**Bonding** occurs rapidly after birth, although there is some minor variation between species, with bonding starting within a few minutes of birth in sheep but taking up to 2 to 3 hours in some horses, for example. The strength of bonding also appears to vary between species. The bonding of the dam to the neonate is usually quite specific, although this can be modulated by management systems, and the neonate may be less selective and will often attempt to suck other dams. With sheep lambing under intensive lambing practices, this can lead to high rates of mismothering and subsequent abandonment, when preparturient “robber” ewes adopt lambs from multiple births. A high degree of shepherding is required to minimize loss in these management systems, whereas in extensive systems a strong bonding is established if the ewe and lamb are allowed to remain relatively undisturbed on the lambing site for 6 hours. A scoring system is available to allow objective assessment of the vigor of newborn lambs (Tables 19-1 and 19-2).

There is evidence of genetic and parental (sire) effects on the ability of lambs to follow

the dam and to avoid mismothering. These effects appear to be modest.<sup>2,4,5</sup>

Vaginal cervical stimulation and the central release of oxytocin are thought to be important in initiating maternal behavior, although caudal epidural anesthesia for delivery does not effect mothering or bonding. Sucking is also a major determinant. Recognition is olfactory and auditory and mediated by the release of neurotransmitters.

Bonding is often slower with primiparous dams and is also delayed where there is postpartum pain. A failure of bonding leads to rejection and abandonment of the neonate.

Maternal care is also important to neonatal survival, and there is significant difference in litter mortality from crushing and injury among sows related to sow behavior and their response to piglet distress calls. A description of normal and abnormal behavioral patterns of the mare and foal is available, and techniques for fostering have been described.

## TEETH CLIPPING OF PIGLETS

It is necessary to shorten the needle teeth of the upper and lower jaw of the newborn pig using a clean pair of sharp nail clippers or a grinding wheel. It is essential to practice good hygiene or infection of tooth roots can occur, leading to local inflammation and infection with the possibility of abscessation associated with *Fusobacterium* and *Trueperella*. It is not done before 6 hours of age because it will interfere with the absorption of colostrum. It is done to prevent damage to the sow's teats or to other piglets before 7 days after birth. Damage to the sow's teats will cause pain and reluctance to allow suckling. Damage to other piglets may interfere with the establishment of the “pecking order” in the litter.

## Failure of Transfer of Passive Immunity (Failure of Transfer of Colostral Immunoglobulin)

The acquisition and absorption of adequate amounts of colostral immunoglobulins is essential to the health of ruminant, porcine, and equine neonates because they are born virtually devoid of circulating immunoglobulin. **Failure of passive transfer (FPT)** has been a commonly used term to describe the transfer of passive immunity (immunoglobulins, specifically IgG1 in colostrum) from the dam to the neonate. The process by which colostral immunoglobulin is absorbed is far from passive; it is an active and focused activity. Accordingly, FPT provides an incorrect summary of this process, and **failure of transfer of passive immunity (FTPI)** provides a more accurate descriptive term. Adequate antibody transfer is the cornerstone of all neonatal preventive health programs, but FTPI remains an important problem particularly affecting the dairy industry. Educational campaigns targeting dairy producers have been launched in the past decades, and, encouragingly, the prevalence of FTPI in dairy heifers in the United States decreased from over 40% in 1992 to 19% in 2007.<sup>1</sup>

Much of the description that follows refers to the calf because more studies on transfer of passive immunity have been conducted in calves. However, most of the information is applicable to the other species; where there are differences, these are mentioned.

## NORMAL TRANSFER OF IMMUNOGLOBULINS

Immunoglobulins in colostrum are present in different concentrations. The major immunoglobulin in colostrum is IgG. IgG consists of two fractions, IgG<sub>1</sub> and IgG<sub>2</sub>, which contribute 80% and 5% to 10%,

respectively, to the total colostral immunoglobulin concentration. IgM and IgA each account for approximately 5% of the colostral immunoglobulin content. IgG is concentrated in colostrum by an **active, selective, receptor-mediated transfer** from the blood of the dam across the mammary secretory epithelium. This transfer to colostrum begins approximately 4 to 6 weeks before parturition and results in colostral IgG concentrations in first milking colostrum that are several-fold higher than maternal serum concentrations. This active IgG transfer ceases suddenly at the onset of lactation, presumably in response to increased prolactin secretion around parturition.<sup>2</sup> IgA and IgM are largely derived from local synthesis by the mammary gland rather than transfer from plasma.

Following ingestion by the newborn, a significant proportion of these immunoglobulins is transferred across the epithelial cells of the small intestine during the first few hours of life and transported via the lymphatic system to the blood. Immunoglobulins in blood are further variably distributed to extravascular fluids and to body secretions depending on the immunoglobulin class.

These absorbed immunoglobulins protect against systemic invasion by microorganisms and septicemic disease during the neonatal period. Unabsorbed immunoglobulins and immunoglobulins resecreted into the gut play an important role in protection against intestinal disease for several weeks following birth. FTPI has unequivocally been associated with increased morbidity and mortality and reduced growth rates of neonates. Adequate immunoglobulin supply at birth is associated with higher first- and second-lactation milk production and decreased risk of culling during the first lactation.<sup>5</sup>

In foals, FTPI presents a significant risk for the development of illness during the first 3 months of life.

### Lactogenic Immunity

The IgG concentration in milk falls rapidly following parturition in all species, and immunoglobulin concentrations in milk are low (Table 19-3). In the sow, the

concentration of IgA falls only slightly during the same period, and it becomes a major immunoglobulin of sows' milk. IgA is synthesized by the mammary gland of the sow throughout lactation and serves as an important defense mechanism against enteric disease in the nursing piglet. IgA in milk is an important mucosal defense mechanism in piglets, whereas in the calf there is little IgA in milk, but some enteric protection is provided by colostral and milk IgG and IgG derived from serum that is resecreted into the intestine.

### FAILURE OF TRANSFER OF PASSIVE IMMUNITY

FTPI is the major determinant of septicemic disease in most species. It also modulates the occurrence of mortality and severity of enteric and respiratory disease in early life and performance at later ages.

In terms of the modulation of disease, there can be no set cut-point for circulating immunoglobulins because this cut-point will vary according to the farm, its environment, infection pressure, and the type of disease. Values are given as guidelines. **FTPI in calves** has been defined as a **serum IgG concentration below 1000 mg/dL (10 mg/mL)** when measured between 24 hours and 7 days of age. With **foals**, the equivalent IgG cutoff concentrations for FTPI and **partial FTPI** are given as **400 mg/dL** and **800 mg/dL**, respectively. Although a serum IgG concentration above 400 mg/dL might be adequate for healthy foals kept in a clean environment with minimal pathogen exposure, a concentration above 800 mg/dL is considered optimal.<sup>6</sup> For **New World camelid crias**, a cut-point value for the serum IgG concentration of **1000 mg/dL** measured at around 36 hours of life has been recommended.<sup>7</sup>

Rates of FTPI in dairy calves can vary widely between farms, but they were estimated to be in the range of 20% in a recent nationwide survey conducted in the United States.<sup>1</sup> In beef calves FTPI rates tend to be lower; a recent Canadian study reported the incidence of FTPI, defined as serum IgG concentrations below 800 mg/dL, of 6% and a rate of marginal transfer of passive immunity (800 mg/dL < IgG < 1600 mg/dL) of

10%.<sup>8</sup> Failure rates in foals reported in the literature are approximate 13% to 16%. Rates in lambs are also comparatively low, and the incidence of FTPI in crias has been estimated to be around 10%.<sup>7</sup>

In animals that are **fed colostrum artificially**, risk for FTPI is primarily dependent on the amount or mass of immunoglobulin present in a feeding of colostrum, the time after birth that this is fed, the efficiency of its absorption from the digestive tract, and possibly also the degree of bacterial contamination.<sup>1</sup> The mass of immunoglobulins fed is determined by the concentration of immunoglobulin in the colostrum and the volume that is fed. Feeding trials with calves suggest that a **mass of at least 150 g** of IgG is required in colostrum fed to a 45-kg calf to obtain adequate ( $\geq 1000$  mg/dL IgG) colostral immunoglobulin concentrations in serum.

In animals that **suck colostrum naturally**, such as foals, risk for FTPI is primarily dependent on the concentration of immunoglobulin in the colostrum, the amount that is ingested, and the time of first suckling. Inadequate colostral immunoglobulin concentration and delay in ingestion of colostrum are the two important factors in FTPI in foals.

### DETERMINANTS OF TRANSFER OF COLOSTRAL IMMUNOGLOBULINS

1. Amount of immunoglobulin in colostrum fed:
  - a. Volume of colostrum fed
  - b. Concentration of immunoglobulins in colostrum
2. Amount of colostrum actually suckled or fed
3. Rate of abomasal or gastric emptying after colostrum ingestion
4. Efficiency of absorption of immunoglobulins by neonate
5. Time after birth of suckling or feeding
6. Time of collection of colostrum after calving (with artificial colostrum feeding)
7. Degree of bacterial contamination of colostrum

**Table 19-3** Failure of transfer of passive immunity;<sup>1</sup> concentrations and relative percentage of immunoglobulins in serum and mammary secretions of cattle and pigs

Animal	Immunoglobulin	CONCENTRATION (mg/ml)			TOTAL IMMUNOGLOBULIN (%)		
		Serum	Colostrum	Milk	Serum	Colostrum	Milk
Cow	IgG <sub>1</sub>	11.0	75.0	0.59	50	81	73
	IgG <sub>2</sub>	7.9	2.9	0.02	36	5	2.5
	IgM	2.6	4.9	0.05	12	7	6.5
	IgA	0.5	4.4	0.14	2	7	18
Sow	IgG	21.5	58.7	3.0	89	80	29
	IgM	1.1	3.2	0.3	4	6	1
	IgA	1.8	10.7	7.7	7	14	70

### Determinants of Immunoglobulin Concentration in Colostrum

Nominal concentrations of immunoglobulin in the first milking colostrum of cows and sows are shown in Table 19-4.<sup>1</sup> Current conventional wisdom posits that **high-quality bovine colostrum** should contain **at least 50 g/L IgG**,<sup>2</sup> and that 3 L of high-quality colostrum should be fed as soon as possible after birth.<sup>3,4</sup> This strategy will provide the needed 150 g of colostral IgG. There can be substantial variation in the concentration of immunoglobulin in colostrum in all species, and the ingestion of a “normal” amount of colostrum that has low immunoglobulin concentration may provide an insufficient amount of immunoglobulin for protection. In a study of over 900 first-milkings colostrum from Holstein Friesian cows, only 29% of the colostrum samples contained a sufficiently high concentration of immunoglobulin to provide 100 g IgG in a 2-L volume. The equivalent percentages for 3- and 4-L volume feedings were 71% and 87%, respectively.

It is apparent that variation in colostral immunoglobulin concentration can be a cause of FTPI. Some causes of this variation are the following:

- The concentrations of immunoglobulin in colostrum fall dramatically after parturition. The concentrations in second-milking colostrum are approximately half those in the first milking, and by the fifth postcalving milking, concentrations approach those found during the remainder of lactation. A similar situation exists with **horses**. The mean concentrations of IgG in colostrum of mares 3 to 28 days before foaling is greater than 1000 mg IgG/dL, whereas at parturition the mean concentrations may vary from 4000 to 9000 mg/dL. The concentrations decrease markedly to 1000 mg/dL in 8 to 19 hours after parturition.
- The immunoglobulin concentration of colostrum decreases after calving even when the cow is not milked. It is important that this colostrum be **milked as soon as possible after parturition**. Colostrum that is collected 6 hours or later after calving has a significantly lower concentration than that collected 2 hours after calving. In a study documenting the effect of time since parturition on colostral IgG concentration, it was observed that colostral IgG concentration decreased by 3.7% during each subsequent hour after calving because of postparturient secretion of IgG-poor milk by the mammary glands.
- Colostrum from cows or mares that have been **premilked** to reduce udder edema or from dams that **leaked colostrum** before parturition have low immunoglobulin concentrations, and alternate colostrum should be fed for immunoglobulin transfer.
- In cattle, **dry periods** of less than 30 days may result in colostrum of lower immunoglobulin concentration.
- **Premature foaling** or the **induction of premature parturition** using long-acting corticosteroids in cattle can result in colostrum with low immunoglobulin concentration and/or low volume.
- In cattle, average colostral immunoglobulin concentrations are higher in cows in third or higher **lactation groups** compared with younger cows. However, colostrum from all lactation numbers can produce adequate immunoglobulin mass. There is no scientific basis for not feeding first-milking colostrum from first-lactation cows.
- Larger-volume first-milking colostrum tends to have lower immunoglobulin concentrations than smaller-volume colostrum, presumably as a result of dilution.
- Immunoglobulin concentrations were found to be higher in the early temporal fractions of a single milking of first-milking colostrum. This might suggest that segregation of the first portion of the first-milking colostrum could provide colostrum with higher immunoglobulin concentration for feeding.
- There are **breed differences** in the concentration of immunoglobulins in first-milking colostrum. In **cattle**, beef breeds have higher concentrations. Many dairy breeds, including Holstein Friesian, produce colostrum of relatively low immunoglobulin concentration, and a significant proportion of calves that suckle cows of these breeds ingest an inadequate mass of immunoglobulin. Channel Island breeds have a greater concentration of immunoglobulin in colostrum than Holstein Friesians. **Breed differences** are also seen in **horses**, with Arabian mares having higher colostral immunoglobulin concentrations than Standardbreds, which in turn are higher than those of Thoroughbreds. Breed differences also occur in **sheep**, with higher concentrations in meat and wool breeds than dairy breeds.
- Heat **stress** to cattle in the latter part of pregnancy results in lower colostral immunoglobulin concentrations.
- Colostral volume but not colostral immunoglobulin concentration is reduced in mastitic quarters, and it is unlikely that mastitis is a major determinant of the high rate of FTPI in dairy calves. Colostrum from cows with clinical mastitis should nonetheless not be fed because it may contain pathogens in large amounts and has unphysiologic composition.
- The **pooling of colostrum** in theory could avoid the variation in immunoglobulin concentration of individually fed colostrum and could provide a colostrum that reflects the antigenic experience of several cattle. In practice, colostrum pools from Holsteins invariably have low immunoglobulin concentrations because high-volume, low-concentration colostrum dilutes the concentration of the other samples in the pool. If pools are used, the diluting influence of low-immunoglobulin-concentration, high-volume colostrum should be limited by restricting any individual cow's contribution to the pool to 9 kg (20 lb) or less. However, pooling increases the risk of disease transmission because multiple cows are represented in a pool and the pool is fed to multiple calves. This can be important in the control of Johne's disease, bovine leukosis, *Mycoplasma bovis*, *E. coli*, and *Salmonella* spp.
- **Bacterial contamination** of colostrum can have a negative effect on transfer of passive immunity. The current recommendation is that fresh colostrum should contain less than 100,000 cfu/mL total bacteria count and less than 10,000 cfu total coliform count.<sup>2</sup> One study found that 85% of colostrums sampled from 40 farms in the United States exceeded this threshold. Colostrum that is to be fed or stored should be collected with appropriate preparation and sanitation of the cow and of the milking equipment used on fresh cows.
- **Pasteurization of colostrum** either at 63°C (145°F) for 30 min or 72°C (162°F) for 15 s was shown to reduce colostrum IgG concentration by at least 30% and to thicken or congeal the colostrum. In contrast, **pasteurization at 60°C (140°F) for 60 min** was found to affect neither colostral IgG concentration nor fluid characteristics while eliminating or at least significantly decreasing the content of major pathogens, including *Mycobacterium avium* subsp. *paratuberculosis*, *M. bovis*, *E. coli*, and *Salmonella* spp.
- **Old mares** (older than 15 years) may have poor colostral immunoglobulin concentration.

