with bracken poisoning in cattle. Hemorrhages are visible in the mucosae; there is also hemorrhagic enteritis. In sheep, *Pasteurella haemolytica* can often be isolated from tissues. The infection is thought to occur as a result of the immunosuppression associated with the toxins. In horses, there is also a subacute or acute myositis. The disease resembles alimentary toxic aleukia (ATA), associated with the ingestion of toxin from *Fusarium poae* and *Fusarium sporotrichioides*, in humans.<sup>3</sup>

### Myrotheciotoxicosis

Roridin, a toxin in the fungus *Myrothecium roridum* and *Myrothecium verrucaria* growing on rye-grass and white clover plants in pasture, or on stored feeds, is associated with sudden death in sheep and cattle, with necropsy lesions of abomasitis, hepatitis, and pulmonary congestion and edema. Smaller intakes are associated with similar lesions, but over a course of 7 to 10 days. Very small doses administered over a 30-day period are associated with loss of weight but no deaths.

A bizarre involvement in what appears to be a plant poisoning is the role that *M. verrucaria* plays in *Baccharis* spp. poisoning. *Baccharis* spp., including *B. cordifolia*, *B. dracunculifolia*, *B. pteronioides* (synonym *B. ramulosa*), and *B. glomeruliflora*, are associated with tremor, stiff gait, and convulsions and some deaths in cattle and sheep. Roridin, a toxin produced by *Myrothecium* spp. growing in close apposition to the roots of the plants, is absorbed and, when eaten by animals, poisons them. In other plants roridin is lethal to the plant when present in very small amounts.

## NONMACROCYCLIC TRICHOTHECENES

T-2 toxin and deoxynivalenol (DON) are well recognized TCT mycotoxins produced by several different genera of fungi, with many growing on cereal grains. Fungi producing these mycotoxins are not fully defined in terms of which toxins they produce, and many produce more than one. Accordingly, the syndromes described here, and attributed to specific fungi and toxins, are tentative. Any one or combination of them can be implicated in toxicity if they produce the specified toxin at the specified time. A partial list of well-known TCT producing fungi includes the following:

- *Cephalosporium* spp.
- *Fusarium acuinatum*
- *F. culmorum*
- *F. graminearum*
- *F. moniliforme*
- *F. nivale*
- *F. poae*

- *F. roseum*
- *F. semitectum*
- *F. sporotrichioides*
- *F. tricinatum*
- *Trichoderma* spp.
- *Trichothecium* spp.

## T-2 Toxin and HT-2 Toxin

A sesquiterpene compound, the T<sub>2</sub> toxin is produced by several different *Fusarium* species, including *F. acuinatum*, *F. poae*, and *F. sporotrichioides* growing in cereal grains.<sup>1</sup> Occasionally, in areas of uncommonly cool and wet weather, pastures used for animal grazing have been contaminated with *Fusarium* production of T-2 toxin, HT-2 toxin, and other mycotoxins.<sup>6</sup> Species, age, amount or dose of toxin ingested, and route of exposure are important determinants in the level of toxicity and production of signs.<sup>1</sup>

Reported signs associated with poisoning include feed refusal, vomiting, weight loss, diarrhea, rough hair coats, and abortion.<sup>1,6</sup> Historically, T-2 toxin has been associated with a hemorrhagic syndrome, but this has not been a consistent finding. Experimental administration of the purified toxin parenterally produced a range of signs including emesis, posterior paresis, lethargy, hunger, and frequent defecation of normal stools, whereas oral administration of the T-2 toxin or cultures containing it to piglets and calves was associated with hemorrhagic disease. Field evidence of the relationship between the ingestion of the fungus and the appearance of hemorrhagic disease is strong, but the identity of the specific toxic agent may be in doubt. Alternatively, other effects have been reported. Ingestion of T-2 toxin is associated with immunosuppression when fed to laboratory animals, sheep, and pigs. This leads to leukopenia, lymphopenia, and atrophy of lymph nodes, thymus, and spleen. Blood coagulability is reduced because of the toxic effects on platelets.

T-2 toxin fed to pigs is associated with necrotic contact lesions on the snout and commissures of the mouth and the prepuce. Topical application of T<sub>2</sub> toxin to pig skin is associated with initial swelling and purple discoloration, followed by separation and sloughing by day 14. It has also been cited as the probable cause of congenital skin defects about the head and tarsus of pigs. The toxin also is associated with reproductive inefficiency when given experimentally to pigs, causing small litters, repeat breeders, and abortion.

## Deoxynivalenol

Deoxynivalenol (synonym vomitoxin) is a sesquiterpene compound found in *Fusarium graminearum* (*roseum*), *F. culmorum*, and other species. It is a potent central emetic, to which pigs are very sensitive and ruminants more resistant.<sup>6,12</sup> The toxin may be associated with severe vomiting, acute diarrhea, dysentery, ataxia, mucosal hemorrhages, and

sudden death.<sup>6,12,13</sup> The most common field observation about the toxic effect of DON fed to pigs is that it is associated with absolute feed refusal or reduction in weight gain and feed intake.<sup>7</sup> Deoxynivalenol is minimally excreted in the milk and accumulation in swine tissues meant for human consumption is low.<sup>6,12</sup>

The only effective method of preventing losses as a result of deoxynivalenol is to dilute affected corn with uncontaminated feed to levels unlikely to result in toxicosis. Mixing the feed with bentonite, sweeteners, or sodium-calcium aluminosilicate is ineffective as a detoxification method, but rinsing and removing floating material is recommended.<sup>6</sup> Feed toxic to pigs may be utilized by diluting and feeding it to adult ruminants.

### Fusaritoxicosis Syndromes Without Specified Toxins

*F. graminearum* (roseum) produces toxins associated with emesis, refusal of feed, toxins lethal to pigs, and estrogenic substances causing infertility in pigs. *F. culmorum* also is associated with inappetence, scouring, ataxia, and a fall in milk yield when fed to cattle. The fungus *F. moniliforme* is associated with food refusal in cattle. Food refusal is also recorded with zearalenone. Ingestion of *Fusarium xylaroides* infected groundnut hay by cattle has resulted in anorexia, rumen atony, colic, tenesmus, and nasal and rectal hemorrhage.<sup>14</sup> Experimentally, when fed infected groundnut, calves developed diarrhea, weakness, ataxia, and conjunctival and cutaneous hemorrhage. Serum concentrations of urea nitrogen, creatinine, aspartate aminotransferase (AST), and alanine aminotransferase (ALT) were elevated. The toxin has not yet been identified.<sup>14</sup>

### TRITERPENE PLANT TOXICOSIS

Toxic triterpenes include the following:

- Cucurbitacins, tetracyclic triterpenes found in *Cucumis africanus* and *Cucumis myriocarpus*, *Stemodia kingii* and *Stemodia florulenta*, and *Ecballium elaterium*
- Lantadenes A and B, and triterpene acids found in *Lantana* spp.<sup>1</sup>
- Icterogenins A, B, and C in *Lippia* spp.
- Meliatoxins A, A<sub>1</sub>, B, and B<sub>1</sub>, tetranortriterpenes, found in *Melia azedarach* (chinaberry tree)<sup>2</sup>
- Colocynthin, a glucoside found in the fruit of the vine *Citrullus colocynthis* (synonym *Colocynthis vulgaris*).

Cucurbitacins are a group of tetracyclic triterpenes found in the fruits of the vines *C. africanus*, *C. melo* var. *agrestis* (Ulcardo melon), *C. myriocarpus* (prickly pad-dymelon), and *E. elaterium* (squirting cucumber). The ripe fruits are most toxic, and in cattle, sheep, and horses are associated with a syndrome of lethargy, dehydration, abdominal pain, diarrhea, dyspnea, and death in a matter of a few hours. Necropsy findings include edema and necrosis of the ruminal epithelium, intense congestion and

hemorrhage in the intestinal mucosa, pulmonary congestion and edema, and hepatopathy in some cases. Seeds of the plant are conspicuous in the ruminal contents.

Icterogenins and lantadenes are associated with liver damage and nephrosis, neither of which is specific, but the lantadenes cause damage to bile canaliculi, gallbladder paralysis, and intrahepatic cholestasis.<sup>3-5</sup> Jaundice, photosensitization, and ruminal stasis result.<sup>3,4</sup> *Lantana* spp. is a very pungent plant, and cattle will eat it only if other feed is scarce.<sup>6</sup> *Bos taurus* cattle at one time were felt to be more susceptible to lantadene poisoning than *Bos indicus* cattle, but that is no felt to be true.<sup>6</sup> Treatment with activated charcoal or bentonite is effective in decreasing absorption of the toxins.

Pigs are most commonly poisoned by meliatoxins, but cattle, sheep, and goats are also susceptible. Meliatoxin administered to pigs is associated with a syndrome of gastroenteritis manifested by diarrhea, melena, and vomiting, plus dyspnea as a result of pulmonary edema. The toxic dose in pigs is 0.5% of body weight. Pigs fed ground chinaberries at 5 g/kg BW developed mild diarrhea and rapidly recovered. Those fed 10 g/kg BW, 15 g/kg BW, and 20 g/kg BW developed muscle tremors, ataxia, incoordination, and recumbency 2 to 24 hours after dosing. Other observed signs included hypothermia and vocalization (moans, screams). Death occurred in the 20 g/kg BW group.<sup>2,7</sup>

# Reference Laboratory Values

Reference values for some frequently measured variables in blood and serum are provided as a guide. Values of these variables from healthy animals vary depending on many factors, including age, breed, sex, diet, geographical habitat, and methods of sample collection and laboratory measurement. The values listed here are compiled from a variety of sources, including the clinical laboratories of the Western College of Veterinary Medicine at the University of Saskatchewan, the College of Veterinary Medicine at The Ohio State University, and Kaneko JJ. *Clinical biochemistry of domestic animals*, 5th ed. New York: Academic Press, 1997.

Tables of reference values for newborn foals and calves are provided elsewhere.

## 3

# Drug doses and intervals for horses and ruminants

Suggested drug doses and intervals for horses and ruminants are provided here. Dosages listed are general recommendations and might not be optimal or efficacious in all instances and might need to be adjusted depending on the disease and its severity; patient factors, including but not limited to age or diet; and because of regulatory considerations regarding milk and meat withholding times in animals intended as human food. The manufacturer's recommendations should be checked before administering any drug, and the effect on withholding time of varying from the manufacturer's recommendation regarding dosing should be considered. Local regulations regarding use of drugs in animals that could be used for human food should be consulted.

Doses are given in milligrams per kilogram body weight (mg/kg) unless otherwise stated (g = gram, IU = international units). Drugs given as total doses, such as intramammary preparations, are denoted by TD. Dosing interval is given in hours, unless otherwise stated, or unless given as a single dose (SD). The route of administration is indicated as follows: intravenous (IV), intramuscular (IM), oral (PO), subcutaneous (SC), intraarticular (IA), intramammary (IMM), intraperitoneal (IP), inhalation (IH), per rectum (PR), topically (TO), or subconjunctivally (IO). Drugs recommended not to be given to certain species are indicated by NR.

Drug	HORSES			RUMINANTS (CATTLE, SHEEP, GOATS)		
	Dose (mg/kg)	Interval (h)	Route	Dose (mg/kg)	Interval (h)	Route
Acepromazine maleate	0.044–0.088	SD	IM, IV, SC	0.01–0.02 0.03–0.1	SD SD	IV IM
Acetazolamide	2.2	6–12	PO			
Acetylcysteine	8 g, TD (for (retained meconium in foal)	SD	PR			
Acetylsalicylic acid (aspirin)	10–20	48	PO	50–100	12	PO
Acyclovir	10 20	12 8	IV as 1-h infusion (foal) PO (adult)			
Adrenaline; see Epinephrine						
Albendazole	25–50	SD-12	PO	10 7.5	SD SD	PO (cattle, goat) PO (sheep)
Albuterol	0.001–0.008	4–8	IH			
Altrenogest	0.044	24	PO			
Aluminum hydroxide	60	6–8	PO	15–60	SD, 8–24	PO
Amantadine hydrochloride	5	4	IV			
Amikacin sulfate	22 (foals) 10 (adults)	24 24	IV, IM IV, IM	NR		
Aminocaproic acid	40 10–20	SD 6	IV IV			
Amiodarone	Intravenous infusion of 5 mg/kg/h for 1 h, then 0.8 mg/kg/h for 23 h, then 1.9 mg/kg/h; for atrial fibrillation					
Aminopropazine fumarate	0.5	SD	IM, IV			
Amitraz	NR			Goats: 11 mL of 19.9% solution diluted in 7.5 liters		Topical
Ammonium chloride	60–520	24	PO	50–200	12–24	PO
Ammonium molybdate				50–200 TD	24	PO
Ammonium tetrathiomolybdate				1.7–3.4	48	IV; SC (3 treatments)
Amoxicillin sodium	11–50	6–8	IM, IV	22	12	SC
Amoxicillin/potassium clavulanate	15–25	6–8	IV			

Drug	HORSES			RUMINANTS (CATTLE, SHEEP, GOATS)		
	Dose (mg/kg)	Interval (h)	Route	Dose (mg/kg)	Interval (h)	Route

## Drug doses and intervals for pigs

Suggested drug doses and intervals for pigs and concentrations of medicaments in feed are given here. Dosages listed are general recommendations and may not be optimal or efficacious in all instances and may need to be adjusted depending on the disease and its severity, patient factors such as age or diet, and because of regulatory considerations regarding milk and meat withholding times in food animals. The manufacturer's recommendations should be checked before administering any drug, and the effect on withholding time of varying from the manufacturer's recommendation regarding dosing should be considered. Local regulations regarding use of drugs in animals that may be used for human food should be consulted.

Doses are given in milligrams per kilogram body weight (mg/kg) unless otherwise stated (g = gram, IU = international units). Drugs given as total doses are denoted by TD. Dosing interval is given in hours, unless otherwise stated, or unless given as a single dose (SD). The route of administration is indicated as follows: intravenous (IV), intramuscular (IM), oral (PO), subcutaneous (SC), or intraperitoneal (IP). One ton = 1016 kg.

Drug	PIGS		
	Dose (mg/kg) or (Concentration in feed or water)	Interval (h)	Route
Acepromazine maleate	0.03–0.5	SD	IM, IV, SC

Ferrous sulfate	0.5–2	24	PO
Flunixin meglumine	2.2	SD	IM
Follicle stimulating hormone	1000–1500 IU TD	SD	IM
Gallamine triethiodide	4 then 0.8 to effect	SD	IV
Griseofulvin	20	24	PO
Guaifenesin	44–88	SD	IV
Hygromycin B	(12 g/ton)		
Iron dextran	100 mg, TD (piglet)	SD	IM
Ivermectin	0.3	SD	IM
Kaolin pectate	0.2 mL/kg	4	PO
Ketamine hydrochloride (after appropriate premedication)	11	SD	IM
Levamisole	8	SD	PO
Lincomycin hydrochloride	11	24	IM
	2–10 (40–200 g/ton)	24	PO
Luprostiol	7.5 TD	SD	IM
Mannitol	1–2 g/kg	SD	IV (slow)
Marbofloxacin	2 mg/kg	24	IM
Mineral oil	2–8 mL/kg	SD	PO
Morphine sulfate	0.2–0.9	SD	IM
Moxidectin	0.4	SD	SC, PO
Neomycin sulfate	7–12	12	PO
Neostigmine	0.06	SD	IM
Oxfendazole	3 mg/kg once orally	SD	PO
Oxibendazole	15	SD	PO
Oxymorphone	0.075 (with ketamine and xylazine)	SD	IV
Oxytetracycline	2–10 / 10–30	12–24 / 12–24	IM, SC / PO
Oxytocin	0.1–0.2 (agalactia) (2–10 IU)	3–4	IM
Penicillin G, benzathine	4.5 (11000–22000 IU/kg)	48–96	IM
Penicillin G, procaine	6–20 (6000–40000 IU/kg)	12–24	IM
Pentazocine	2.0	SD	IM
Pentobarbital	30 (to effect)	SD	IV