### Volume of Colostrum Ingested

#### Dairy Cows

The volume of colostrum that is fed has a direct influence on the mass of immunoglobulin ingested at first feeding. The average volume of colostrum ingested by nursing Holstein Friesian calves in the first 24 hours of life is reported as 2.4 L, but there is wide variation around this mean. In **natural suckling** situations, calves may fail to ingest

adequate colostrum volumes before onset of the closure process and therefore absorb insufficient colostral immunoglobulin. Early assisted suckling may help avoid this. In dairy calves the volume of colostrum that is ingested can be controlled in **artificial feeding systems** using nipple bottle feeders or esophageal tube feeders. **Bucket feeding** of colostrum is not recommended because training to feed from a bucket can be associated with erratic intakes.

The **traditional recommendation** for the volume of colostrum to feed at first feeding to calves is 2 L (2 quarts). However, only a small proportion of first-milking colostrum from Holsteins contains a sufficiently high concentration of immunoglobulin to provide 100 g IgG in a 2-L volume, and higher volumes of colostrum are required to achieve this mass intake. Some calves fed with a **nipple bottle** will drink volumes greater than 2 L, but others will refuse to ingest even 2 L of colostrum in a reasonable period of time, and calf rearers may lack the time or patience to persist with nipple bottle feeding until the required volume has been ingested by all calves.

Larger volumes of colostrum can be fed by an **esophageal feeder**, and single feedings of large volumes of colostrum (3.5 to 4.0 L per 45 kg of body weight) result in the lowest percentage of calves with FTPI by allowing calves fed colostrum with relatively low immunoglobulin concentrations to receive an adequate immunoglobulin mass before closure. Feeding this volume by an esophageal feeder causes no apparent discomfort to a minimally restrained calf and was not found to negatively affect intestinal IgG absorption compared with voluntary intake of the same (large) volume.<sup>10</sup> There is nonetheless some debate around the recommendation to systematically tube feed neonatal calves because of animal welfare concerns. In several European countries animal welfare legislation prohibits force-feeding of animals without medical indication.<sup>20</sup>

### Beef Cows

With beef breeds very effective colostral immunoglobulin transfer is achieved with natural sucking. This is thought to be a result of the greater vigor at birth exhibited by these calves and the higher immunoglobulin concentrations in beef colostrum, requiring a smaller volume intake to acquire an adequate mass. **Natural sucking** will give an adequate volume intake, and there is no need to artificially feed colostrum unless the dam is observed to refuse nursing or the calf's viability and sucking drive are compromised. The **yield of colostrum** and colostral immunoglobulins in beef cows can vary widely, and range beef heifers may produce critically low volumes of colostrum. Differences in yield can be attributed to breed or to nutritional status, although undernutrition is not an effect unless it is very severe.

### Ewes

Colostrum yield is high in ewes in good condition at lambing, but it may be low in ewes with condition scores of 1.5 to 2.0.

### Sows

In sows there is also very effective colostral immunoglobulin transfer with natural sucking, and piglets average an intake of 5% to 7% of body weight in the first hour of life. There is between-sow variation in the amount of colostrum, and there can be a large variation in colostrum supply from teat to teat, which may explain variable health and performance. During farrowing and for a short period following, colostrum is available freely from the udder, but thereafter it is released in ejections during mass suckling. A strong coordinated sucking stimulus is required by the piglet for maximum release of colostrum, and this requires that the ambient temperature and other environmental factors be conducive to the optimum vigor of the piglets. Small-birth-weight piglets, **late-birth-order** piglets, and piglets sucking posterior teats obtain less colostrum.

### All Species

In all species a low-volume intake may also occur because of the following factors:

- Poor **mothering behavior**, which may prevent the newborn from sucking; occurrence of disease; or milk fever
- Poor **udder and/or teat conformation** so that the newborn cannot suck normally or teat seeking is more prolonged. Udder-to-floor distance is most critical, and low-slung udders can account for significant delays in intake. Bottle-shaped teats (35-mm diameter) also significantly reduce intake.
- Delayed and **inadequate colostral intake** frequently accompanies perinatal asphyxia or acidemia because of the greatly decreased vigor of the calf in the first few hours of life. Perinatal asphyxia can occur in any breed and is greatly increased by matings resulting in fetal-maternal disproportion and dystocia.
- The newborn may be weak, traumatized, or unable to suck for other reasons; a **weak sucking drive** can be a result of congenital iodine deficiency, cold stress, or other factors.
- Disease of the periparturient dam, such as clinical hypocalcemia in cattle or the mastitis metritis agalactia complex in sows, may preclude adequate colostrum intake by offspring.
- Failure to allow newborn animals to ingest colostrum may occur under some management systems.

### Efficiency of Absorption

After ingestion of colostrum by the newborn, colostral immunoglobulins are absorbed

from the small intestine, by a process of pinocytosis, into the columnar cells of the epithelium. In the newborn calf this is a very rapid process, and immunoglobulin can be detected in the thoracic duct lymph within 80 to 120 minutes of its being introduced into the duodenum. The **period of absorption** varies between species and with immunoglobulin class. The mechanism by which absorption ceases is not well understood, but it may be related to replacement of the fetal enterocyte. The region of maximum absorption is in the lower small intestine, and peak serum concentrations are reached by 12 to 24 hours in all species. Absorption is not limited to immunoglobulin, and **proteinuria** during the first 24 hours of life is associated with the renal excretion of low-molecular-weight proteins such as  $\beta$ -lactoglobulin.

### Feeding Methods, "Closure of the Gut," and Immunoglobulin Absorption

Under normal conditions complete loss of the ability to absorb immunoglobulin (closure of the gut) occurs by 24 to 36 hours after birth in all species, and there is a significant reduction in absorptive ability (as much as 50% in some studies but minimal in others) by 8 to 12 hours following birth. The **time from birth to feeding** is a crucial factor affecting the absorption of colostral immunoglobulin in all species, and any delay beyond the first few hours of life, particularly after 8 hours, significantly reduces the amount of immunoglobulin absorbed.

The recommendation is that all neonates should be fed colostrum within the first 2 hours of life.

### Natural Sucking

**Natural sucking** is the desired method of intake of colostrum and is the most efficient, but it is influenced by the sucking drive and **vigor** of the neonate at birth. Newborns that suck colostrum can achieve very high concentrations of colostral immunoglobulin, and the efficiency of absorption is best with this feeding method. However, in dairy calves natural sucking is commonly associated with a high rate of FTPI because of **delays in sucking** coupled with low intake. Rates of FTPI in calves allowed to obtain colostrum via voluntary nursing reported in the literature can be as high as 40% to 60%.<sup>1</sup> Many factors influence the occurrence of delayed sucking, but calf vigor and birth-related asphyxia are the most important. Parity of the dam, conformation of the udder, and breed were also found to be significantly associated with the rate of FTPI. One older study reported that 46% of all calves born to multiparous cows had failed to nurse within 6 hours of birth compared with 11% of calves of primiparous cows.<sup>11</sup> Jersey calves have better rates of successful transfer of passive immunity with natural sucking than do Holsteins Friesians.

### Artificial Feeding

In contrast, when calves are **fed colostrum artificially**, minimal delays from birth to the time of colostrum feeding occur, and maximal colostrum immunoglobulin absorption results. In breeds such as Holstein Friesians, where colostrum immunoglobulin concentrations tend to be low and maximal efficiency of absorption is necessary, the logical way to minimize risk of FTPI is to feed the maximum volume of colostrum that is well tolerated within the first few hours of life. The published literature consistently reports higher calf serum IgG concentrations and a lower rate of FTPI in response to larger colostrum feeding volumes.<sup>2,10,12</sup>

### Other Influences

Even with the best available on-farm colostrum-selection methods, **large colostrum-feeding volumes are essential** to minimize the risk of FTPI in breeds with relatively low colostrum immunoglobulin concentrations. The method is particularly advantageous where time constraints of other farm activities limit the time available for calf feeding. The major detrimental influence on absorptive efficiency of immunoglobulin is **delayed feeding after birth**. Other factors that may affect absorptive efficiency include the following:

- **Perinatal asphyxia or acidemia** may have both direct and indirect effects on colostrum immunoglobulin transfer. Asphyxia has a major effect on subsequent sucking drive, and acidemic calves ingest far less colostrum than calves with more normal acid-base status at birth. In carefully controlled colostrum feeding studies, a significant negative correlation between the degree of hypercapnia and the efficiency of absorption of colostrum immunoglobulin in the first hours of life was demonstrated. However, this effect was only transient because there was no difference in serum IgG concentration at the time of gut closure between normoxic and hypoxic calves.
- In one early study, a **mothering effect** was reported in which calves remaining with their dams absorbed colostrum immunoglobulin more efficiently than calves removed immediately to individual pens. However, other studies have shown much smaller or no effects of mothering using similar experimental designs. The different results of these studies have not been reconciled.
- There can be **seasonal and geographic** variations in transfer of immunoglobulin in calves, although these are not always present on farms in the same area, and their cause is unknown. Where seasonal variation occurs in temperate climates, the mean monthly serum IgG concentrations are lowest in the winter and increase during

the spring and early summer to reach their peak in September, after which they decrease. The cause is not known, but a decrease in sucking drive is observed in colder months and may contribute. In subtropical climates, peak levels occur in the winter months, and low levels are associated with elevated temperatures during the summer months. **Heat stress** in late pregnancy will reduce colostrum immunoglobulin concentration, but high ambient temperature is a strong depressant of absorption, and the provision of shade will help to obviate the problem.

- The efficiency of absorption may be decreased in **premature calves** that are born following induced parturition using long-acting corticosteroids; in contrast, medical **induction of parturition** with short-acting corticosteroids in cattle does not interfere with the efficiency of absorption of immunoglobulins in calves.
- The absorption of small volumes (1 to 2 L) fed by an esophageal feeder is usually suboptimal and inferior to the absorption after sucking the same small volume.<sup>10</sup> This effect may at least in part be attributable to retention of some colostrum in the immature forestomachs for several hours. The calf will feel satiated and not inclined to suck naturally for the next few hours.
- A **trypsin inhibitor** in colostrum may serve to protect colostrum IgG from intestinal degradation. It varies in concentration between colostrums. The addition of a trypsin inhibitor to colostrum improves immunoglobulin absorption.
- In a study of **mare-associated determinants of FTPI** in foals (based on serum Ig measurements), there was a trend to increase rates of FTPI in foals from mares aged over 12 years, but no significant association with age, parity, or gestational age of foals over 325 days was found. There was an association with season, with a lower incidence in the late spring compared with foals born earlier in the year and with a foal score based on a veterinary score of foal health and "fitness."

Traditionally it has been considered that the **movement** of animals, either the dam just **before parturition** or the newborn animal during the first few days of life, is a special hazard for the health of the calf. The postulated reason is that the dam may not have been exposed to pathogens present in the new environment and thus not have circulating antibodies against these pathogens. The newborn animal may be in the same position with regard to both deficiency of antibodies and exposure to new infections. Although this may be the case in some

situations, the developing practice of contract-rearing of dairy heifers away from the farm to be brought back as close-up springers and the practice of purchase of close-up heifers on the farm are not associated with appreciable increase in mortality in their calves.

### Decline of Passive Immunity

Colostrum antibody concentrations in blood fall quickly after birth and have usually disappeared by 6 months of age. In the **foal**, they have fallen to less than 50% of peak level by 1 month of age and to a minimum level between 30 and 60 days. This is the point at which naturally immunodeficient foals are highly susceptible to fatal infection.

In **calves**, the level of IgG declines slowly and reaches minimum values by 60 days, in contrast to IgM and IgA, which decline more rapidly and reach minimum values by approximately 21 days of age. The half-lives for IgG, IgM, and IgA in calves are approximately 20, 4, and 2 days, respectively, and the half-lives of IgG, IgGb, IgG(T), and IgA in foals are approximately 18, 32, 21, and 3.5 days, respectively.

**Immunologic competence** is present at birth, but endogenous antibody production does not usually reach protective levels until 1 month, and maximum levels are not reached until 2 to 3 months of age. The endogenous production of intestinal IgA in the piglet begins at about 2 weeks of age and does not reach significant levels until 5 weeks of age.

Foals that acquire low concentrations of immunoglobulins from colostrum may experience a transitory hypogammaglobulinemia at several weeks of age as the levels fall and before autogenous antibodies develop. They are, as expected, more subject to infection than normal.

### OTHER BENEFITS OF COLOSTRUM

In addition to its immunoglobulin content, colostrum contains considerably more protein, fat, vitamins, and minerals than milk and is especially important in the transfer of fat-soluble vitamins. It has **anabolic effects**, and lambs that ingest colostrum have a higher summit metabolism than colostrum-deprived lambs. Colostrum also contains growth-promoting factors that stimulate DNA synthesis and cell division, including high concentrations of insulin-like growth factor (IGF)-1.

Colostrum contains approximately  $1 \times 10^6$  leukocytes/mL, and several hundred million are ingested with the first feeding of colostrum. In calves, 20% to 30% of these are lymphocytes and cross the intestine into the circulation of the calf. It is postulated that they have importance in the development of neonatal resistance to disease, but there is little tangible evidence. Calves fed colostrum depleted of leukocytes are thought to be more poorly protected against neonatal disease than those fed normal colostrum.