Continued

Drug	PIGS		
	Dose (mg/kg) or (Concentration in feed or water)	Interval (h)	Route
	120–200 (for euthanasia)	SD	IV
Pentobarbitone see pentobarbital			
Phenylbutazone	4	24	PO, IV
Phytomenadione (vitamin K <sub>1</sub> )	0.5–2.5	SD	IM, IV (slow)
Piperazine	110	SD	PO
Prednisolone sodium succinate	0.2–1.0	SD, 24	IV, IM
Pyrantel pamoate	22	SD	PO
	6.6 (pot-bellied pigs)	SD	PO
Pyrantel tartrate	22 (96 g/ton)	SD	PO
Pyriminylamine maleate	0.5–1.0	SD	IM
Roxarsone	182 g/ton		
Sodium arsenilate see arsenilate, sodium			
Sodium chloride (hypertonic, 7.0%)	4 mL	SD	IV
Sodium sulfate	0.25–0.5	SD	PO
Spectinomycin HCl	11	12–24	PO
	6.6–22	24	IM
Streptomycin	13	12–24	IM
Sulfachloropyridazine	44–70	24	PO
Sulfadiazine/trimethoprim	48	24	PO
Sulfadoxine/trimethoprim	15	12–24	IM
Sulfonamide/trimethoprim	15–30	24	IM, PO
Suxamethonium chloride	2	SD	IV
Tetracycline hydrochloride	10–40	12/24	PO
Thiabendazole	50–75	SD	PO
Thiamine hydrochloride (vitamin B <sub>1</sub> )	5–10 mg/kg	SD	IV, IM, PO
Thiamylal sodium	6.6–11	SD	IV
Thiopental	5.5–11	SD	IV
Tiaprost	0.3–0.6 TD	SD	IM
Tiamulin	2–10 / 10–15 (35–200 g/ton)	24 / 24	PO / IM
Tildipirosin	4	SD	IM
Tilmicosin	10–20 (180–360 g/ton)	24	PO
Tripelennamine hydrochloride	1	8–12	IV, IM
Tubocurarine chloride	0.4 then 0.08	SD, to effect	IV
Tylosin	8.8 (40–100 g/ton)	12	IM, PO
Valnemulin	1.25–10	24 / 24	PO
Virginiamycin	(25–100 g/ton)

## C

*C. pseudotuberculosis* biovar *equi*, 1449  
 Cache valley virus disease, 1511b, 1514–1515  
   clinical findings of, 1513  
   clinical pathology of, 1513

in congenital defects, 1836  
 differential diagnosis of, 1513b  
 epidemiology of, 1511  
 necropsy findings of, 1513  
 pathogenesis of, 1512  
 risk factors of, 1512  
 source of infection of, 1512  
 Caddis flies (*Dicosmoecus gilvipes*), 382  
 Cadmium toxicosis, 2181  
 Calcification, arterial thromboembolism, 710  
 Calcinogenic glycoside poisoning, 1504–1505, 1504b–1505b  
 Calcinosis, of cattle, 1390  
 Calcium  
   absorption of, 1482–1483  
   deficiency, 1482–1485, 1483b  
   clinical findings of, 1484  
   clinical pathology of, 1484  
   control of, 1484–1485  
   differential diagnosis of, 1484b  
   epidemiology of, 1483–1484  
   etiology of, 1483  
   necropsy findings of, 1484  
   pathogenesis of, 1484  
   primary, 1484  
   secondary, 1484  
   treatment for, 1484  
 dietary  
   in milk fever, 1677  
   requirements of, 1486t  
 homeostasis, in milk fever, 1677  
 for intestinal absorption, in milk fever, 1686–1690  
 intravenous administration of, 122  
 in macromineral evaluation, 1670  
 metabolism of, 1482–1483, 1483f  
 oral administration of, 122  
 osteodystrophy and, 1388  
 serum  
   osteodystrophy and, 1390  
   vitamin D deficiency and, 1493  
   subcutaneous administration of, 122  
 Calcium borogluconate, 141  
   for hypocalcemia, 121–122  
 Calcium (Ca) borogluconate  
   intravenous, 1684  
   for lactation tetany, of mares, 1737  
   for milk fever, 1684  
 Calcium carbonate  
   crystalluria, 1103  
   iron deficiency and, 814  
 Calcium chloride, 1689  
 Calcium gluconate, 662  
   23%, 141  
   for hypocalcemia, 121–122  
 Calcium versenate, for lead poisoning, 1208–1209  
 Calcium:phosphorus ratio, vitamin D deficiency and, 1493  
 Calf Antibiotic and Sulfa Test (CAST), 168  
 Calf barns, for enzootic pneumonia of calves, 945  
 Calf enterotoxemia, 547  
 Caliciviruses, porcine, 341  
 Calicivirus-like (Norovirus) agent, 389  
 California Mastitis Test, 1918, 1918t  
   for coliform mastitis, 1949  
   for *Corynebacterium bovis*, 1940  
   *Staphylococcus aureus* mastitis and, 1934  
 Calves  
   abdomen, examination of, 455–456  
   abdominal distension in, 456, 456t  
   abdominocentesis for, 190  
   abomasal bloat (tympany) in, 522–523  
   abomasal volvulus, 510  
   acute heart failure and, 707  
   acute undifferentiated diarrhea, 373–377, 374t  
   aortoiliac thrombosis in, 711  
   arthrogryposis, Akabane disease and, 1513  
   auricular vein of, 146, 148f  
   birth, assisted traction and, 1389

## Calves (Cont'd)

bovine immunodeficiency-like virus and, 786  
 carbohydrate engorgement, 462  
 coccidiosis, 401  
 cold injury in, 51  
 colibacillosis in, 1879–1880, 1885–1886  
 congenital defects in, 1839  
 critical temperature in, 1846  
 cryptosporidiosis, 397  
 with diarrhea, 114–115, 143  
   decision tree for, 144f  
   feeding of milk to, 149  
   oral electrolyte solutions for, 149  
 dietary diarrhea, 214  
 digestive tract, examination of, 456  
 doddler, 1331  
 enterotoxemia in, associated with *Clostridium perfringens* type D, 1228, 1230  
 enzootic pneumonia of, 939–946, 939b, 944b, 946b, 946f  
 with experimentally induced infectious arthritis, 1412  
 femoral nerve paralysis in, 1362  
 glomerulonephritis and, 1111  
 hand-fed, abomasal ulcer in, 519  
 heart rates, fetal, 668  
 hemonchosis in, 611–612  
 hepatic enzyme profile of, 629  
 hydranencephaly, Akabane virus and, 1513  
 hypokalemia in, 119  
 hypomagnesemic tetany of, 1706–1707, 1706b–1707b  
 hypothermia in, 1846  
 indigestion from milk replacers, 460–461  
 inherited ataxia of, 1333  
 Johne's disease, 554–555  
 left-side displacement of abomasum (LDA) and, 502, 506  
 malnutrition, 90  
 management, 834–835  
 metabolic acidosis in, 128  
 neonatal, diarrhea of, 582  
 neonatal hypothermia in  
   prevention of, 50  
   risk factors for, 47  
   treatment for, 50  
 neonatal infection in, 1874–1875  
 in neonatal streptococcal infection, 1901–1902  
 newborn, systemic disease in, 956  
 oral fluid therapy in, 147–150  
 otitis media/interna in, 1335  
 parturition, induction of, 1758–1759  
 peritoneal fluid of, 190  
 plasma for, 142  
 portosystemic shunts in, 632  
 prevention of infection in, enzootic bovine leukosis, 840  
 primary copper toxicosis, 2182  
 prolonged gestation with fetal gigantism in, 1828–1829  
 pulmonary edema and, 707  
 radiographs of, 856–857  
 rickets in, 1495  
 septic arthritis synovitis and, 1411–1412  
 septicemia in, 57  
 serum biochemical values of, 1862t  
 sodium bicarbonate 8.4% for, 141  
 temperature, lower critical, 45, 46f  
 terminal colon, atresia, 433  
 transportation stress and, 85  
 unthriftiness (pine) of, 2169  
 vertebral osteomyelitis in, 1346–1347  
 viral diarrhea, 384–393  
   clinical findings, 389  
   differential diagnosis, 391  
   epidemiology, 385–388  
   oral vaccines, 392  
   pathogenesis, 388–389  
 water intoxication in, 116