## ASSESSMENT OF TRANSFER OF PASSIVE IMMUNITY

Because of the importance of transfer of colostral antibodies to the health of the neonate, it is common to quantitatively estimate the levels of immunoglobulins, or their surrogates, in colostrum and in serum to predict risk of disease and to take preventive measures in the individual or to make corrective management changes where groups of animals are at risk.

### Assessment in the Individual Animal

When samples are taken from an individual animal to determine the risk for infection, sampling is undertaken early so that replacement therapy can be given promptly if there has been inadequate transfer. IgG is detectable in serum 2 hours following a colostrum feeding and **sampling at 8 to 12 hours** after birth will give a good indication of whether early sucking has occurred and has been effective in transfer. This type of monitoring is commonly performed in foals and camelid crias.<sup>7,13</sup> There are a number of different tests that can be used; some are quantitative and others semiquantitative. In calves, sampling may be undertaken for similar reasons, but the cost of replacement therapy is limiting.

### Assessment Tests on Serum

Sampling to **monitor** the efficacy of a farm policy for feeding and handling colostrum, to evaluate the passive immunity status in **calves to be purchased**, or to determine the **rates of FTPI** in investigations of neonatal disease can be conducted at any time in the first week of life after 24 hours with most tests. Numerous tests are currently available, some of which directly measure serum IgG concentration and some of which estimate the IgG concentration based on the serum concentration of the total globulin or other protein fractions.

### Radial Immunodiffusion

The radial immunodiffusion (RID) is based on the precipitation of antigen and antibody to an insoluble precipitin complex and thus directly measures IgG concentration in serum or plasma. The RID is considered the reference method to measure serum/plasma IgG, but it takes at least 24 h to perform and thus longer than is desirable for most clinical purposes. In a recent study two commercial RID test kits for calves were compared, and a large bias and wide limits of agreements between the two tests were found, which has raised questions about the reliability of the results.<sup>21</sup>

### Lateral-Flow Immunoassay

The lateral-flow immunoassay is a calf-side test directly measuring IgG in serum or plasma with reportedly high sensitivity and specificity. Although the test can be performed on-site and results are available

within 20 min, it only provides a pass/fail result using a cutoff value of 10 mg/mL.<sup>2</sup>

### Turbidimetric Immunoassay

The turbidimetric immunoassay (TIM) is commercially available and can be run on a handheld chemistry analyzer to be used with bovine serum. In a preliminary study conducted at the University of Minnesota, the test was found to be more accurate than indirect tests such as serum refractometry.

### Zinc Sulfate Turbidity Test

The zinc sulfate turbidity test is based on a selective precipitation reaction of the salt with high molecular weight proteins such as immunoglobulin (not specifically IgG). The test is commonly used with a test solution containing 200 mg/L zinc sulfate but was found to have poor specificity and would only classify 69% of tested calves correctly. Increasing the zinc sulfate concentration from 200 to 350 mg/L considerably improved the specificity and positive predictive values of the test, but this test modification is not widely used.<sup>15</sup> Another inconvenience is that hemolyzed blood samples will give artificially high readings, and the reagent must be kept free of dissolved carbon dioxide.

### Sodium Sulfite Precipitation Test

The sodium sulfite precipitation test is based on the selective precipitation of high-molecular-weight proteins with sodium sulfate at different concentrations. Test solutions of 14%, 16%, and 18% sodium sulfite are commonly used, and the development of turbidity at a certain concentration allows for a crude estimate of the serum immunoglobulin concentration; the lower the concentration at which turbidity occurs, the higher is the concentration of immunoglobulin. Particularly the use of the 14% and 16% sodium sulfite solutions was found to result in an unacceptably high percentage of calves being misclassified as FTPI while having adequate serum immunoglobulin concentrations.<sup>15</sup>

### Serum $\gamma$ -Glutamyltransferase Activity

Serum  $\gamma$ -glutamyltransferase (GGT) activity has been used as a surrogate for determining the efficacy of transfer of passive immunity in calves and lambs (not in foals). GGT activity is high in the colostrum of ruminants (but not horses), and serum GGT activity in calves and lambs that have sucked or been fed colostrum is 60 to 160 times greater than normal adult serum activity and correlates moderately well with serum IgG concentrations. The half-life of GGT from colostrum is short, and serum GGT activity falls significantly in the first week of life. Serum GGT values equivalent to a serum IgG concentration of 10 mg/mL are 200 IU/L on day 1 of life and 100 IU/L on day 4. Serum GGT concentrations less than 50 IU/L indicate FTPI.

### Serum Total Protein

Measuring total protein concentrations in serum or plasma with a refractometer is a practical, rapid, and inexpensive method to estimate the immunoglobulin concentration by extrapolating it from the total protein concentration. Despite the indirect nature of the test, there is a reliable correlation between the refractometer reading and total immunoglobulin concentration measured by RID. In healthy calves a serum total protein of 5.5 g/dL or greater is associated with adequate transfer of passive immunity.

Serum total protein has a good predictive value for fate of the newborn, and the facile and practical nature of the test and its predictive ability commend it for survey studies in calves and lambs but not foals. Cut-points will vary with the environment and the infection pressure to the calves. The sensitivity of the test is maximal using a cut-point of 5.5 g/dL, and the specificity is maximal at a cut-point of 5.0 g/dL. Because serum total protein concentration measured by refractometry can result in an incidental misclassification of an individual calf, this test is primarily recommended as a screening tool to assess the colostrum management on a herd level, but not as diagnostic tool for an individual animal. Herd screening could be conducted by testing a minimum of 12 calves on a farm between 24 hours and 7 days old. At least 80% of tested calves should have serum protein concentrations above 5.5 g/dL to consider the colostrum management satisfactory at the herd level.

Serum total protein concentration can also be estimated using the same Brix refractometer used for measuring colostral IgG concentration, with an appropriate adjustment factor.<sup>14</sup>

### Glutaraldehyde Coagulation Test

The glutaraldehyde test was initially introduced to identify hypergammaglobulinemia in adult cattle with chronic inflammatory disease. The semiquantitative test is based on a clotting reaction of glutaraldehyde in the presence of high immunoglobulin concentration, where the time to clot formation is negatively correlated with the serum IgG.<sup>16</sup> A modified glutaraldehyde coagulation test is also available for the detection of hypogammaglobulinemia in neonatal calves, but it is less accurate.<sup>15</sup> The test may yield false-positive results with hemolysis and is difficult to quantitate.

### Latex Agglutination Test

A commercial latex agglutination test is available for horses. It is rapid and provides semiquantitative results, but results were reported to be inconsistent.

### ELISA Snap-Test

ELISA snap-tests are foal-side immunologic tests directly measuring IgG in a

semiquantitative manner. Test kits are commercially available for foals and have been available for calves. In foals the available snap-tests were found to be rapid and accurate.

### Monitoring Colostrum Brix Refractometry

The most accurate and practical way to ensure that an adequate colostrum mass is fed is to test the colostrum using a Brix refractometer (the digital version is preferred). This instrument was designed for use in food processing but was adapted in the late 1970s to provide a low-cost test of colostrum quality. A Brix refractometer value of 21% or 22% or higher indicates acceptable colostrum (same value for fresh or frozen samples; approximately equivalent to a colostrum IgG concentration of 50 g/L); colostrum with a value below 21% or 22% should be discarded.<sup>17,18</sup>

### Specific Gravity

Specific gravity, determined by refractometry, can be used as a measure of the immunoglobulin content of colostrum. In **mares** the concentration of immunoglobulin in colostrum is highly correlated with the specific gravity of the colostrum, which in turn is highly correlated with the serum immunoglobulin levels achieved in foals. Temperature-corrected measurements are most accurate. Measurement of colostrum specific gravity provides a rapid and easy method of identifying foals likely to be at a high risk for FTPI and the need to provide them with colostrum of a higher Ig content. To prevent FTPI, it is recommended that the colostrum specific gravity should be equal to or greater than 1.060, and the colostrum IgG concentration should be a minimum of 3000 mg/dL.

In **cattle** the relation of specific gravity of colostrum to colostrum immunoglobulin concentration is linear but is better in Holstein Friesian than in Jersey cows. The measurement is simple, but there is a correction for temperature, and air trapped in colostrum taken by a milking machine can give a false reading if the measurement is taken too quickly after milking. The cut-point recommended to distinguish moderate from excellent colostrum has been set at 1.050, approximating an IgG concentration of 50 g/L, and is based on the amount of immunoglobulin required for a 2-L (2-quart) feeding. Specific gravity is not a perfect surrogate for immunoglobulin concentration with cattle colostrum. It has good negative prediction, but it will falsely pass 2 out of 3 colostrums that have unacceptably low immunoglobulin concentrations. An analysis of first-milking colostrum in mid-western U.S. dairies found that specific gravity differed among breeds and was influenced by month of calving, year of calving, lactation number, and protein yield in

previous lactation and that it was more closely associated with colostrum protein concentration ( $r = 0.76$ ) than IgG<sub>1</sub> concentration ( $r = 0.53$ ).

### Glutaraldehyde Test

This test for mare colostrum is available commercially and is reported to have a high predictive value for colostrums that contain more than 38 mg/mL of IgG and have a specific gravity greater than 1.060.

### ELISA

Recently a cow-side immunoassay kit has become available commercially in the United States. The kit provides a positive or a negative response, with the cut-point being a concentration of 50g/L of IgG in colostrum, and has accuracy sufficient to recommend its use for rejection of colostrums with low immunoglobulin concentration.

## CORRECTION OF FAILURE OF TRANSFER OF PASSIVE IMMUNITY Oral Therapy

Oral therapy can be considered in individual animals (generally foals and crias), provided that FTPI—or the risk thereof—is diagnosed and the treatment is administered before gut closure (i.e., not later than 18 h of life). For foals, oral administration of at least 0.5 L frozen equine colostrum of good quality (specific gravity > 1.060) that has been properly stored and thawed is recommended. Alternatives include colostrum substitutes containing lyophilized IgG or good-quality bovine colostrum. The latter option is probably the least effective and requires at least 4 L of good-quality (specific gravity > 1.050) colostrum.

### Parenteral Immunoglobulins

Blood transfusion is commonly used in food animal practice, and the method is described elsewhere in this text. Fresh plasma from a random donor or purified hyperimmune plasma that is commercially available for foals and crias in some countries are alternatives. Large amounts are required to obtain the required high serum concentrations of immunoglobulins, and intravenous infusion can be accompanied by transfusion-type reactions.

## AVOIDANCE OF FAILURE OF TRANSFER OF PASSIVE IMMUNITY

With all species, with the exception of dairy calves, the common practice is to allow the newborn to suck naturally. The policy for avoidance of FTPI with naturally sucking herds should be to provide supplemental colostrum by artificial feeding of those neonates with a high risk for FTPI, based on the risk factors detailed earlier. In the dairy calf, rates of FTPI with natural sucking are so high that many farms opt to remove the calf at birth and feed colostrum by hand to ensure adequate intake.

## Colostrum

Colostrum can be stripped from the dam and fed fresh, or the neonate can be fed stored (banked) colostrum.

### Colostrum for Banking

With **dairy cows**, first-milking colostrum from a cow with a first-milking yield of less than 10 kg should be used. The temptation for the farmer is to store the leftover from the feeding of large-volume colostrum. The leftover colostrum should not be used because it has a high probability of containing a low immunoglobulin concentration.

Colostrum from **mares** should have a specific gravity of 1.060 or more, and 200 mL can be milked from a mare before the foal begins sucking.

### Storage of Colostrum

Colostrum can be kept at **refrigerator temperature** for approximately 1 week without significant deterioration in immunoglobulins; bacteria counts, however, may reach unacceptably high levels (above 100,000 cfu/mL) after 2 days in refrigerated milk.<sup>2</sup> Addition of potassium sorbate in a 0.5% final solution impairs bacterial growth for several days.<sup>2</sup> The addition of 5 g of propionic or lactic acid per liter extends the storage life to 6 weeks, but, more commonly, colostrum is frozen for storage. **Frozen colostrum**, at  $-20^{\circ}\text{C}$  ( $-4^{\circ}\text{F}$ ), can be stored for at least 1 year, and there is no impairment in the subsequent absorption of immunoglobulins. Frozen colostrum should be stored in flat plastic bags in the amount required for a feeding, which facilitates thawing. **Thawing** should be at temperatures below  $55^{\circ}\text{C}$  ( $131^{\circ}\text{F}$ ). Higher temperatures and microwave thawing result in the deterioration of immunoglobulins and antibodies in frozen colostrum and frozen plasma.

### Pasteurization of Colostrum

There are several indications for pasteurization of colostrum. This procedure can be a suitable instrument in a program for the control of specific infectious diseases, such as paratuberculosis, salmonellosis, or *M. bovis* infection, but it can also be useful to ameliorate calf health by improving colostrum quality and reducing the exposure of the neonate to pathogens. On-farm pasteurization of bovine colostrum for 60 min at  $60^{\circ}\text{C}$  ( $140^{\circ}\text{F}$ ) results in elimination or at least significant reduction of bacterial contamination without impairing fluid characteristics or availability of IgG for intestinal absorption.<sup>9</sup> One recent study reported significantly higher serum IgG concentrations at 24 h of life when calves were fed pasteurized colostrum compared with calves receiving the same quality and amount of raw colostrum.<sup>19</sup> The authors attributed this effect to reduced bacterial interference with intestinal IgG absorption. Pasteurization extends the shelf life of refrigerated colostrum without

additives to 8 to 10 days when stored in clean, sealed containers.

### Cross-Species Colostrum

Colostrum from another species can be used to provide immunologic protection when same-species colostrum is not available. Bovine colostrum can be fed to a number of different species. Although absorption of immunoglobulin occurs and significant protection can be achieved, the use of cross-species colostrum is not without risk, and the absorbed immunoglobulin has a short half-life. Bovine colostrum has been successfully used for many years to improve the survival rate of hysterectomy-produced artificially reared pigs. It has also been used as an alternate source of colostral antibody for rearing goats free of caprine arthritis-encephalitis (CAE). Colostrum from some cows can result in the development of hemolytic anemia, occurring at around 5 to 12 days of age, in lambs and kids because the IgG of some cows attaches to the red cells and their precursors in bone marrow, resulting in red cell destruction by the reticuloendothelial system. Bovine colostrum can be tested for "antisheep" factors by a gel precipitation test on colostral whey, but this test is not generally available. Bovine colostrum can provide some protection to newborn foals against neonatal infections, and protection appears to result from factors in addition to the immunoglobulins, which have a short half-life in foals.

### Colostrum Supplements

In recent years there has been a move to develop supplements or even replacements for colostrum to feed calves. These have been attempted using IgG concentrated from bovine colostrum, milk whey, eggs, or bovine serum. The search for colostrum substitutes or colostrum replacers has been prompted by the problem of the variability of IgG concentration in natural colostrum. It has also been prompted by possible limitations of availability of high-quality colostrum on dairy farms as a result of discarding colostrum from cows that test positive for diseases that can transmit through colostrum, such as paratuberculosis, bovine leukosis, and *M. bovis*.

There is evidence that the inclusion of **colostrum replacer (CR)** or **colostrum supplement (CS)** products can impair the efficiency of colostral immunoglobulin, and if they are fed, they should be fed after normal colostrum rather than mixed into the colostrum. It has been proposed that the distinction between a colostrum supplement and a colostrum replacer should be the immunoglobulin mass contained in the product, with a colostrum supplement containing less than 100 g IgG per dose and a colostrum replacer having sufficient immunoglobulin mass in a dose to result in a serum IgG concentration greater than 10 mg/mL following a feeding.

Furthermore, CR products are formulated to provide adequate protein, energy, minerals, and vitamins to completely replace colostrum, which is not the case for CS supplement products. When fed as the sole source of immunoglobulin to colostrum-deprived calves, CS products achieve circulating concentrations of immunoglobulin that are lower than those achieved by natural colostrum containing equivalent amounts of immunoglobulin.

A large mass of immunoglobulin is required for acquisition of adequate serum immunoglobulin concentrations. Calves fed a colostrum replacement containing a high mass (250 g) of an IgG derived from bovine serum and fed at 1.5 and again at 13.5 hours after birth achieved equivalent serum IgG concentrations to calves fed normal colostrum and showed no difference in gain or health parameters during the first 4 weeks of life. However, the performance of commercially available products for IgG supplementation varies greatly, with many of them faring badly. The choice of a specific product should therefore be based on the availability of convincing data supporting the efficacy of the product in question.

The use of colostrum replacers should be limited to situations where sufficient amounts of colostrum of adequate quality are unavailable. There can be little justification for more widespread use, particularly because there are limited independent health-related publications documenting their efficacy. Also, as mentioned earlier, in addition to immunoglobulin, natural colostrum contains various substances important to neonatal physiology.

### Lacteal-Secretion-Based Preparations

Colostrum supplements prepared from whey or colostrum are available commercially in many countries. Depending on the manufacturer, they contain varying amounts of immunoglobulin, but significantly less than first-milking colostrum. The amount of immunoglobulin contained varies, but the recommendations for feeding that accompany these products indicate that they will supply approximately 25% or less of the immunoglobulin required to elevate calf serum IgG concentrations above 1000 mg/dL. There is a further problem in that the immunoglobulins in products made from colostrum or whey are poorly absorbed, and trials assessing their ability to increase circulating immunoglobulins when fed with colostrum have generally shown little improvement and no improvement in health-related parameters.

### Bovine-Serum-Based Preparations

Colostrum supplements prepared from bovine serum are also available commercially, but regulations governing the feeding of blood or blood products to calves (risk reduction for bovine spongiform

encephalopathy) may limit their availability in some countries. The absorption of immunoglobulin from these bovine-serum-derived commercial products appears better than from milk-protein-derived products, and consequently they are also marketed as colostrum replacers.

The IgG in a commercially available bovine serum colostrum replacer has been shown to be effectively absorbed when fed to newborn lambs. The feeding of 200 g of IgG in the first 24 hours of life resulted in a mean plasma concentration of 1800 mg/dL.

### Administration of Colostrum

#### Foals

Foals should be allowed to suck naturally. The specific gravity of the mare's colostrum can be checked at foaling; if this is less than 1.060, supplemental colostrum may be indicated. Foals that do not suck, or that have serum IgG concentrations less than 400 mg/dL at 12 hours of age, or that require supplementation for other reasons, should be fed colostrum with a specific gravity of 1.060 or more at an amount of 200 mL at hourly feedings.

#### Dairy Calves

##### *Assisted Natural Sucking*

Leaving the newborn dairy calf with the cow is no guarantee that the calf will obtain sufficient colostrum, and a high proportion of dairy calves fail either to suck early or to absorb sufficient immunoglobulins from ingested colostrum. This problem can be alleviated to some extent by **assisted natural sucking**, but this can fail because not all calves requiring assistance are detected. An alternate approach is to milk 2 L of colostrum from the dam, bottle feed each calf as soon after birth as possible, then leave the calf with the cow for 24 hours and allow it to suck voluntarily. Although this will not be as effective as a system based entirely on artificial feeding of selected colostrum, it is an approach that is suitable for the smaller dairy farm.

##### *Artificial Feeding Systems*

With **artificial feeding systems**, the calf is removed from the dam at birth and fed colostrum by hand throughout the whole absorptive period. Nipple bottle feeding can be used, with 2 L of colostrum given every 12 hours for the first 48 hours of life. The first feeding is usually milked from the cow by hand, and the remaining feedings are from the colostrum obtained from the cow after the first machine milking. With care and patience, this system can result in good transfer of passive immunity in all calves except those born to dams that have very low concentrations of immunoglobulin in their colostrum. Unfortunately, with Holstein Friesians this can be a significant percentage. An extension of this system is to bottle feed at the same frequency but to feed stored

colostrum selected for its superior immunoglobulin content. Bottle feeding of newborn calves requires considerable **patience**, and its success is very much dependent on the calf feeder and on the availability of the feeder's time when faced with a calf that has a slow intake.

Where the diligence of the calf feeders is poor, or where there is a time constraint on their availability, the feeding of a large volume of colostrum (4 L to a 45 kg calf) by **esophageal feeder** at the initial feeding immediately after birth can be a successful practice. The **large-volume feeding** also allows the delivery of an adequate mass of immunoglobulin with colostrum that has low immunoglobulin concentrations without impairing the intestinal IgG absorption rate compared with voluntary intake of the same large amount of colostrum.<sup>10</sup> The practice usually uses stored colostrum, and the feeding can be achieved within a few minutes. It can be supplemented by bottle feeding of a second feeding at 12 hours of life.

The practice of feeding stored colostrum as the sole source of colostrum is limited to larger dairy herds, but it does allow the selection of superior colostrum for feeding, with selection based on weight and specific gravity as detailed earlier.

### Beef Calves

Beef calves should be allowed to suck naturally, and force-feeding of colostrum to beef breeds should not be practiced unless there is obvious failure of sucking. Where colostrum is required, as with weak beef calves, calves with edematous tongues, and calves that have been subjected to a difficult birth, it can be administered with an esophageal feeder or a stomach tube.

### Lambs

Lambs are allowed to suck naturally, but there can be competition between siblings for colostrum; one large single lamb is capable of ingesting, within a short period of birth, all the available colostrum in the ewe's udder. Lambs require a total of 180 to 210 mL colostrum/kg body weight during the first 18 hours after birth to provide sufficient energy for heat production. This amount will usually provide enough immunoglobulin for protection against infections. **Supplemental feeding** of colostrum may be advisable for lambs from multiple birth litters, lambs that lack vigor, and those that have not nursed by 2 hours following birth. This can be done with a nipple bottle or an esophageal feeder.

### Piglets

Colostrum supplementation is not commonly practiced with piglets. An immunoglobulin dose of 10 g/kg body weight on day 1 followed by 2 g/kg on succeeding days for 10 days is sufficient to confer passive immunity on the colostrum-deprived pig.

## Clinical Assessment and Care of Critically Ill Newborns

The following discussion focuses on care and treatment of critically ill foals, although the principles are applicable to any species. The increasing availability of secondary and

tertiary care for ill newborns has allowed the development of sophisticated care for newborns of sufficient emotional or financial value.<sup>1</sup> This level of care, at its most intensive, requires appropriately trained individuals (both veterinarians and support staff) and dedicated facilities. True intensive care of newborns requires 24-hour monitoring. The following discussion is not a comprehensive guide to intensive care of newborns, but is rather an introduction to the general aspects of advanced primary or basic secondary care. Sophisticated interventions, such as mechanical ventilation and cardiovascular support, are mentioned but not discussed in detail.

### CLINICAL EXAMINATION

Initial assessment of an ill newborn should begin with collection of a detailed history, including length of gestation, health of the dam, parturition, and behavior of the newborn after birth, including the time to stand and to commence nursing activity. Physical examination should be thorough, with particular attention to those body systems most commonly affected. A form similar to that in [Figure 19-4](#) is useful in ensuring that all pertinent questions are addressed and that the physical examination is comprehensive.

Examination of ill neonates should focus on detection of the common causes of disease in this age group: sepsis, either focal or systemic; prematurity or dysmaturity; metabolic abnormalities (such as hypoglycemia or hypothermia); birth trauma; diseases associated with hypoxia; and congenital abnormalities. Detailed descriptions of these conditions are provided elsewhere in this chapter.

### Sepsis

**Sepsis** is an important cause of illness in neonates that can manifest as localized infections without apparent systemic signs, localized infections with signs of systemic illness, or systemic illness without signs of localized infection.<sup>2</sup>

**Localized infections** without signs of systemic illness include septic synovitis or osteomyelitis and omphalitis. Signs of these diseases are evident on examination of the area affected and include lameness, distension of the joint, and pain on palpation of the affected joint in animals with synovitis or osteomyelitis and an enlarged external umbilicus with or without purulent discharge in animals with infections of the umbilical structures. Specialized imaging and hematologic and serum biochemical examinations (see following discussion) are useful in confirming the infection.

**Systemic signs** of sepsis include depression, failure to nurse or reduced frequency of nursing, somnolence, recumbency, fever or hypothermia, tachypnea, tachycardia, diarrhea, and colic, in addition to any signs of

**Foal Examination Protocol**

**Fig. 19-4, cont'd**

localized disease. Fever is a specific, but not sensitive, sign of sepsis in foals. The presence of petechia in oral, nasal, ocular, or vaginal mucous membranes, the pinna, or coronary bands is considered a specific indicator of sepsis, although this has not been documented by appropriate studies. A similar comment applies for injection of the scleral vessels. A scoring system (the sepsis score) has been developed to aid in the identification of foals with sepsis.

The **sepsis score** was developed with the intention of aiding identification of foals with sepsis, thereby facilitating appropriate treatment. A table for calculation of the sepsis score (the modified sepsis score) is provided in [Table 19-11](#). Foals with a score of 12 or greater are considered to be septic, with a sensitivity of 94% in the original report. However, more recent studies, including one of 1095 foals, have found the sensitivity and specificity of the sepsis score to be less than the original report. The modified sepsis score detected sepsis with a sensitivity of 56% and a specificity of 73% using a cutoff value of 11 or more. A cutoff value of 7

yielded a sensitivity of 84% and specificity of 42%.<sup>3</sup> These recent studies are broadly consistent with earlier studies that demonstrate that the sepsis score has limited sensitivity (67%, 95% CI 59% to 75%) and specificity (76%, 95% CI 68% to 83%) in foals less than 10 days of age. Similarly, 49% of 101 foals with positive blood cultures had a sepsis score of 11 or less, indicating a low specificity of the test. The low to moderate sensitivity of the sepsis score for detection of sepsis or bacteremia means that many foals with sepsis are incorrectly diagnosed as being nonseptic (i.e., a high false-negative rate), whereas a moderate to low specificity means that the false-positive rate might be excessive, with a number of foals being considered septic when they are not. This is an important shortcoming of the test because accurate and prompt identification of foals with sepsis is assumed to be important for both prognostication and selection of treatment. The sepsis score might be useful in some situations, but its shortcomings should be recognized when using it to guide treatment or determine prognosis.

### Prematurity and Dysmaturity

Detection of **prematurity** is important because it is a strong risk factor for development of other diseases during the immediate postpartum period. The detection of prematurity is often based on the length of gestation. However, the duration of gestation in Thoroughbred horses varies considerably, with 95% of mares foaling after a gestation of 327 to 357 days. The generally accepted “average” gestation is 349 days, with fillies having shorter gestations than do colts (348 versus 350 days) and gestation length declining by approximately 20 days, from 360 to 340 days, in Standardbred mares in New Zealand.<sup>4</sup> Ponies have a shorter gestation (333 days, range 315 to 350 days). Therefore a diagnosis of prematurity should be based not just on gestational age but also on the results of physical, hematologic, and serum biochemical examination of the newborn. Factors helping in the determination of prematurity are listed in [Table 19-4](#). Foals that are immature (premature) at birth typically have low birth weight and small body size, a short and silky hair coat, and laxity of the

**Table 19-4** Criteria to assess stage of maturity of the newborn foal

Criterion	Premature	Full term
<b>Physical</b>		
Gestational age	320 d	Normally > 330 d
Size	Small	Normal or large
Coat	Short and silky	Long
Fetlock	Overextended	Normal extension
<b>Behavior</b>		
First stand	>120 min	<120 min
First stand	>3 h	<3 h
Suck reflex	Poor	Good
Righting reflexes	Poor	Good
<b>Adrenal activity</b>		
Plasma cortisol values over first 2 h postpartum	Low levels (<30 ng/mL)	Increasing levels (120–140 ng/mL) at 30–60 min postpartum
Plasma ACTH values over first 2 h postpartum	Peak values (≈650 pg/mL) at 30 min postpartum and declining subsequently	Declining values from peak (300 pg/mL at birth)
Response to synthetic ACTH1-24 (short-acting Synacthen), dose 0.125 mg IM	Poor response shown by a 28% increase in plasma cortisol and no changes in neutrophil:lymphocyte ratio	Good response shown by a 208% increase in plasma cortisol and widening of neutrophil:lymphocyte ratio
<b>Hematology</b>		
Mean cell volume (fl)	>39	<39
White blood cell count ( $\times 10^9/L$ )	6.0	8.0
Neutrophil:lymphocyte ratio	<1.0	>2.0
<b>Carbohydrate metabolism</b>		
Plasma glucose levels over first 2 h postpartum	Low levels at birth (2–3 mmol/L), subsequently declining	Higher levels at birth (4.1 mmol/L), maintained
Plasma insulin levels over first 2 h postpartum	Low levels at birth (8.6 $\mu U/mL$ ), declining	Higher levels at birth (16.1 $\mu U/mL$ ), maintained
Glucose tolerance test (0.5 mg/kg body weight IV)	Slight response demonstrated by a 100% increase in plasma insulin at 15 min postadministration	Clear response demonstrated by a 250% increase in plasma insulin at 5 min postadministration
<b>Renin–angiotensin–aldosterone system</b>		
Plasma renin substrate	Higher and/or increasing levels during 15–60 min postpartum	Low (<0.6 $\mu g/mL$ ) and declining levels during 15–30 min postpartum
Acid–base status (pH)	<7.25 and declining	>7.3 and maintaining or rising

IM, intramuscularly; IV, intravenously.

flexor and extensor tendons. The cranium is rounded, and the pinnae lack tone (droopy ears). The foals are typically weak and have trouble standing, which is exacerbated by laxity of the flexor tendons and periarticular ligaments. **Dysmature** (postmature) foals are typically large, although they can be thin, and have a long hair coat and flexure tendon contracture. These signs are consistent with prolonged gestation combined with inadequate intrauterine nutrition. Healthy foals stand approximately 65 min (interquartile range, 45 to 100 minutes) after birth.<sup>4</sup> Examination of the placenta, either by ultrasonographic examination before birth or by direct examination, including histologic and microbiologic testing, after birth is useful in identifying abnormalities that have significance for the newborn.