## Calving

in control and prevention, of infectious diseases, 1877–1879  
 draft-free environment for, 50  
 hypomagnesemic tetany and, 1705  
 seasonal feeding changes and, 1671  
 Calving paralysis, 1362, 1694  
 Cambendazole, poisoning of, 1211  
 Camelids  
   idiopathic nasal/perioral hyperkeratotic dermatosis of, 1563–1564  
   New World, parenteral nutrition for, 151–152  
 Camels, peste des petits ruminants (PPR), 574  
 CAMP test, *Streptococcus agalactiae* mastitis, 1938  
*Campylobacter coli*, 320  
*Campylobacter* infection, antimicrobial sensitivity, 155–156  
*Campylobacter jejuni*, 320  
   mastitis and, 1962  
   water supply contamination, 540  
*Campylobacter lari*, 320  
*Campylobacter perfringens*, diarrhea, 275  
*Campylobacter* spp., wild boar, 2008  
*Campylobacteriosis*, in pigs, 320–322  
 Canada  
   bovine viral diarrhea infection in, 578  
   brucellosis in, 1774  
   ovine progressive pneumonia in, 974  
   ovine pulmonary adenocarcinoma in, 978  
   rabies in, 1239  
 Canadian horsepox, 1576, 1576b

## Liver (Cont'd)

- introduction, 622
- laboratory tests, 626–629
- liver failure and, 631
- manifestations of, 623–625
  - abdominal pain, 625
  - alteration in size of liver, 625
  - black livers of sheep, 625
  - constipation, 625
  - diarrhea, 625
  - displacement of liver, 625
  - edema, 624
  - emaciation, 624
  - hemorrhagic diathesis, 625
  - hepatic encephalopathy, 624
  - jaundice, 623–624, 623f
  - photosensitization, 625
  - rupture of liver, 625
- nervous signs, 631
- with phytotoxins, 645–648
- portal circulation, 623
- primary, 622
- secondary, 622
- systemic involvement, 639–640
- telangiectasis, 635
- treatment in, 629–632
- trematodes, associated with, 641–645
- enlargement of, traumatic reticulopericarditis, 498
- lead in, 1207
- postvaccinal hepatitis, 639–640
- rupture of, trauma at parturition and, 1843
- selenium and, 1471
- ultrasonography of, 1720
- Liver abscess, 632–635, 632b–633b
  - clinical findings, 634
  - clinical pathology, 634
  - control, 635
  - diagnosis, 634
  - differential diagnosis, 634b
  - epidemiology of, 633–634
  - etiology of, 633
  - farm animals, risk factors in, 633–634
  - feed management, 635
  - grain-fed cattle, risk factors in, 633
  - necropsy findings, 634
  - occurrence, 633
  - pathogen risk factors, 633
  - pathogenesis, 634
  - prophylactic antimicrobial therapy, 635
  - treatment, 634, 634b–635b
  - vaccination, 635
  - young lambs, 635
  - see also Hepatic abscess
- Liver atrophy
  - acute, 630
  - in horses, 625
- Liver biopsy, 626
  - alimentary tract, examination of, 190
  - of horses, 626, 632
  - technique, 626
- Liver cobalt, 817
- Liver failure, 743
  - liver disease and, 631
- Liver fluke disease. see Fasciolosis (liver fluke disease)
- Liver function tests, for puerperal metritis, 69
- Liver tumors, 655
- Livestock
  - movement, role of, 2069
  - neighboring, controlling contact by, 39
  - at pasture, history taking of, 7
- Llamas
  - eperythrozoonosis and, 785
  - tooth root abscess in, 77
- Lobeline, 1200
- Local analgesia, laminitis, horse and, 1402
- Local antimicrobials, 162
- Local hyperkeratosis, 1544
- Local spread, of brain abscess, 1190
- Locus for enterocyte effacement (LEE),
  - enterohemorrhagic *Escherichia coli*, 540
- Lolium perenne*, 966

- Long bones, angular deformities of joints of, 1388
- Longus capitis muscle, rupture of, 987, 987f
- Lophyrotoma interrupta*, 654
- Lophyrtomina toxicosis, 654–655
- Lotastralrin poisoning, 827
- Lotusin poisoning, 827

- Louping-ill virus, 777
- Louse infestations, 1623–1625, 1624b
  - chewing lice in, 1624–1625
  - clinical findings and diagnosis of, 1624–1625
  - etiology of, 1624
  - life cycle and epidemiology of, 1624
  - sucking lice in, 1624
  - treatment and control of, 1625
- Low inspired oxygen tension, in hypoxic hypoxia, 847
- Low milk fat syndrome, 1990
- Low serum iron concentration, iron deficiency and, 813
- Lower motor neuron, lesion of, 1163
- Lower motor neuron disease
  - inherited, 1193
  - inherited spontaneous, 1350
- Lower respiratory tract
  - pneumonic pasteurellosis in, colonization of, 916
  - small particles into, in pneumonia, 888
- Low-milk-fat syndrome, 1754
- Lumbosacral cistern, in cerebrospinal fluid collection, 1173, 1173t
- Luminal blockages, 524–525
- Lumpy jaw (actinomycosis), 531–532, 531b
  - differential diagnosis, 532b
  - treatment, 532b
- Lumpy skin disease, 1589–1591, 1589b
  - differential diagnosis of, 1591b
- Lumpy wool, of sheep, 1570–1573
- Lung, rupture of, in pneumothorax, 899
- Lung biopsy, 867–868
  - in heaves, 1008
- Lung parenchyma, diseases of, 880–882
  - acute respiratory distress syndrome in, 892
  - aspiration pneumonia in, 892–893
  - atelectasis in, 883, 883f
  - drowning in, 893–894
  - edema in, 880–882, 881b
  - pneumonia in, 885–892, 885t, 887f, 890b–891b
  - pulmonary abscess in, 894–895, 895b
  - pulmonary congestion in, 880–882, 881b
  - pulmonary emphysema in, 883–885, 884f, 885b
  - pulmonary hemorrhage in, 883, 883f
  - pulmonary hypertension in, 882–883
- Lung sounds, abnormal, heaves in, 1007
- Lungworm
  - in cattle, 961–965, 961b, 963b–964b
  - in goats, 980–981, 980b–981b
  - in horses, 1047, 1047b
  - in pigs, 1086–1087, 1086b
  - in sheep, 980–981, 980b–981b
- Lupinus angustifolius*, 652
- Lycorine, alimentary tract and, 428
- Lyme disease. see Borreliosis
- Lymnaea columella*, 642
- Lymnaea tomentosa*, 642
- Lymnaea truncatula*, 642

## Piglets (Cont'd)

- parturient disease in, 1833–1834
- parturition, induction of, 1759
- porcine coronavirus, 388
- porcine reproductive and respiratory syndrome, 1800
- porcine rotavirus, 387–388
- postnatal disease in, 1834
- postpartum dysgalactia syndrome and, 2000
- septic arthritis synovitis and, 1412
- septicemia in, 57
- streptococcal arthritis and, 1416
- streptococcal infection in, 1901
- teeth clipping of, 1848
- vaccination of, 2131
- viable weight of, 1833

## Pigs

- age-related changes in, 1418–1420
- anaphylaxis of, 750–751
- anthrax in, 2013
- ascariasis, 409–411
- asymmetric hindquarter syndrome of, 1529
- biotin and, 1503
- botulism in, 1368
- bronchitis in, 878
- cerebellar abiotrophy in, 1334
- changes in behavior of, stray voltage, 105
- chlamydial infection in, 2057–2058
- coccidiosis, 402
- congenital cardiac defects and, 704
- congenital progressive ataxia and spastic paresis, 1350
- congenital skin tumors in, 1643
- congenital tremor of, 1355
- control of tuberculosis in, 2023
- copper deficiency, 2170
- cryptosporidiosis, 397
- electrocution of, 104
- eperythrozoosis and serology, 781–784
  - source of transmission, 779
- granulomatous lesions in, 1559
- hemorrhagic shock, 72
- infected by bovine tuberculosis, 2018
  - necropsy findings of, 2021
- inherited congenital hydrocephalus in, 1329–1331
- inherited deficiency in, 1747
- inherited dermatosis vegetans in, 1646
- injections for, selenium, 1475–1476
- iodine deficiency in, 1744
- kidney worm disease in, 1134–1135, 1134b
- lameness in, 1418–1424
- laryngitis in, 878
- lead poisoning in, 1206
- leptospirosis and, 1118, 1122
- listeriosis in, 1340
- lungworm in, 1086–1087, 1086b
- with *M. bovis*, 2017
- major pathogenic *Mycoplasma* spp. of, 885t
- malignant catarrh in, 2080
- malignant catarrhal fever, 2079
- meloidosis, clinical findings, 2030
- methicillin-resistant *Staphylococcus aureus* in, 1566–1567
- muscular dystrophy in, 1470
- mycobacteriosis associated with MAC and with atypical mycobacteria, clinical and necropsy findings of, 2025
- mycoplasmal hyosynoviae in, 1455–1456
- neonatal, iron toxicosis, 2188
- neonatal infection in, 1874
- newborn
  - splayleg syndrome in, 1529–1530
  - splaylegs of, 1378
- organophosphorus poisoning in, 1215
- osteochondrosis and, 1409
- osteodystrophia fibrosa in, 1388, 1498
- osteomalacia in, 1497
- otitis media/interna in, 1335–1336
- parasitic gastritis in, 417–418
- phosphorus deficiency in, 1487