### Hypoxia

Hypoxia during late gestation, birth, or the immediate postpartum period has a variety of clinical manifestations depending on the tissue or organ most affected. Signs of central nervous system dysfunction are often assumed to be a result of cerebral hypoxia during birth, although neonatal maladjustment syndrome does not appear to be related to hypoxia (see “Neonatal Maladjustment Syndrome,” page 1871). Other signs suggestive of peripartum hypoxia include colic and anuria.

### Hypoglycemia

Foals that are hypoglycemic because of inadequate intake, such as through mismothering, congenital abnormalities, or concurrent illness, are initially weak, with rapid progression to somnolence and coma.

### Endocrine Abnormalities

Abnormalities in endocrine function of foals are common and often associated with risk of death.<sup>1,5-10</sup> Septic foals have higher serum ACTH, cortisol, and ACTH:cortisol ratios, and higher serum parathyroid hormone concentrations (but not calcitonin concentrations) than do healthy foals of the same age.<sup>5,6</sup> Septic foals have lower insulin and IGF-1 and higher ghrelin, growth hormone, and glucagon concentrations than do healthy foals.<sup>7,8</sup> Arginine vasopressin concentrations are higher in septic foals.<sup>9</sup> Plasma adrenomedullin concentrations are highest in sick foals (both septic and nonseptic) and might be a useful marker of foal health.<sup>10</sup> Critically ill foals may also have evidence on nonthyroidal illness syndrome (see “Diseases of the Thyroid,” Chapter 17).<sup>11</sup>

### DIAGNOSTIC IMAGING

Radiographic and ultrasonographic examination of neonates can be useful in determining maturity and the presence of abnormalities. Prematurity is evident as failure or inadequate ossification of cuboidal bones in the carpus and tarsus. Radiographs

of the thorax should be obtained if there is any suspicion of sepsis or pneumonia because thoracic auscultation has poor sensitivity in detecting pulmonary disease in newborns. The severity of abnormalities in the lungs of foals detected by radiographic examination is related to prognosis, with foals with more severe disease having a worse prognosis for recovery. Abdominal radiographs may be useful in determining the site of gastrointestinal disease (see discussion of foal colic).

**Ultrasonography** is a particularly useful tool for examination of neonates, in large part because their small size permits thorough examination of all major body cavities. Ultrasonography of the umbilical structures can identify omphalitis and abscesses of umbilical remnants and, when available, is indicated as part of the physical examination of every sick neonate.

Examination of the **umbilical structures** can reveal evidence of infection, congenital abnormalities, and urachal tears. Examination of the umbilicus can be achieved using a 7.5-MHz linear probe (such as that commonly used for reproductive examination of mares), although sector scanners provide a superior image. Examination of the umbilical structures should include examination of the navel and structures external to the body wall, the body wall, the umbilical stump as it enters the body wall and separates into the two umbilical arteries, the urachus and apex of the bladder, and the umbilical vein. The size and echogenicity of each of these structures should be determined. For foals less than 7 days of age, the intraabdominal umbilical stump should be less than 2.4 cm in diameter, the umbilical vein less than 1 cm, and the umbilical arteries less than 1.4 cm (usually < 1 cm). Examination of these structures should be complete: the umbilical vein should be visualized in the umbilical stump and then followed as it courses along the ventral abdominal wall and into the liver; the umbilical arteries should be visualized in the umbilical stump and then as they separate from that structure and course over the lateral aspects of the bladder; the urachus should be visualized from the external umbilical stump through the body wall and as it enters the bladder.

Abnormalities observed frequently in the umbilical structures include overall swelling, consistent with omphalitis; gas shadows in the urachus or umbilical stump, which are indicative of either a patent urachus allowing entry of air or growth of gas-producing bacteria; and the presence of flocculent fluid in the urachus, vein, or artery, which is consistent with pus. Urachal tears can be observed, especially in foals with uroperitoneum.

Ultrasonographic examination of the **abdomen** is useful in identifying abnormalities of gastrointestinal function and structure, including intestinal distension or thickening of the intestinal wall. Thickness of the wall of the intestinal tract of healthy

Standardbred foals of less than 5 days of age are as follows (95% predictive interval): 1.6 to 3.6 mm for the stomach, 1.9 to 3.2 mm for the duodenum, 1.9 to 3.1 mm for the jejunum, 1.3 to 2.2 mm for the colon, and 0.8 to 2.7 mm for the cecum.<sup>12</sup> Intussusceptions are evident as “donut” lesions in the small intestine, but evaluation of the clinical importance of these findings should be considered in the context of the foal. Intussusceptions are detected in a large proportion of healthy neonatal foals as incidental findings.<sup>12</sup> Gastric outflow obstruction should be suspected in foals with a distended stomach evident on ultrasonographic examination of the abdomen. Herniation through the umbilicus or inguinal ring can be confirmed by ultrasonographic examination.<sup>13</sup> Uroperitoneum is readily apparent as excessive accumulation of clear fluid in the abdomen. Hemorrhage into the peritoneum can be detected as accumulation of echogenic, swirling fluid. Accumulation of inflammatory fluid, such as in foals with ischemic intestine, is detected by the presence of flocculent fluid.

Ultrasonographic examination of the **chest** can reveal the presence of pleural abnormalities, consolidation of the lung (provided that the consolidated lung is confluent with the pleura), accumulation of fluid in the pleural space (hemorrhage secondary to birth trauma and fractured ribs, inflammatory fluid in foals with pleuritis), pneumothorax (usually secondary to lung laceration by a fractured rib), or congenital abnormalities of the heart.

Advanced imaging modalities, such as **computed tomography (CT) and magnetic resonance imaging (MRI)**, are available at referral centers and are practical in foals and other neonates because of the small size of the animals. These modalities are useful in detection of intrathoracic and intraabdominal abnormalities, including abscesses, gastrointestinal disease, and congenital abnormalities. MRI is particularly useful for diagnosis of diseases of the brain and spinal cord.

### CLINICAL PATHOLOGY

#### Serum Immunoglobulin Concentration

Serum or plasma immunoglobulins are associated with the risk of death in hospitalized foals. Foals with serum IgG concentration less than or equal to 4.0 g/L were 4.7 (95% CI 2.6 to 8.5) times as likely to die as were foals with a concentration greater than 8 g/L. Foals with an IgG of greater than 4 g/L and less than 8 g/L were 3.7 (2.0 to 6.8) times as likely to die as were foals with concentrations above 8 g/L.<sup>14</sup>

Serum immunoglobulin G (IgG) concentration, or its equivalent, must be measured in every ill or at-risk newborn and should be repeated every 48 to 96 hours in critically ill neonates. A variety of tests are available for

rapid detection of FTPI in foals and calves. Although measurement of serum IgG concentration is ideally performed by the gold standard test, a radial immunodiffusion, this test requires at least 24 hours to run, whereas the stall-side or chemistry analyzer tests can be run in a few minutes. The sensitivity and specificity have been determined for a number of these rapid tests. Overall, most tests have high sensitivity (>80%), meaning that the few foals that have low concentrations of IgG are missed, but poor specificity (50% to 70%), meaning that many foals that have adequate concentrations of immunoglobulin are diagnosed as having inadequate concentrations. The exact sensitivity and specificity depend on the test used and the concentration of immunoglobulin considered adequate. The high sensitivity and low specificity of most of the available rapid tests result in a number of foals that do not need a transfusion receiving one. However, this error is of less importance than that of foals that should receive a transfusion not receiving one.

Serum or plasma concentrations of IgG should be measured after approximately 18 hours of age, and preferably before 48 hours

of age—the earlier FTPI is recognized, the better the prognosis for the foal. Foals that ingest colostrum within the first few hours of birth have minimal increases in serum IgG concentration over that achieved at 12 hours of age, suggesting that measurement of serum IgG concentration as early as 12 to 18 hours after birth is appropriate. This early measurement of serum IgG concentration could be especially important in high-risk foals. The oldest age at which measurement of serum IgG is useful in foals is uncertain, but depends on the clinical condition of the foal. Typically, immunoglobulin concentrations of foals that have adequate concentrations of IgG within the first 24 hours reach a nadir at about 6 weeks of age and then rise to concentrations similar to adults over the next 2 to 3 months.

### Hematology

It is important to recognize that the hemogram of neonates differs from that of older animals (Table 19-5) because these differences can affect the clinical assessment of the animal. The hematologic and serum biochemical values of foals and calves can vary markedly during the first days and weeks of

life, and it is important that these maturational changes are taken into account when assessing results of hematologic or serum biochemical examination of foals. Hematologic examination can reveal evidence of hemolytic disease, bacterial or viral infection, or prematurity/dysmaturity (Table 19-4). Repeated hemograms are often necessary to monitor for development of sepsis and responses to treatment.

Foals with sepsis can have a leukocyte count in the blood that is low, within the reference range, or high. Approximately 40% of foals with sepsis have blood leukocyte counts that are below the reference range. Most foals with sepsis (approximately 70%) have segmented neutrophil counts that are below the reference range, with fewer than 15% of foals having elevated blood neutrophil counts. Concentrations of band cells in blood are above the reference range in almost all foals with sepsis. Some foals born of mares with placentitis have a very pronounced mature neutrophilia without other signs of sepsis; these foals typically have a good prognosis. Lymphopenia is present in foals with equine herpesvirus-1 septicemia or Arabian foals with severe

**Table 19-5** Hematologic values of normal foals and calves

combined immunodeficiency. Thrombocytopenia occurs in some foals with sepsis. Hyperfibrinogenemia is common in foals that have sepsis, although the concentration might not be above the reference range in foals examined early in the disease.

Hyperfibrinogenemia is common in foals born of mares with placentitis and reflects systemic activation of the inflammatory cascade even in foals that have no other evidence of sepsis. Serum amyloid A concentrations are above 100 mg/L in foals with sepsis. Septic foals also have blood concentrations of proinflammatory cytokines, and of plasma C-reactive protein,<sup>15</sup> that are higher than those in healthy foals. Plasma haptoglobin concentrations are not different between surviving and nonsurviving foals and are only minimally lower in foals with sepsis than in nonseptic hospitalized foals.<sup>15</sup> Indices of coagulation are prolonged in foals with sepsis, and concentrations of antithrombin and protein C antigen in plasma are lower than in healthy foals. These abnormalities indicate that coagulopathies are common in septic foals.

**Prematurity** is associated with a low neutrophil:lymphocyte ratio (<1.5:1) in blood and red cell macrocytosis (Table 19-4). A neutrophil:lymphocyte ratio above 2:1 is considered normal. Premature foals that are not septic can have low blood neutrophil

counts but rarely have immature neutrophils (band cells) or toxic changes in neutrophils.

### Serum Biochemistry

Care should be taken in the interpretation of the results of serum biochemical examinations because normal values for newborns are often markedly different from those of adults, and they can change rapidly during the first days to weeks of life (Table 19-6). Serum biochemical examination can reveal electrolyte abnormalities associated with renal failure, diarrhea, and sepsis. Elevations in serum bilirubin concentration or serum enzyme activities may be detected. As a minimum, blood glucose concentrations should be estimated using a chemical strip in depressed or recumbent newborns.

Markedly elevated serum **creatinine** concentrations are not uncommonly observed in foals with no other evidence of renal disease. The elevated serum creatinine in these cases is a consequence of impaired placental function during late gestation, with the consequent accumulation of creatinine (and probably other compounds). In foals with normal renal function, which most have, the serum creatinine concentration should decrease to 50% of the initial high value within 24 hours. Other causes of high serum creatinine concentration that should be ruled out are renal failure (dysplasia, hypoxic

renal failure) and postrenal azotemia (uroperitoneum).

Blood or plasma **l-lactate concentrations** are useful indicators of the presence and severity of systemic disease that impairs oxygen delivery to tissue (hypoxemia, poor perfusion, anemia) or use by tissue (endotoxemia), but it is not specific for any one disease or group of diseases, with the exception that septic foals have higher concentrations than do nonseptic foals.<sup>16-19</sup> However, the difference between septic and nonseptic foals (4.8 [range, 0.6 to 37] and 3.3 [range, 0.3 to 21] mmol/L) is not sufficiently different to make it useful in an individual animal.<sup>20</sup> Blood lactate concentrations of healthy foals are greatest at birth to 12 hours of age and then decline.<sup>16</sup> Blood lactate concentrations of foals that do not survive their acute illness do not decline in response to therapy,<sup>16</sup> and risk of death increases by 1.1 for each mmol/L increase in blood lactate concentration of foals at time of admission to a veterinary hospital.<sup>17,20</sup> Serial measurement of blood lactate concentrations and calculation of an “area-under-the-curve” measure also provides useful information related to risk of death, but not the cause of the disease.

**Sepsis** is usually associated with hypoglycemia, although septic foals can have normal or elevated blood glucose concentrations. Hypoglycemia is attributable to failure

Table 19-6 Serum biochemical values of normal foals and calves

to nurse, whereas hyperglycemia indicates loss of normal sensitivity to insulin. Indicators of renal, hepatic, or cardiac (troponin) damage can increase in foals with sepsis, causing organ damage or failure. Foals with sepsis tend to have elevated concentrations of cortisol in serum.

**Prematurity** is associated with low concentrations of cortisol in plasma or serum and minimal increase in response to intramuscular administration of 0.125 mg of exogenous ACTH (corticotropin). Plasma cortisol concentration of normal full-term foals during the first 24 hours of life increases from a baseline value of approximately 40 ng/mL to over 100 ng/mL 60 minutes after ACTH administration, whereas plasma cortisol concentrations in premature foals do not increase from values of slightly less than 40 ng/mL. At 2 and 3 days of age, plasma cortisol concentrations of full-term foals increase twofold after ACTH administration, albeit from a lower resting value, but do not increase in premature foals. Blood glucose concentrations of premature foals are often low, probably because of inability to nurse.