- phosphorus requirements for, 1491
- pleuritis in, 896
- pleuropneumonia of, with *Actinobacillus pleuropneumoniae*, 1055–1064
- pneumonia in, 886
- primary vitamin A deficiency in, 1322
- pruritus in, 1543
- pseudorabies in, 1248
- rabies in, 1241
- reactivity to voltage levels, 105
- reproductive performance, selenium and vitamin E deficiency, 1465
- respiratory tract of, diseases of, 1047–1054
  - rhinitis in, 874
- ricketts in, 1495
- selenium and vitamin E deficiency and, 1472–1473
- selenium supplementation in, 1475
- selenium-responsive reproductive performance in, 1477–1478
- septic arthritis synovitis and, 1412
- septicemia in, 57
- Streptococcus suis* infection, 2045–2051, 2045b
- thiamine deficiency in, 1319
- thick forelimbs of, 1537
- thorny-headed worm in, 419
- tracheitis in, 878
- transfer of selenium and vitamin E in, 1467
- tuberculin testing in, 2020
- tularemia, clinical findings, 2028
- ulcerative dermatitis of, 1579–1580
- vesicular stomatitis, 396
- vitamin E-selenium deficiency in, 1470
- water medication of, 161
- zinc toxicosis
  - acute poisoning, 2195
  - chronic poisoning, 2195
- Pilobolus*, 962
- Pinching, 1174

- Pituitary abscess syndrome, 1191, 1191b
- Pituitary gland
  - abscesses of, 1191
  - adenoma of the pars intermedia of, 1221
  - hypophysis of, 1221
- Pituitary pars intermedia dysfunction, equine, 1727–1731
  - clinical findings of, 1727–1728
  - clinical pathology of, 1728
  - control of, 1730
  - diagnostic confirmation of, 1728–1730, 1729t
  - differential diagnosis of, 1730b
  - epidemiology of, 1727
  - etiology of, 1727
  - necropsy findings of, 1730
  - pathogenesis of, 1727
  - treatment of, 1730
- Pityriasis, 1543–1544
- Pityriasis rosea, 1544, 1648
  - differential diagnosis of, 1648b
  - treatment of, 1648
- Pizzle rot, 1152, 1152b–1153b
  - differential diagnosis of, 1154b
  - treatment and prophylaxis of, 1154b
- Placenta
  - abnormalities, in cloned offspring, 1871
  - in ovine enzootic abortion, 1787

- premature-like signs, in foals, 1843
- retained fetal, selenium and vitamin E deficiency and, 1465
- retention of, 68
- Placental cotyledons, 1787
- Placentitis
  - brucellosis associated with *Brucella ovis*, 1775
  - precocious lactation and, 1843
- Plant phenols (gossypol and tannins), 2207
- Plant poisoning, 1506
  - caused by toxins, 1137
  - in interstitial pneumonia, 966
  - miscellaneous, 1137
  - from unidentified toxins, 1137
  - volcanic ash fallout, 109
- Plant toxicosis, miscellaneous, 2207–2212
- Plants
  - abortion and, 1827
  - affecting nervous system, 1195, 1203
  - awns or spines, stomatitis, 192
  - causing pulmonary disease, 1088
  - containing hepatotoxins, 1550
  - containing steroidal saponins, 1550
  - materials, causing physical damage, 427
  - poisoning
    - associated with known toxins, 1637
    - associated with unidentified toxins, 1637–1638
  - selenium in, 1461
  - toxins, affecting the alimentary tract, 427–429
  - unidentified toxins, affecting the gastrointestinal tract, 429
- Plaque
  - in dourine, 1820
  - peste des petits ruminants, 575
- Plasma, 142, 1864
  - decreased oncotic pressure in, 128–129
  - hyperimmune, 142
  - in neonatal infection, 1877
  - pH, 124
  - transfusion, hypofibrinemia and, 719
  - transfusion of, in newborn, 1864
- Plasma  $\delta$ -aminolevulinic acid, in lead poisoning, 1207
- Plasma fibrinogen concentration, in *Rhodococcus equi* pneumonia, 1016
- Plasma glucose, and naturally occurring combined abnormalities of free water, electrolyte, acid-base balance, and oncotic pressure, 134–135
- Plasma L-Lactate concentration
  - and anion gap, 135
  - and naturally occurring combined abnormalities of free water, electrolyte, acid-base balance, and oncotic pressure, 134
- Plasma oncotic pressure, 882
- Plasma potassium concentration, in acute hypokalemia, 1691–1692
- Plasma protein, naturally occurring combined abnormalities of free water, electrolyte, acid-base balance, and oncotic pressure and, 132
- Plasma transfusion, for endotoxemia, 66
- Plasmacytoma, 745–746
- Plasmid-determined antimicrobial resistance, 156–157

## R

Rabbits, Johne's disease in, 570  
 Rabies, 1239b, 1269–1272  
     animal vectors for, 1239  
     clinical findings of, 1240–1241  
     clinical pathology of, 1241  
     control of, 1243  
     differential diagnosis of, 1244b  
     economic importance of, 1240  
     epidemiology of, 1238  
     etiology of, 1238  
     furious in, 1243  
     intraspecific transmission of, 1241  
     latent infection of, 1239–1240  
     necropsy findings of, 1241–1242  
     paralytic form in, 1243  
     pathogenesis of, 1240  
     postexposure vaccination for, 1243–1244  
     preexposure vaccination for, 1243  
     prevention of exposure to, 1243  
     quarantine and biosecurity, 1244  
     samples for diagnostic confirmation of, 1242  
     seasonal spread of, 1239  
     transmission methods of, 1239–1242  
     treatment for, 1243  
     vaccination of wildlife for, 1244–1247  
     vaccines for, 1244  
     virus variant distribution of, 1239  
     zoonotic implications of, 1239–1240  
 Racehorses  
     anemia, 734  
     benign atrial fibrillation, 681  
     gastric ulcers in, 247–248  
     poor performance, 97–99  
     vaccines for, in equine influenza, 1037–1038  
 Radial immunodiffusion, in assessment of transfer of passive immunity, 1853  
 Radial nerve, traumatic damage to, 1359f, 1362  
 Radiation injury, 107–109, 107b  
     acute syndrome, 108  
     case fatality, 107  
     chronic exposure, 108  
     clinical findings in, 108  
     clinical pathology of, 108  
     control of, 108–109  
     diagnosis of, samples for confirmation of, 108  
     differential diagnosis of, 108b  
     epidemiology of, 107–108  
     etiology of, 107  
     incidence of, 107  
     nature of radiation in, 107  
     necropsy findings in, 108  
     pathogenesis, 108  
     risk factors for, 107  
     subacute syndrome, 108  
     zoonotic implications, 107–108  
 Radiation therapy, for sarcoid, 1587  
 Radioactive isotopes, protein-losing enteropathy, 186  
 Radiographic examination  
     in caudal vena caval thrombosis, 902  
     in equine pleuropneumonia, 992  
     in exercise-induced pulmonary hemorrhage, 1000