### Blood Gas

Arterial blood pH,  $P_{CO_2}$ , and  $P_{O_2}$  should be measured to determine the newborn's acid-base status and the adequacy of respiratory function. Foals with hypoxemia are five times more likely to have pulmonary radiographic abnormalities. Prolonged lateral recumbency of foals compromises respiratory function, and arterial blood samples should be collected with the foal in sternal recumbency. Repeated sampling may be necessary to detect changes in respiratory function and to monitor the adequacy of oxygen supplementation or assisted ventilation.

### Blood Culture

Identification of causative organisms of sepsis in foals can aid in prognostication and potentially in selection of therapy, although there does not appear to be a relation between antimicrobial sensitivity of organisms isolated from blood, as determined by Kirby-Bauer testing, and survival of foals. Anaerobic and aerobic blood cultures should be performed as early in the disease process as possible, and preferably before initiation of antibiotic treatment, although antimicrobials should not be withheld from a newborn with confirmed or suspected sepsis to obtain a result from blood culture. Strict aseptic technique should be used when collecting blood for culture. Blood cultures should also be collected if there is a sudden deterioration in the newborn's condition.

Gram-negative enteric bacteria are the most common isolates from blood of newborn foals, with *E. coli* the most common isolate. *A. equuli* is also a common isolate from foals. There are important differences in diseases produced by the various organisms, with foals with *A. equuli* septicemia

being twice as likely to die, seven times more likely to have been sick since birth, six times more likely to have diarrhea, five times more likely to have a sepsis score of more than 11, and three times more likely to have pneumonia than foals with sepsis associated with other bacteria.

A problem with blood culture is the time needed to obtain either interim or final results because this can delay detection of infection or decisions to use focused antimicrobial therapy. Use of real-time polymerase chain reaction (PCR) to detect bloodstream infection of foals will likely supplement conventional blood culture in foals.<sup>21</sup>

### Other Body Fluids

Synovial fluid should be submitted for aerobic and anaerobic culture, Gram stain, and cytologic examination when signs of synovitis, such as lameness, joint effusion, or joint pain, are present.

Analysis of cerebrospinal fluid (CSF) is indicated in newborns with signs of neurologic disease. Samples of CSF should be submitted for cytologic examination, measurement of total protein concentration, Gram stain, and bacterial culture.

Urinalysis may provide evidence of renal failure (casts) or urinary tract infection (white blood cells).

Abdominal fluid should be collected in foals with abdominal pain or distension and should be submitted for cytologic examination and, if uroperitoneum is suspected, measurement of creatinine concentration.

### TREATMENT

The principles of care of the critically ill newborn farm animal are as follows:

- The newborn should be kept in a sanitary environment to minimize the risk of nosocomial infections.
- Systemic supportive care should be provided to maintain homeostasis until the newborn is capable of separate and independent existence.
- There should be frequent and comprehensive reevaluations of all body systems to detect signs of deterioration and allow early correction.
- Provision should be made to ensure adequate passive immunity (serum or plasma IgG concentration > 8 g/L) to reduce the risk of secondary infections or to treat existing infections. Transfer of passive immunity should be evaluated using laboratory methods that measure serum or plasma IgG concentration.

The level of care provided depends on the value of the animal and the available facilities, personnel, and expertise. Newborns of limited financial worth are usually treated on the farm, whereas valuable foals and calves can be referred for specialist care. Referral of sick neonates to institutions and practices with expertise in provision of critical care to newborns should be timely and prompt and,

when necessary, should be recommended on the first visit.

### Nursing Care

The sophistication of care for critically ill newborns depends on the facilities and personnel available, with intensive management requiring dedicated facilities and trained personnel available 24 hours a day. The minimum requirement for providing basic care of ill newborns is a sanitary area in which the newborns can be protected from environmental stress. Often this means separating the newborn from its dam.

Excellent nursing care is essential for maximizing the likelihood of a good outcome. Critically ill animals might benefit from constant nursing care. Strict attention must be paid to maintaining the sanitary environment to minimize the risk of nosocomial infections. The newborn should be kept clean and dry and at an ambient temperature in its thermoneutral zone. Bedding should prevent development of decubital ulcers. Foals should be maintained in sternal recumbency, or at least turned every 2 hours, to optimize their respiratory function.

### Correction of Failure of Transfer of Passive Immunity

#### Colostrum Immunoglobulin

Ideally, adequate transfer of passive immunity is achieved by the newborn nursing its dam and ingesting an adequate amount of colostrum containing optimal concentrations of immunoglobulins, principally IgG (IgGb) in foals. Foals need approximately 2 g of IgG per kilogram of body weight to achieve a plasma concentration of 2000 mg/dL (20g/L); therefore a 45-kg foal needs approximately 90 g of IgG to attain a normal serum IgG concentration (or approximately 40 g to achieve a serum IgG concentration of 800 mg/dL [8 g/L]). Assuming that colostrum contains on average 10,000 mg/dL (100 g/L), foals must ingest at least 1 L of colostrum to obtain sufficient immunoglobulin. Because colostrum IgG concentration varies considerably (from 2000 to 30,000 mg/dL), specific recommendations regarding the quantity of colostrum to be fed to neonatal foals cannot be made with certainty. However, colostrum with a specific gravity of more than 1.060 has an IgG concentration of more than 3000 mg/dL (30 g/L), suggesting that foals should ingest at least 1.5 L to achieve serum IgG concentrations above 800 mg/dL (8 g/L).

### Critical Plasma IgG Concentrations in Foals

There is some debate as to what constitutes a critical serum or plasma IgG concentration. Foals that ingest an adequate amount of colostrum typically have serum immunoglobulin concentrations during the first week of life greater than approximately 2000 mg/dL (20 g/L). Both 400 mg/dL

(4 g/L) and 800 mg/dL (8 g/L) have been recommended as concentrations below which foals should be considered to have increased likelihood of contracting infectious disease, but recent evidence strongly supports the use of 800 mg/dL (8 g/L) as the minimal concentration in hospitalized foals. However, on a well-managed farm the serum IgG concentration was not predictive of morbidity or mortality among foals, suggesting that serum immunoglobulin concentration in some populations of foals is not an important risk factor for infectious disease. The foals in this study were from an exceptionally well-managed farm. Other researchers have found that foals with serum IgG concentration below 800 mg/dL (8 g/L) are at markedly increased risk of subsequent development of infectious disease, including sepsis, pneumonia, and septic arthritis. It is likely that there is no single concentration of IgG in serum that is protective in all situations, and the concentration of IgG in serum that is desirable in an individual foal depends on the risk factors for infectious disease of that foal. Our opinion is that a minimum serum IgG in foals free of disease and housed in closed bands on well-managed farms is 400 mg/dL (4 g/L). For foals at increased risk of disease—for instance, those on large farms with frequent introduction of animals and foals that are transported or housed with foals with infectious disease—the minimum advisable serum IgG concentration is 800 mg/dL (8 g/L). Foals that have infectious disease should have serum IgG concentrations of at least 800 mg/dL, and it might be advantageous for these foals to have even higher values, as indicated by the enhanced survival of foals with septic disease administered equine plasma regardless of their serum IgG concentration. This therapeutic advantage could be because of the additional IgG or because of other factors included in the plasma. Transfusion of plasma to sick foals improves neutrophil function, an important advantage given that oxidative burst activity of neutrophils from septic foals is reduced compared with that in healthy foals.

### Plasma Transfusion

The ability of foals to absorb macromolecules, including immunoglobulins, declines rapidly after birth, being 22% of that at birth by 3 hours of age and 1% of that at birth by 24 hours of age. Consequently, by the time that FTPI is recognized, it is no longer feasible to increase serum IgG concentrations by feeding colostrum or oral serum products. Foals should then be administered plasma or serum intravenously. The **amount of plasma** or serum to be administered depends on the target value for serum IgG concentration and the initial serum IgG concentration in the foal. For each gram of IgG administered per kilogram of body weight of the foal, serum IgG concentration increases

by approximately 8.7 mg/dL (0.87 g/L) in healthy foals and 6.2 mg/dL (0.62 g/L) in sick foals. To achieve serum IgG concentrations above 800 mg/dL (8 g/L) in foals with serum IgG concentrations below 400 mg/dL (4 g/L), they should be administered 40 mL/kg of plasma containing at least 20 g/L of IgG. Similarly, foals with serum IgG concentrations above 400 mg/dL (4 g/L) but below 800 mg/dL (8 g/L) should be administered 20 mL/kg of plasma. For 45-kg foals, these recommendations translate to administration of 1 or 2 L of plasma, respectively.

The ideal product for transfusion into foals with FTPI is **fresh frozen plasma** harvested from horses that are Aa and Qa antigen-negative and that do not have antibodies against either or both of these red blood cell antigens (see the discussion of neonatal isoerythrolysis). The donor horses should have been vaccinated against the common diseases of horses and have tested negative for equine infectious anemia. Good-quality commercial products specify the minimum concentration of IgG in the plasma. Concentrated serum products that do not need to be frozen until use are available. These are much more convenient for field use than are plasma products that must be frozen until immediately before transfusion. However, the IgG concentration of these products is often not specified, and the manufacturer's recommendations for dosing often result in administration of inadequate amounts of immunoglobulin. Serum products can produce adequate concentrations of IgG in foals, but the dose is usually two to three times that recommended by the manufacturer. An adequate dose of concentrated serum products is approximately 1 L for some products. The crucial point is that it is not the volume of plasma or serum that is administered that is important, but rather the quantity of immunoglobulin delivered to the foal. A total of 20 to 25 g of IgG is required to raise the serum IgG concentration of a 50-kg foal by 400 mg/dL (4 g/L).

**Plasma** should be administered intravenously; oral administration is likely to be wasteful, especially in foals more than a few hours old. Frozen plasma should be thawed at room temperature or by immersion in warm (<37°C, 100°F) water. Thawing by immersion in water at temperatures higher than body temperature can cause denaturation and coagulation of proteins, with loss of efficacy of transfused immunoglobulins. Plasma should never be thawed or warmed using a microwave because this denatures the proteins.

**Administration of plasma** should be intravenous; intraperitoneal administration, such as used in pigs or small ruminants, has not been investigated in foals. The thawed plasma should be administered through a jugular catheter using a blood administration set containing a filter (160- to 270- $\mu$ m mesh) to prevent infusion of particulate

material. Strict asepsis should be used. The foal should be adequately restrained for the procedure, with some active foals needing moderate tranquilization. Premedication with antihistamines or nonsteroidal anti-inflammatory drugs is usually not necessary. The plasma should be infused slowly at first, with the first 20 to 40 mL administered over 10 minutes. During this period the foal should be carefully observed for signs of transfusion reaction, which is usually evident as restlessness, tachycardia, tachypnea, respiratory distress, sweating, or urticaria. If these signs are observed, the transfusion should be stopped, and the foal should be reevaluated and treated if necessary. If no transfusion reactions are noted during the first 10 minutes, the infusion can then be delivered at 0.25 to 1.0 mL/kg/min (i.e., about 1 L/h for a 50-kg foal). Rapid infusion can result in acute excessive plasma volume expansion, with the potential for cardiovascular and respiratory distress.

Serum IgG concentration should be measured after the infusion to ensure that an adequate concentration of IgG has been achieved. Serum IgG can be measured as early as 20 minutes after the end of the transfusion.

### Nutritional Support

Provision of adequate nutrition is essential to the recovery of ill newborns. Healthy newborn foals have estimated energy requirements of 500 to 625 kJ/kg/d (120 to 150 kcal/kg/d) and consume approximately 20% of their body weight as milk per day. Measurements of foal energy expenditure using indirect calorimetry reveal expenditure of ~60 to 80 kcal/kg/d in healthy foals, which is reduced to ~50 kcal/kg/d for critically ill foals.<sup>22</sup>

The best food for newborns is the dam's milk, and newborns that are able to do so should be encouraged to nurse the dam. However, if the foal is unable to nurse or the dam is not available, then good-quality milk substitutes should be used. Soy and other plant-protein-based milk replacers are not suitable for newborns. Commercial products formulated for foals, calves, and lambs are available. Human enteral nutrition products supplying 0.7 to 1 kcal/mL (2.8 to 4.1 kJ/mL) can also be used for short-term (several days to a week) support of foals.

It is preferable to provide enteral, rather than parenteral, nutrition to ill newborns with normal or relatively normal gastrointestinal function. Sick neonatal foals should initially be fed 10% of their body weight as mare's milk, or a suitable replacer, every 24 hours, divided into hourly or 2-hour feedings. If the foal does not develop diarrhea or abdominal distension, then the amount fed can be increased over a 24- to 48-hour period to 20% to 25% of the foal's body weight (or 150 kcal/kg/day; 620 kJ/kg/day). Newborns can be fed by nursing a

bottle or bucket or via an indwelling nasogastric tube such as a foal feeding tube, stallion catheter, human feeding tube, or enema tube. Every attempt should be made to encourage the newborn to nurse its dam as soon as the newborn can stand. Adequacy of nutrition can be monitored by measuring blood glucose concentrations and body weight.

**Parenteral nutrition (PN)** can be provided to newborns that are unable to be fed by the enteral route. This can be achieved by administration of various combinations of solutions containing glucose (dextrose), amino acids, and fat. A commercial product that does not include lipid has been used successfully for up to 12 days in foals. One product that has been used successfully for foals is a solution of amino acids (5%), dextrose (25%), and electrolytes (Clinimix E; Baxter Healthcare Corporation, Deerfield, IL). Lipid emulsion is not added to the preparation. Additional multivitamin supplements including calcium gluconate (provided 2.5 mmol/L), magnesium sulfate (6 mEq/L), B-vitamin complex (thiamine 12.5 mg/L; riboflavin 2 mg/L; niacin 12.5 mg/L; pantothenic acid 5 mg/L; pyridoxine 5 mg/L; cyanocobalamin 5 µg/L), and trace elements (zinc 2 mg/L; copper 0.8 mg/L; manganese 0.2 mg/L; chromium 8 µg/L) are added. Administration is through a catheter, a single-lumen 14-gauge over-the-wire catheter (Milacath), inserted in the jugular vein with its tip placed in the cranial vena cava. A double-T extension set is used to allow concurrent constant-rate infusion of isotonic crystalloid fluids and intravenous administration of medication in one line and PN solution in the other. An infusion pump is used for continuous-rate infusion of the solutions. The PN solution should be prepared under aseptic conditions just before administration and used for only a period of 24 hours after preparation. A 0.22-µm filter is included in the administration line to remove all bacteria, glass, rubber, cellulose fibers, and other extraneous material in the PN solution. The filters and administration sets are changed with each new bag of PN solution.