- Radiographic examination (*Cont'd*)  
 in guttural pouch empyema, 985–986  
 in heaves, 1007  
 in nasal discharge, 854  
 in progressive atrophic rhinitis, 1051  
 in respiratory system, 856–857, 857b, 857f  
 in *Rhodococcus equi*, 1015  
 uroperitoneum in foals and, 1142
- Radiography  
 abdomen examination, 452–453  
 abdominal, 183–184  
 cardiovascular system examination, 673  
 caudal abdominal obstruction, 254  
 for degenerative joint disease, 1405, 1410, 1500  
 enterolith, 265, 266f  
 for equine cervical vertebral stenotic myelopathy, 1354f, 1359  
 equine colic, 229, 239  
 esophageal, 183  
 gastric dilatation, in horses, 241  
 gastric ulcers, 245  
 for laminitis  
   horse and, 1400, 1400f–1401f  
   in ruminants and swine, 1405  
 of liver, 626  
 monitoring of lesions in, lameness in pigs and, 1423  
 for musculoskeletal system disease, 1376  
 in nervous system examination, 1175–1176  
 for osteodystrophy, 1390  
 for osteomyelitis, 1393  
 pericarditis and, 709  
 reticulum, 486  
 for rickets, 1496  
 sand colic, 266, 267f  
 for septic arthritis synovitis, 1414  
 for urachitis, 1901  
 urinary system examination, 1107–1108  
 urolithiasis and, 1148
- Radioimmunoassay, 838–839
- Radioimmunoprecipitation assay, 838
- Radionuclides, 107
- Radiosensitivity, 107
- Rafoxanide, 614
- Ramaria flavo-brunnescens*, 2204
- Ranitidine  
 for abomasal ulcer, 522  
 gastric ulcers, 245, 246t, 251
- Rat-tail syndrome, 602, 1644–1645
- Rattling sounds, 852
- RDA. *see* Right-side displacement of the abomasum (RDA)
- Rebreathing (“bagging”) examination, 850
- Receptors, of porcine reproductive and respiratory syndrome virus, 1800
- Reciprocal translocation, 1828
- Recombinant bovine somatotropin, 1665  
 in bovine mastitis, risk factor of, 1910  
 in mastitis control program, 1979
- Recombinant human erythropoietin, 736
- Recommended dose, of antimicrobial therapy, 154
- Record keeping, biosecurity and, 41
- Rectal biopsy, 190  
 diarrhea, chronic undifferentiated, 281  
 granulomatous enteritis, of horses, 282
- Rectal examination, 20–21  
 aortoiliac thrombosis, 710  
 cecal dilatation/ceocolic volvulus, 529, 530f  
 diarrhea, acute, 278  
 enteritis, proximal, 256  
 enteroliths and fecaliths, 265  
 equine colic  
   foals, 239  
   postparturient mare, 236–237  
 equine grass sickness, 284–285  
 gastric dilatation, in horses, 241  
 large (ascending) colon, impaction, of horses, 264  
 left dorsal displacement, of large colon, 261  
 left-side displacement of abomasum and, 506  
 peritonitis, 218  
 rectal tear, 272–273  
 reticuloperitonitis, traumatic, 485  
 retroperitoneal abscess, 270  
 right dorsal displacement, of large colon, 261–262  
 small colon obstruction, 268  
 urinary system examination, 1130  
 vagus indigestion, 493  
 volvulus, of large colon, 262
- Rectal pack, 272
- Rectal palpation, 449  
 abdomen, of cattle, 449, 450f  
 of enzootic bovine leukosis, 833  
 of pregnancy, 1837  
 sand colic, 266  
 “Rectal paralysis,” luminal blockage, 525
- Rectal prolapse, 291, 434  
 in pigs, 291–292  
 postparturient mare, equine colic, 236–237  
 small colon obstruction, 268
- Rectal stricture, 292
- Rectal tears, 271–273  
 classification, 271–272  
 clinical pathology, 272  
 clinical signs, 271–272  
 epidemiology, 271  
 etiology, 271  
 iatrogenic rupture, 271  
 pathogenesis, 271  
 prevention, 273  
 prognosis, 272  
 risk factors, 271  
 spontaneous or noniatrogenic rupture, 271
- Rectovaginal constriction, inherited, 434
- Recumbency  
 duration of, 1694  
 experimental sternal, 1695  
 horses  
   complications and prevention, 2006  
   diagnosis and care, 2003–2006, 2004t–2005t  
   epidemiology, 2003  
   examination, 2003–2006  
   history, 2003  
   management and care, 2006  
   myopathy and, 1386  
   physical examination, 2003–2006  
   laminitis, horse and, 1400  
   prolonged, 1694–1695
- Recumbent animal, 1173–1174
- Recurrent airway obstruction, 1003–1012, 1003b, 1005f, 1008f, 1009b
- Recurrent laryngeal neuropathy, 989–991, 990b
- Recurrent uveitis, leptospirosis, 1121
- Red cell aplasia, 731–734
- Red cell function, abnormal, 744–745
- Red clover (*Trifolium pratense*), poisoning in, 1822
- Red deer, farmed  
 selenium and, 1472  
 selenium subcutaneous injections for, 1475–1476
- Red fire ant stings (*Solenopsis invicta*), 2179
- Red foot disease, of sheep, 1646
- Red maple leaf (*Acer rubrum*) toxicosis, 837–838
- Red squill (sea onion), 2191
- Red urine, caused by pigmented substance from plant, 1137
- Red water disease. *see* Bacillary hemoglobinuria
- Reduction, of progressive atrophic rhinitis, 1053
- Redworm infestation, 411–415
- Reference range  
 laboratory data and, 23–24  
 problems with, 24
- Reflux  
 enteritis, proximal, 256  
 equine colic, 228–229, 232
- Regional ileitis, 209, 324
- Regional limb perfusion, septic arthritis synovitis and, 1416

  - host risk factors of, 1442
  - methods of transmission of, 1441
  - necropsy findings of, 1444
  - pathogenesis of, 1443
  - scoring systems for, 1443
  - source of infection of, 1441
  - symptomless carriers for, 1443–1444
  - treatment for, 1444–1447, 1446b
  - vaccination for, 1447
- inherited congenital hydrocephalus in, 1329–1331
- inherited goiter in, 1747
- interstitial pneumonia in, 967
- intestinal obstruction in, 528–530
- intraruminal selenium pellets for, 1478
- iodine deficiency in, 1744, 1745f
- laryngitis in, 878
- lead poisoning in, 1204–1206
- leptospirosis and, 1117–1118, 1122
- listerial abortion in, 1338
- listerial encephalitis/meningitis in, 1337–1338
- lumpy wool of, 1570–1573
- lungworm in, 980–981, 980b–981b
- lymphosarcoma, outbreaks of, 837
- with *M. bovis*, 2017
- mastitis of, 1991–1993, 1993b
  - differential diagnosis of, 1993b
- maternal nutrition in, 1847
- meliodosis, clinical findings, 2030
- methicillin-resistant *Staphylococcus aureus* in, 1567
- mycobacteriosis associated with MAC and with atypical mycobacteria, clinical and necropsy findings of, 2025
- Mycoplasma* spp. of
  - diseases of the respiratory tract associated with, 924
  - major pathogenic, 885t
  - neuraxonal dystrophy of, 1353–1354
  - nonprotein nitrogen toxicosis in, 619
  - nutritional advice for, 1751–1752
  - organophosphorus poisoning in, 1215
  - osteogenesis imperfecta in, 1532
  - parenteral nutrition for, 151–152
  - pasteurellosis of, 2042–2043
  - periparturient period in, 1662–1667
  - phosphorus deficiency in, 1487
  - plasma and liver copper in, 2171–2172
  - pleuritis in, 896
  - pneumonia in, 886
  - posthitis and, 1153
  - postshearing hypothermia in, 48
  - primary copper toxicosis, 2182
  - pruritus in, 1543
  - pseudorabies in, 1248
  - psoroptic mange in, 1621
  - pulmonary and pleural neoplasms in, 1088
  - rabies in, 1240
  - red foot disease of, 1646
  - reproductive performance, selenium and vitamin E deficiency, 1465
  - respiratory tract, diseases of, 969–970
  - rhinitis in, 874
  - salmonellosis, 358
  - salt-mineral mixture for, 1476–1477
  - sarcocystosis, 2139
  - seasonal allergic dermatitis in, 1560–1561, 1561f
  - selenium subcutaneous injections for, 1475–1476
  - selenium-responsive reproductive performance in, 1477
  - septic arthritis synovitis and, 1412
  - septicemia and thrombotic meningoencephalitis in, associated with *Histophilus somni*, 2038–2039, 2038b
  - septicemia in, 57
  - shorn, hypothermia in, 49
  - slow-release treatments in, 2175
  - starvation in, 90
  - strawberry footrot of, 1575–1576
  - systemic mycoplasmoses of, 971t
  - temperature, upper critical, 52
  - tick-borne fever and, 777–778
  - tooth root abscess in, 77
  - toxoplasmosis, 2142
  - tracheitis in, 878
  - transportation, stress, 85
  - tuberculin testing in, 2020
  - tularemia, clinical findings, 2028
  - ulcerative dermatosis of, 1596
- Sheep ked (*Melophagus ovinus*), 1623–1624
- Sheep scab, 1621–1622
  - differential diagnosis of, 1622b
- SheepMAP, 571–572
- Sheepox, 1591–1593, 1591b
  - differential diagnosis of, 1592b
- Sheepshad, 1534–1535