The rate of PN infusion is determined based on the weight and physical and metabolic condition of the foal. The general protocol is based on the assumption that sick foals expend approximately 50 kcal/kg body weight per day (basal rate).<sup>22</sup> The PN is started at half the basal rate for 12 hours, increasing to the basal rate over 24 to 48 hours, and then in some foals increased slowly to 75 kcal/kg/d if tolerated by the foal. The clinical condition of the foal is assessed frequently. Blood glucose concentrations should be measured every 6 to 8 hours during the introduction and weaning of PN until the blood glucose concentration is stabilized. Insulin can be administered during hyperglycemic crises ( $\geq 250$  mg/dL) at a

dose of 0.1 to 0.4 U/kg regular insulin intramuscularly, but this is rarely needed. When a constant rate of PN is achieved, glucose concentrations should be measured every 8 to 12 hours, depending on the clinical condition of the foal. Foals are weaned off the PN as their clinical condition improves, and enteral feeding is gradually increased. The rate of PN is halved every 4 to 12 hours if blood glucose concentration is stable until half the basal rate is obtained, at which time the infusion is discontinued if the foal is bright, alert, and nursing well.

PN is supplemented with isotonic fluid therapy administered intravenously. The fluid rate and composition are determined based on clinical condition, packed cell volume, total protein, and serum electrolyte concentrations (Na, Cl, Ca, K and  $\text{HCO}_3$ ). The composition and rate are adjusted to maintain normal hydration and electrolyte and acid-base status. During the period that foals receive PN, enteral feeding is initially withdrawn, and the foals are muzzled or separated from the mare. Beginning 24 hours after the institution of PN, 20 to 40 mL of mare's milk ("trophic" feeding) is administered enterally every 4 hours. The trophic feeding provides nutrition to enterocytes and stimulates production of lactase in the small intestine in preparation for resumption of enteral feeding. As the foals are weaned off the PN, enteral feedings are gradually increased from small trophic feeding every 4 hours to allowing the foal to nurse from the mare for 2 to 5 minutes every 2 hours and eventually unrestricted nursing from the mare.

### Antimicrobial Treatment

Normal newborns are at risk of acquiring life-threatening bacterial infections, and the risk increases when they do not ingest adequate colostrum in a timely fashion or are subjected to environmental stresses (see the discussion on [neonatal infection](#)). Newborns in which bacterial infection is suspected and those at high risk of developing an infection, such as sick newborns with FTPI, should be administered antimicrobials. Antimicrobial therapy should not be delayed pending the results of bacterial culture and antimicrobial sensitivity testing.

The choice of antimicrobial is determined by the likely infecting agent and clinical experience with antimicrobial susceptibility of local strains of pathogens. In general, broad-spectrum antimicrobials are chosen because it is almost impossible to predict, based on clinical signs, the nature of the infecting agent and its antimicrobial susceptibility. Although *Streptococcus* spp. were historically reported to be the cause of most infections in neonatal foals, currently infections of neonatal foals are usually a result of gram-negative organisms, including *E. coli*, *Klebsiella* spp., and *Salmonella* spp. Because of the wide variety of infecting agents and

their varying antimicrobial susceptibility, it is possible to make only general recommendations for antimicrobial therapy of neonates. A frequently used antimicrobial regimen is an aminoglycoside (gentamicin or, more commonly, amikacin) and penicillin. Some commonly used drugs and their doses are listed in [Table 19-7](#). Dosage of antimicrobials in foals differs somewhat from that of adults, and the pharmacokinetics of drugs in normal foals are often different from those of the same drug in sick foals. Consequently, higher dosages administered at prolonged intervals are often indicated in sick foals, especially when concentration-dependent drugs such as the aminoglycosides are used.

The response to antimicrobial therapy should be monitored, using physical examination and clinical pathology data, on at least a daily basis. Failure to improve should prompt a reconsideration of the therapy within 48 to 72 hours, and a worsening of the newborn's condition may necessitate changing the antimicrobial sooner than that. The decision to change antimicrobial therapy should be guided, but not determined, by the results of antimicrobial sensitivity testing of isolates from the affected newborn. These antimicrobial susceptibility patterns should be determined locally because the results can vary geographically, although results of studies are published.<sup>23,24</sup> The utility of antimicrobial sensitivity testing in determining optimal antimicrobial therapy for foals has not been determined, although it is likely that, as with mastitis in cows, sensitivity to antimicrobials determined by the Kirby-Bauer method will not be useful in predicting efficacy.

### Fluid Therapy

Fluid therapy of newborns differs from that of adult animals because of important differences in fluid and electrolyte metabolism in newborns. The following guidelines are suggested:

- **Septic shock**—sequential boluses of 20 mL/kg delivered over 5 to 20 minutes with reevaluation after each bolus. Usually, 60 to 80 mL/kg is the maximum dose before use of pharmacologic support of blood pressure is considered. Care should be taken to avoid fluid overload, and the foal should be reevaluated after each bolus and the need for continued fluid therapy determined. Continuous infusion of fluid is not indicated.
- **Maintenance support**—this should be determined based on the ongoing losses and the clinical status of the animal. However, general recommendations are as follows:
  - First 10 kg of body weight—100 mL/kg/d
  - Second 10 kg of body weight—50 mL/kg/d

Table 19-7 Antimicrobials used in neonatal foals

Antimicrobial	Dose and route	Frequency	Comments
Amikacin sulfate	25 mg/kg, IM or IV	24 h	Excellent Gram-negative activity, potentially nephrotoxic. Use with a penicillin.
Amoxicillin trihydrate	25 mg/kg, PO	6–8 h	Variable absorption decreasing with age. Limited Gram negative spectrum.
Amoxicillin-clavulanate	15–25 mg/kg, IV	6–8 h	Enhanced Gram-negative spectrum.
Amoxicillin sodium	15–30 mg/kg, IV or IM	6–8 h	Limited Gram-negative spectrum. Use with an aminoglycoside. Safe.
Ampicillin sodium	10–20 mg/kg, IV or IM	6–8 h	Limited Gram-negative spectrum. Use with an aminoglycoside. Safe.
Ampicillin trihydrate	20 mg/kg, PO	6–8 h	Limited Gram-negative spectrum. Variable absorption decreasing with age.
Cefotaxime sodium	15–25 mg/kg, IV	6–8 h	Use for bacterial meningitis. Expensive.
Cefoperazone sodium	20–30 mg/kg, IV	6–8 h	Use for <i>Pseudomonas</i> spp. infections.
Cefpodoxime proxetil	10 mg/kg PO	8–12 h	Broad spectrum and well absorbed by foals after oral administration.
Ceftazidime sodium	20–50 mg/kg, IV	6–8 h	Third-generation cephalosporin. Save for refractory infections.
Ceftiofur sodium	10 mg/kg, IV over 15 min	6 h	Broad spectrum. Note higher dose than used in adults.
Chloramphenicol palmitate	50 mg/kg, PO	6–8 h	Broad spectrum, bacteriostatic. Human health risk. Restricted use.
Chloramphenicol sodium succinate	50 mg/kg, IV	6–8 h	Broad spectrum, bacteriostatic. Human health risk. Restricted use.
Ciprofloxacin	5 mg/kg, IV	12 h	Broad spectrum. Potentially toxic to developing cartilage.
Enrofloxacin	5–7.5 mg/kg, PO or IV	12–24 h	Broad spectrum. Potentially toxic to developing cartilage.
Gentamicin sulfate	12 mg/kg, IV or IM	36 h	Good Gram-negative spectrum. Nephrotoxic. Use with a penicillin. Dose should be decreased to 6.6 mg/kg IV or IM every 24 hours for foals > 2 weeks of age.
Metronidazole	15–25 mg/kg, IV or PO	8–12 h	Active against obligate anaerobes and protozoa only.
Oxytetracycline	5 mg/kg, IV	12 h	Variable Gram-negative activity. Safe. Cheap. High and prolonged dose protocols have the potential to result in discoloration of the teeth.
Procaine penicillin G	20,000–40,000 IU/kg, IM	12 h	Very limited Gram-negative activity. Muscle soreness. Cheap.
Sodium or potassium penicillin G	20,000–40,000 IU/kg, IV or IM	6 h	Limited Gram-negative activity. Use with an aminoglycoside.
Pivampicillin	15–30 mg/kg, IV or IM	8 h	Ampicillin prodrug.
Ticarcillin sodium	50 mg/kg, IV	6 h	Active against Gram-negative organisms. Expensive.
Ticarcillin-clavulanate	50 mg ticarcillin/kg, IV	6 h	Extended activity. Expensive.
Trimethoprim-sulfonamide	15–30 mg/kg, PO, IV	12 h	Cheap. Broad spectrum. Limited efficacy in treating septicemia in foals.

- Weight in excess of 20 kg—25 mL/kg/d

Neonates with high ongoing losses, such as those with diarrhea or gastric reflux, can have higher fluid requirements.

Care should be taken to prevent administration of **excess sodium** to foals because they have a limited ability to excrete sodium. The recommended intake is 2 to 3 mEq/kg/d, and this includes sodium administered in parenteral fluids. One liter of isotonic sodium chloride provides a 50-kg foal's sodium requirements for 1 day.

A suitable maintenance fluid for foals is isotonic dextrose (5%) with supplemental potassium (10 to 40 mEq/L).

### Respiratory Support

Respiratory failure, evidenced by elevated arterial  $PCO_2$  and decreased  $PO_2$ , may be a result of depressed central activity, weakness of respiratory muscles, or lung disease. Regardless of the cause, should the hypoxemia become sufficiently severe, oxygenation must be improved by increasing respiratory drive, increasing the inspired oxygen tension, or employing mechanical ventilation. Foals should always be maintained in sternal recumbency to allow optimal respiratory function.

Provision of respiratory support should be considered when the arterial  $PO_2$  is less than 60 mm Hg (8 kPa) and the arterial  $PCO_2$  is more than 60 mm Hg (8 kPa) in a

foal in sternal recumbency. Pharmacologic respiratory stimulants have only a very short duration of action and are of limited use. Nasal insufflation of oxygen is achieved by placing a nasopharyngeal tube and providing oxygen at a rate of 5 L/min.

Mechanical ventilation is useful for maintaining oxygenation in foals with botulism, with more than 80% of foals surviving in one small study. However, this intervention requires considerable expertise and sophisticated equipment. The prognosis is much worse for foals with diseases of the lungs that require mechanical ventilation.

### Gastroduodenal Ulcer Prophylaxis

Ill neonatal foals are often treated with antacid drugs in an attempt to prevent the development or progression of gastroduodenal ulcers, although the efficacy of this approach is unproven. There is a trend toward not administering antiulcer medications to foals except for those with demonstrated gastric ulceration, in part because of the recognition that critically ill foals often have gastric pH above 7.0, and administration of ranitidine does not affect this pH. (See "Gastric Ulcers in Foals" for further discussion.)

### COMMON COMPLICATIONS

Complications of the neonate's disease or its treatment occur frequently:

- Entropion is common in critically ill foals and, although readily treated, can cause corneal ulceration if undetected.
- Aspiration pneumonia occurs in weak foals, often as a result of aggressive bottle feeding or regurgitation of milk around a nasogastric tube.
- Nosocomial infections can be severe and life-threatening and are best prevented by strict hygiene and asepsis.
- Septic synovitis/arthritis occurs as a consequence of bacteremia and should be treated aggressively.
- Omphalitis and omphalophlebitis occur and can be an undetected cause of fever and relapse. These are best detected by ultrasonographic examination of the abdomen.
- Patent urachus, evident as urine at the navel, usually resolves with time and local treatment.
- Uroperitoneum as a result of urachal rupture occurs in critically ill foals and should be suspected in any ill foal that develops abdominal distension.
- Angular limb deformities and excessive flexor tendon laxity occur frequently in ill neonatal foals but usually resolve with minimal symptomatic treatment as the foal recovers its strength.

### PROGNOSIS

The prognosis for critically ill neonates depends on many factors, including the

nature and severity of the disease, facilities available for care, and the expertise of the personnel caring for the neonate. There is a consensus that the recovery rate for severely ill foals has improved over the last decade because of provision of better care. There are reports of survival rates of around 80% for foals treated at a specialized intensive care unit. However, the high cost of providing care for these animals has prompted studies to determine outcome, as a means of deciding whether, financially, treatment is warranted. Surviving Thoroughbred foals do not differ from siblings with regard to percentage of starters, percentage of winners, or number of starts, but surviving foals achieve significantly fewer wins and total earnings.<sup>25</sup>

The increased number of foals being treated intensively has resulted in prospective studies of outcome. The prognosis for athletic activity for foals with septic arthritis is poor. Thoroughbred foals with **septic arthritis** have odds of 0.28 (95% CI 0.12 to 0.62; roughly one-quarter of the likelihood) for racing compared with a cohort of healthy foals. Multisystemic disease, in addition to the presence of septic arthritis, decreased the likelihood of racing to one-tenth that of healthy foals (OR 0.12, 95% CI 0.02 to 0.90). Affected foals that survive take almost 40% longer to race for the first time. Approximately 30% to 48% of affected Thoroughbred foals eventually race, compared with approximately 65% of normal foals.

Attempts to determine prognostic indicators for survival of foals have been partially successful, but they tend to be most applicable to the intensive care unit in which they were developed. The common theme is that sicker foals are less likely to be discharged from the hospital alive.

Characteristics of foals that are more likely to survive include ability to stand when first examined, normal birth, white blood cell (WBC) count in blood that is within or above the reference range, lack of dyspnea, normal plasma fibrinogen concentration, and short duration of disease. The odds of a hospitalized neonatal foal surviving can be calculated using the following formula:

$$\begin{aligned} \text{Logit (Probability of survival)} \\ = & -0.3072 - 2.0115 (\text{Cold extremities}) \\ & - 0.8166 (\text{Prematurity}) \\ & - 0.7685 (\geq 2 \text{ Infection/} \\ & \text{inflammation sites}) + 0.9877 (\text{IgG}) \\ & + 1.1331 (\text{Glucose}) + 0.9043 (\text{WBC}) \end{aligned}$$

In addition, the survival odds can be summarized in a much more useful form by the methods shown in [Tables 19-8 and 19-9](#). An app to calculate survival probabilities is available for Android phones.<sup>26</sup>

**Table 19-8 Method for calculating survival score in hospitalized neonatal foals<sup>1</sup>**

Variables	Score

## STILLBIRTH/PERINATAL WEAK-CALF SYNDROME

### SYNOPSIS

**Etiology** Uncertain; probably multiple etiologies and multifactorial.

**Epidemiology** Most commonly several cases on a farm; several farms affected in a geographic region in a single season; problem may not occur for several years and then occur as “epidemic” in a region.