## V

### Vaccination

- African horse sickness, [2096](#)
- Akabane disease, [1513](#)
- anaplasmosis and, [775–776](#)
- babesiosis of, [805–806](#)
- bacillary hemoglobinuria, [637](#)
- black disease, [638](#)
- for blackleg, [1432](#)
- bluetongue, [2075–2076](#)
- bovine digital dermatitis, [1440](#)
- bovine footrot, [1435](#)
- caseous lymphadenitis, [775–776](#)
- coccidiosis, [408](#)
- coliform gastroenteritis, [319](#)
- enterohemorrhagic *Escherichia coli* (EHEC), [539](#), [542](#)
- enterotoxemia

  - Clostridium perfringens* associated, [548](#)
  - Clostridium perfringens* type D associated, [1232](#)

- environmental streptococci, [1957](#)
- enzootic bovine leukosis, [840](#)
- epizootic hemorrhagic disease and, [785–794](#)
- equid herpesvirus-1 myeloencephalopathy, [1287–1290](#)
- erysipelas in swine, [2056](#)
- fasciolosis (liver fluke disease), [645](#)
- foot-and-mouth disease, [2065–2067](#)
- for Glässer's disease, [1454](#)
- hemochromosis, [613](#)
- Histophilus* septicemia, [2038](#)
- in increasing specific resistance of the newborn, [1897](#)
- infectious footrot in sheep, [1447](#)
- John's disease, [563–564](#), [571](#)
- laminitis, ruminants and swine and, [1405](#)
- leptospirosis and, [1127–1128](#)
- porcine intestinal spirochetosis, [337](#)
- porcine proliferative enteropathy, [326–327](#)
- of pregnant dam, [392](#)

- Vaccination (*Cont'd*)  
 rabies, [1244](#)  
 serum-virus, [2109](#)  
 for *Streptococcus agalactiae* mastitis, [1939](#)  
*Streptococcus suis* infection, [2050](#)  
 with subunit vaccines, 809  
 swine dysentery, 334  
 Venezuelan viral encephalomyelitis, [1284](#), [1297t](#)  
 viral diarrhea, 391–393  
 West Nile encephalitis, [1271](#)  
 Western encephalitis, [1278](#)  
 winter dysentery, of cattle, 601
- Vaccines  
 for acute undifferentiated bovine respiratory disease, 911b, 912–913  
 for African swine fever (ASF), [2117](#)  
 attenuated, [2109–2110](#)  
 for Bang's disease, [1770–1772](#)  
 for *Bordetella* rhinitis, 1055  
 for bovine herpesvirus-1 infection, 958–960  
 for bovine respiratory syncytial virus, 951  
 for brucellosis, [1776–1778](#), [1784](#)  
 for contagious bovine pleuropneumonia, 931  
 contaminated, with bovine viral diarrhea virus, 580  
 for enzootic pneumonia of calves, 945–946, 946f  
 for equine hendra virus infection, 1045  
 for equine herpesvirus-1 and -4 infections, 1042  
 for equine influenza, 1036–1037  
 inactivated, [2110](#)  
 killed-virus, [2069](#)  
 live attenuated, [2069](#)  
 for lungworm, 964  
 for *Mannheimia haemolytica*, 922–923  
 mutagen attenuated, [2069](#)  
 for *Mycobacterium avium* subspecies paratuberculosis (MAP), 563  
 for *Mycoplasma bovis*, 938  
 for *Mycoplasma* mastitis, [1942](#)  
 for *Mycoplasma* pneumonia, 1070  
 for ovine enzootic abortion, [1787–1791](#)  
 for ovine progressive pneumonia, 977  
 for peste des petits ruminants, 576  
 for pleuropneumoniae, of pigs, 1063  
 for pneumonic pasteurellosis, 922–923  
 for porcine reproductive and respiratory syndrome, [1812–1814](#)  
 for progressive atrophic rhinitis, 1053–1054  
 for Q fever, [1793](#)  
 for respiratory tract disease, 873  
 for Rift Valley fever, [2069](#)  
 for septicemic pasteurellosis of cattle, [2042](#)  
 for strangles, 1024–1026  
 for swine influenza, 1083
- Vacuum regulator, [1971](#)  
 Vacuum reserve tank, [1970–1971](#)  
 Vaginal discharge, in postpartum dysgalactia syndrome, [1999](#)  
 Vaginal examination, postparturient mare, 237  
 Vaginal fluid, analysis of, 68–69  
 Vagus indigestion, 490–496, 490b–491b  
 clinical findings in, 493–494, 493f  
 clinical pathology, 494  
 differential diagnosis, 494b–495b  
 epidemiology of, 491  
 etiology of, 491  
 necropsy findings, 494  
 pathogenesis of, 491–493  
 prevention, 496  
 reticulorumen contractions in, 446, 448  
 treatment, 495–496, 496b
- Vagus nerve, 437, 440, 491  
 assessment of, [1169](#)
- Valve lesions, murmurs and, 685–686  
 Valve predilection, endocarditis, 689  
 Valvular abnormalities, 706  
 Valvular defects, echocardiography and, 672
- Valvular disease, 685–688, 685b  
 acquired, 685  
 cattle, 685  
 clinical findings of, 686–688  
 clinical pathology of, 688  
 congenital, 685  
 differential diagnosis of, 688b  
 effects of, 686  
 epidemiology of, 685  
 etiology of, 685  
 examination of, 686–687  
 heart failure, chronic (congestive), 659  
 horses, 685  
 insufficiency of, 687  
 necropsy findings of, 688  
 pathogenesis of, 685–686  
 pigs, 685  
 stenosis of aortic valve, 688  
 treatment of, 688
- Vanadium toxicosis, [2193](#)  
 Vancomycin, 174  
 Vancomycin-resistant enterococci (VRE), 157  
 Vanilloids, for pain, 83  
 Vap A, in *Rhodococcus equi* pneumonia, 1013–1014  
 Variable surface proteins (VSPs), in *Mycoplasma bovis*, 933
- Vascular obstruction, gangrene from, [1558](#)
- Vasculitis  
 bovine virus diarrhea virus infection, 584  
 hemorrhage and, 721  
 necrotizing, 721

# How to Use This Book

We would like you to get the most out of this book. To do that, you should follow the directions provided in this section. And if you keep doing this every time you use the book, you will develop a proper diagnostic routine of going from:

... and become what we wish for every one of you: a thinking clinician.

## FOR EXAMPLE

A yearling bull has a sudden onset of dyspnea, fever, anorexia, abnormal lung sounds, and nasal discharge.

**Step 1** The bull's problem is dyspnea. Go to the index and find the principal entry for dyspnea.

**Step 2** The discussion on dyspnea will lead you to respiratory tract dyspnea and cardiac dyspnea.

**Step 3** Via the index, consult these and decide that the system involved is the respiratory system and that the lungs are the location of the lesion in the system.

**Step 4** Proceed to diseases of the lungs and decide on the basis of the clinical and other findings that the nature of the lesion is inflammatory and is pneumonia.

**Step 5** Proceed to pneumonia, and consult the list of pneumonias that occur in cattle. Consult each of them via the index and decide that pneumonic pasteurellosis is the probable specific cause.

**Step 6** Proceed to the section on pneumonic pasteurellosis and determine the appropriate treatment for the bull and the chances of saving it.

**Step 7** Don't forget to turn to the end of the section on pneumonic pasteurellosis and remind yourself of what to do to protect the rest of the herd from sharing the illness.

## Guidelines for Selection and Submission of Necropsy Specimens for Confirmation of Diagnosis

In this edition we continue with the subheading *Samples for Confirmation of Diagnosis* to serve as a rough guideline for the collection of samples at necropsy. Several points must be emphasized with regard

to this section. First and foremost, **collection of these samples is not advocated as a substitute for a thorough necropsy examination.** Furthermore, the samples listed are selected to confirm the diagnosis, but a conscientious diagnostician should also collect samples that can be used to rule out other disease processes. Even the best of practitioners can make an incorrect tentative diagnosis, but it is an even more humbling experience if there are no samples available to pursue alternate diagnoses. Also, recall that some diseases may be the result of several different etiologic factors (e.g., neonatal diarrhea of calves), and the veterinarian who samples to confirm one of these factors but does not attempt to investigate others has not provided a good service to the client.

A huge variety of veterinary diagnostic tests have been developed, but each veterinary diagnostic laboratory (VDL) offers only a selected panel, chosen after consideration of a number of factors. Such factors may include cost, demand, reliability, sensitivity and specificity, and the availability of appropriate technology at the lab. The array of diagnostic tests is constantly improving, and it is beyond the scope of this text to list all the tests available for a given disease or to recommend one test method to the exclusion of others. Under the *Samples for Confirmation of Diagnosis* sections, we have merely listed some of the more common tests offered. Advances in molecular biology are providing exciting avenues for disease diagnosis, but many of these tests have limited availability in VDLs at present. For optimal efficiency in the confirmation of a diagnosis at necropsy, the practitioner must contact the VDL to determine what tests are offered and to obtain the preferred protocol for sample collection and submission to that particular laboratory. Most VDLs publish user guidelines, which include the tests available and the samples required. The guidelines listed here are broad, and individual VDLs may have very specific requirements for sample handling.

Several general statements can be made with regard to the submission of samples to VDLs:

- The samples should be accompanied by a clearly written and concise clinical history, including the signalment of the animal and feeding and management information. Failure to provide this information deprives the owner of the full value of the expertise available from the laboratory staff.
- If a potentially zoonotic disease is suspected, this should be clearly indicated in a prominent location on the submission form.
- All specimens should be placed in an appropriate sealed, leak-proof container and clearly labeled with a waterproof marker to indicate the tissue/fluid collected, the animal sampled, and the owner's name. At some VDLs, pooling of tissues within a single bag or container is permitted for specific tests (such as virus isolation), but in general, all fresh samples should be placed in separate containers. When packaging samples for shipment, recognize that condensation from ice packs and frozen tissues will damage any loose paper within the package; the submission sheet should be placed within a plastic bag for protection or taped to the outside of the shipping container.
- Samples for histopathology can be pooled within the same container of 10% neutral-buffered formalin. An optimal tissue sample of a gross lesion should include the interface between normal and abnormal tissue. For proper fixation, tissue fragments should not be more than 0.5 cm in width, and the ratio of tissue to formalin solution should be 1:10. If necessary, large tissues such as brain can be fixed in a larger container and then transferred to a smaller one containing only a minimal quantity of formalin for shipping to the laboratory. To speed fixation and avoid artifactual changes, formalin containers should not be in direct contact with frozen materials during shipment.

- In the *Samples for Confirmation of Diagnosis* sections, the tests are listed under various discipline categories (bacteriology, virology, etc.). The appropriate sample(s) is noted, followed by the types of test that might be applied to these samples. The following is a list of these different tests, including any abbreviation used in this section of the text. A brief discussion of how the samples collected for each test should be handled is also provided. Again, it must be emphasized that this is by no means a complete listing of diagnostic tests available, and different VDLs often have differing sample handling procedures.
- **Aerobic culture** = (CULT). These samples should generally be kept chilled during shipment. If a transit time of greater than 24 hours is anticipated the samples should be frozen, then packaged appropriately so that they are still frozen upon arrival at the VDL. Various bacterial species cannot be recovered using routine culture techniques, and most of these are highlighted in the text by the phrase “special culture requirements.”
- **Agar gel immunodiffusion** = (AGID). A type of serologic test. Chilled or frozen serum may be submitted.
- **Anaerobic culture** = (ANAEROBIC CULT). Confirmation of the diagnosis requires that any swabs be transported in special transport media and that the VDL attempts to grow bacteria from the samples under anaerobic culture conditions. Transport requirements are as for (CULT) (aerobic culture) specimens.
- **Analytical assay** = (ASSAY). This refers to a broad range of tests in which a substance is quantitatively measured. The substance to be assayed is listed in brackets, e.g. (ASSAY [Ca]) denotes a test for calcium levels. The method used to perform the assay is not listed, but in general, frozen samples may be submitted for most of these analytical assays.
- **Bioassay** = (BIOASSAY). This typically refers to tests in which the sample material is administered to an animal under experimental conditions. Preserved material is inappropriate, and some bioassays cannot be performed using samples that have been frozen. The VDL performing the test should be contacted for instructions prior to sample collection
- **Complement fixation** = (CF). A serologic test. Ship chilled or frozen serum.
- **Cytology** = (CYTO). Air-dried impression smears are usually adequate. Keep dry during transport.
- **Direct smear** = (SMEAR). The type of test is usually given in brackets (e.g., [Gram]). Air-dried smears are usually adequate but must be kept dry during shipment.
- **Enzyme-linked immunosorbent assay** = (ELISA). Chilled or frozen samples are usually acceptable. There are many variants of ELISA (e.g., antigen-capture, kinetic, indirect, direct, etc.), and the specific type used is not specified in this portion of the text.
- **Electron microscopic examination** = (EM). Appropriate sample collection and handling varies with the specimen being examined. Most of the diagnostic specimens submitted to VDLs for EM are fecal samples, and these do not require any special preservative.
- **Fecal floatation** = (FECAL). Sample can be fresh, chilled, or frozen.
- **Fluorescent antibody test** = (FAT). This may refer to either a direct or indirect method of antigen detection. Generally, cryostat sections are utilized, and therefore the tissue received by the laboratory should still be frozen upon arrival to provide the best results. Freeze/thaw cycles should be avoided. If impression smears are being shipped, they should be kept dry.
- **Fungal culture** = (FCULT). Special media is required. Transport as per (CULT) specimens.
- **Immunohistochemical testing** = (IHC). Many of these tests can be performed on formalin-fixed material, but in some instances frozen tissues must be delivered to the laboratory. In such instances the test is listed under a heading distinct from histology (e.g., virology, bacteriology, etc.).
- **Indirect hemagglutination** = (IHA). A serologic test. Ship chilled or frozen serum.
- **In-situ hybridization** = (IN-SITU HYBRID). Samples should be shipped chilled, although some test methods can use formalin-fixed material. These tests utilize nucleic acid probes that bind with complementary nucleic acid sequences in the specimen. Although not widely used in routine diagnostics at present, these methods may gain more prominence as their use is refined,
- **Virus isolation** = (ISO). Samples should be kept chilled during shipment or maintained in a frozen state if prolonged transit times are anticipated,
- **Latex agglutination** = (LATEX AGGLUTINATION). Fresh, chilled, or frozen samples are acceptable.
- **Light microscopic examination** = (LM). Formalin-fixed tissues are preferred. The shipment of fresh tissues to the VDL permits more tissue autolysis prior to fixation, resulting in less useful specimens. If Bouin's fixative is available, it is the preferred preservative for eye globes.
- **Microagglutination test** = (MAT). A type of serologic test. Ship chilled or frozen serum.
- **Mycoplasmal culture** = (MCULT). These types of organism have specific growth requirements that are usually not met by standard bacteriologic culture techniques. Transport as per (CULT) specimens. Culture swabs cannot be submitted in media containing charcoal or glycerol.
- **Polymerase chain reaction** = (PCR). Tissues should be frozen and maintained in that state until arrival at the VDL. Swabs and fluids submitted for PCR testing should be chilled but not frozen. These tests are capable of detecting minute quantities of nucleic acid, so if multiple animals are tested, the samples should be “clean” to avoid false positives through cross-contamination (i.e., blood/tissue from one animal contaminating the sample from another)
- **Serum urea nitrogen** = (SUN). A useful test to determine degree of renal compromise. Sample can be shipped chilled or frozen.
- **Virus neutralization** = (VN). A serologic test. Ship chilled or frozen serum.