**Clinical findings** Calves may be born weak and unable to stand. More commonly, they are born apparently normal and stand but subsequently collapse with hypothermia and die within a few hours of birth.

**Lesions** Petechial hemorrhages, subcutaneous edema, and hemorrhage commonly in the subcutaneous tissue of the carpal and tarsal joints.

**Diagnostic confirmation** Specific to cause.

**Treatment** Supportive.

**Control** Specific to cause.

## HISTORICAL ASPECTS

A syndrome of newborn calves called *weak-calf syndrome* was first recognized in Montana in 1964. It has been recognized throughout the United States and other countries since then, and it is considered a major economic loss in beef cattle herds. In the earlier descriptions of the syndrome, calves were affected by 10 days of age, and approximately 20% were affected at birth. Morbidity ranged from 6% to 15%. In some herds, sporadic abortions occurred before calving season of the herd began. In some cases, affected calves died within minutes after being born with varying degrees of obstetric assistance.

In calves that survived for a few days, clinical findings included lassitude, depression, weakness, variable body temperature, a reddened and crusty muzzle, lameness, reluctance to stand, enlargement of the carpal and tarsal joint capsules along with periarticular subcutaneous swellings, and a hunched-up back if they stood. Diarrhea occurred in some calves after a few days of illness, but it was not a major clinical finding. Treatment was ineffective, and the case fatality rates ranged from 60% to 80%.

At necropsy, the prominent lesions were hemorrhage and edema of the subcutaneous tissues over the tarsal and carpal joint regions and extending distally. Polysynovitis with

hemorrhagic synovial fluid often containing fibrin was also common. Erosive and hemorrhagic lesions of the forestomachs and abomasum also occurred. Several different pathogens were isolated from these calves, but no consistent relationship between the pathogens and the lesions was ever determined.

In retrospect, the case definitions were not well described, and it is probable that several different diseases of newborn calves were lumped into the enigma of weak-calf syndrome. As more detailed clinical and laboratory examinations of sick newborn calves have been done over the years, some of the causes of the original syndrome have been identified as specific diseases of newborn calves.

Widely ranging clinical and pathologic findings have been associated with weak-calf syndrome. In the most common situation, calves are born weak and die within 10 to 20 minutes after birth; sometimes they live for up to a few days. At necropsy there are no obvious or only few lesions to account for the illness. Calves that are weak after birth because of traumatic injuries associated with dystocia or other significant lesions can be accounted for according to the nature and severity of the lesions. Reports from Northern Ireland in recent years indicate that in dairy herds the incidence of weak-calf syndrome has ranged from 10% to 20% of all calves born. Field observations in problem herds found that the gestation period is of normal duration, but parturition is usually prolonged, with the first and second stages of labor lasting 24 hours. Affected calves usually are born alive but are unable to sustain breathing following birth. Despite resuscitation efforts, they commonly die within 10 minutes, often accompanied by prominent uncoordinated movements of the limbs. Some calves are stillborn, and whether or not this is a variation of the syndrome is uncertain. In a report from the United Kingdom, the syndrome occurred in calves born from heifers and was characterized by failure to breathe at birth or breathing with difficulty, and/or failing to move after birth, and failure to suck. The term *stillbirth/perinatal weak-calf syndrome* has been suggested as more appropriate.

### Dummy-Calf Syndrome

A variation of weak-calf syndrome is dummy-calf syndrome, which has been reported in the southern United States. Affected calves appear normal at birth and are generally alert, but they lack the instinct or the desire to seek the teat or suck after birth and for up to several hours later. The syndrome may occur in calves of any birth weight. The incidence has been highest in purebred Brahman females, but it has also occurred in Aberdeen Angus, Hereford, Chianina, and Brown Swiss breeds of cattle. Field observations indicate that affected

calves did not stand for up to 1 to 2 hours after birth to initiate teat-seeking behavior. Dummy calves appear to lack the sensitivity to teat-seek, and if they fail to locate a teat by about 4 to 5 hours after birth, they commonly lose the sucking reflex and then require intensive nursing care by bottle feeding to initiate sucking. In calves that fail to suck and ingest colostrum, hypothermia, hypoglycemia, and neonatal infections are common complications. Concurrently, the dam loses interest in the calf and may abandon it.

### ETIOLOGY AND EPIDEMIOLOGY

The etiology of weak-calf syndrome is unclear, but several epidemiologic observations have suggested some possible causes. These include the following:

- Fetal infection near term
- Underdevelopment because of nutritional inadequacy of the maternal diet during pregnancy
- Placental insufficiency
- Maternal dietary deficiencies of selenium and vitamin E
- Hypothyroidism
- Traumatic injuries associated with dystocia and excessive force during obstetric assistance
- Fetal hypoxia from prolonged parturition

### Fetal Infections

Fetal infections in the last few days before term can result in stillbirth or weak calves that may die within hours or days after birth. In one series of 293 weak calves in Northern Ireland, **leptospirosis** was present in 25% of the calves. Calves in which leptospiral antigen was detected in the placenta were significantly lighter by an average of 6 kg to 10 kg than calves with no antigen in the placenta. Calves infected with *Leptospira* in utero were more likely to be infected by *T. (formerly Arcanobacterium) pyogenes* or *Bacillus* species, and infection of the placenta is associated with a lower body weight. The adrenal gland, lung, and placenta are the most useful tissues to examine for leptospiral antigen.

**Bovine viral diarrhea (BVD)** virus infection has been identified in several herds with high occurrence rates of weak-calf syndrome. Effects of intrauterine infection with this virus will depend on the stage of pregnancy at which infection occurs, but birth of stillborn, weak, or dummy calves certainly warrants taking this differential into consideration (see also "Bovine Viral Diarrhea").

An unidentified type of adenovirus has been associated with weak-calf syndrome on a large dairy farm in Israel. At birth the calves were reluctant to suck or drink colostrum and were force-fed colostrum with an orogastric tube. Affected calves were weak at birth and unable to rise without assistance; when forced to move they walked stiffly,

suggestive of polyarthritis. An adenovirus was detected in the feces, synovial fluid, and aqueous humor of affected calves.

### Maternal Nutritional Deficiency Causing Fetal Underdevelopment

**Hypothyroidism as a result of iodine deficiency** in the pregnant dam has been considered on the basis of thyroid hyperplasia in some calves. Analysis of the laboratory data from 365 calves that died from the stillbirth/perinatal weak-calf syndrome in Ireland found some differences between calves with abnormal versus normal thyroid glands. Glands weighing more than 30 g were probably abnormal. Abnormal glands were heavier, constituted a greater percentage of the calf's body weight, and had a lower iodine concentration. A higher proportion of calves with an abnormal thyroid gland had uninflated lungs and pneumonia. Abnormal thyroid glands had a lower selenium concentration in the kidneys.

Hypothyroidism as a result of iodine deficiency can be caused by either inadequate dietary iodine supply or the presence of goitrogens in feed. Goitrogens are substances that impair thyroid hormone synthesis, either by inhibiting iodine uptake (cyanogenic goitrogens) or by inhibiting organic binding of iodine by the thyroid glands (goitrogens of the thiouracil type).<sup>1</sup>

However, the experimental reproduction of iodine deficiency in pregnant heifers by feeding an iodine-deficient diet over the last 4 to 5 months of pregnancy resulted in clinicopathologic changes and pathologic changes in the thyroid glands of both the heifers and their calves, but all calves in the iodine-deficient group were born clinically normal.

Because selenium plays a role in the function of the thyroid glands, selenium deficiency can cause hypothyroidism despite adequate dietary iodine supply. **Maternal dietary deficiency of selenium** in pregnant cattle has also been examined, but field trials have failed to show any protective effect from the parenteral administration of pregnant cattle with selenium. The parenteral administration of both selenium and iodine to pregnant cattle did not have any effect on the incidence of the syndrome between treated and untreated herds; the incidences were 7.9% and 7.4%, respectively.

A general nutritional inadequacy in the maternal diet can result in underdevelopment of the fetus and the birth of smaller-than-normal calves, but the deficiency usually must be grossly inadequate. A clinical trial showed that feeding a protein-restricted ration (7% crude protein) during the last trimester of pregnancy resulted in 11.4% lower birth weights than in control animals and in compromised thermogenic ability of the newborn calves, which has been proposed as a contributing factor to perinatal mortality of calves.<sup>2</sup> Another study

reported a selective decrease in absorption of colostral IgG<sub>1</sub> and IgG<sub>2</sub> from the gut in calves from heifers fed protein-deficient diets during the last trimester of pregnancy, which implies a higher risk for FTPI in these calves.<sup>3</sup>

#### *Placental Insufficiency*

Intrauterine growth retardation associated with feto-placental dysfunction has been described in Japanese Black beef calves.<sup>4</sup> Affected calves were weak when born at term and were underweight compared with normal calves. Anemia as a result of bone marrow dysfunction was present in affected calves and presumably was associated with intrauterine growth retardation. Thymic hypoplasia is another common finding in Japanese Black calves that died during the perinatal period, which also has been attributed to intrauterine growth retardation and is thought to contribute to perinatal weak-calf syndrome, which has a high occurrence rate in this breed.<sup>4,5</sup> There is some evidence that an immune inadequacy based on T-lymphocyte function may be associated with weak-calf syndrome in Japanese Black calves, which could be related to the thymic hypoplasia because the thymus is the site of T-cell maturation.

Dams delivering weak calves also had lower serum concentrations of estrone sulfate during late pregnancy than those of normal calves, suggesting a feto-placental dysfunction. The dysfunction was influenced by sires and maternal families.

#### *Fetal Hypoxemia*

Fetal hypoxemia resulting from prolonged parturition or dystocia may be a cause or contributing factor to weak-calf syndrome. Various predisposing factors can cause prolonged interference with fetal blood or oxygen supply, which can result in death during delivery or shortly after.

Examination of blood-gas values in newborn calves has shown that a prolonged parturition or delivery terminated by forced extraction results in a severe acidemia as a result of oxygen deprivation and ensuing anaerobic glycolysis with lactate accumulation in combination with hypercapnia, resulting in respiratory acidosis. As blood pH drops, first vitality is reduced, subsequently vital organs such as the brain are damaged, and ultimately the fetus dies.

The bovine fetus appears relatively susceptible to hypoxia and hypercapnia, which has been studied experimentally by clamping the umbilical cords of fetuses for 4 to 8 minutes, at 24 to 48 hours before expected birth, followed by a cesarean section 30 to 40 minutes later. Calves born following this procedure may die in 10 to 15 minutes after birth or survive for only up to 2 days. Under these experimental conditions, fetuses can survive anoxia for 4 minutes, but most will die following 6 or 8 minutes of anoxia.<sup>6</sup> During the clamping there is also increased

fetal movement and a release of meconium that stains the calf and the amniotic fluid. Those that survive for a few hours or days are dull and depressed, cannot stand, and have poor sucking and swallowing reflexes, and their temperatures are usually subnormal. They respond poorly to supportive therapy. Some calves whose umbilical cords were clamped for 4 minutes were born weak and made repeated efforts to raise their heads and move onto the sternum, but they were unable to maintain an upright position for long. These calves become hypothermic and dull, and their sucking and swallowing reflexes are present but weak. These calves are usually too weak to suck the cow even when assisted, and they commonly develop diarrhea and other complications.

#### *Dystocia and Traumatic Injuries at Birth*

Over 50% of perinatal mortality is generally attributed to dystocia, and dystocia may be an important contributing factor to weak-calf syndrome because of fetal hypoxia or traumatic injuries associated with obstetric assistance.<sup>7</sup> In a study of 13,296 calvings over a period of 15 years in two research herds in Montana, calf mortality as a result of dystocia accounted for the single largest loss category through the first 96 hours postpartum. Reported ORs vary widely (2.7 to 14.6), but they suggest that calves requiring assisted delivery had a 2.7 to 14.6 higher risk of death in the perinatal period than spontaneously born calves.<sup>8</sup> At necropsy of the calves that died as a result of dystocia, the findings included a froth-filled trachea, nonfunctional lungs, bruises, contusions, hemorrhages, bone fractures, and joint dislocations. It was concluded that the provision of adequate obstetric assistance at the right time could have reduced the mortality associated with dystocia.

**Traumatic injuries of calves at birth** are caused primarily by the mechanical influence of traction during delivery and can result in asphyxia and a high perinatal mortality rate. Excessive traction is the most important cause of rib and vertebral fractures in the calf during dystocia. A series of 235 calves that died perinatally were examined by necropsy to determine the possible causes of death related to dystocia. Most of the parturitions were protracted and needed veterinary assistance, and 58% of the calves had pathologic evidence of asphyxia. Calves delivered by extraction had pathologic evidence of asphyxia more often than those born unassisted or delivered by cesarean section. Intrapulmonary amniotic material may be present in the lungs, representing evidence of perinatal respiratory distress. The aspiration of small amounts of amniotic fluid with or without meconium is common in calves and is not associated with hypoxemia, respiratory acidosis, or failure of passive transfer.

#### *Premature Expulsion of Placenta*

Premature expulsion of the placenta has been associated with perinatal calf mortality. Field observations indicate that the majority of affected fetuses die of fetal hypoxia during stage 2 of calving. The most significant risk factor associated with premature expulsion of the placenta was fetal malpresentation and malposture. Prolongation of the second stage of parturition allows for sufficient detachment of the placenta for it to occupy the posterior part of the genital tract. The placenta is frequently expelled together with the calf. In one series of cases, there was no significant relationship between the occurrence of premature expulsion of the placenta and parity, calving difficulty, previous calving history, or sex of the calf.

#### **NECROPSY FINDINGS**

All calves that die should be examined by necropsy to identify possible causes. It is important to establish if there is one disease complex or several different diseases of newborn calves.

In the weak-calf syndrome described in Northern Ireland, at necropsy many calves had petechial hemorrhages in the thymus gland, on the ventricular epicardium, and in the parietal pleura and endocardium. These lesions were similar to those present in animals that died of acute terminal asphyxiation. The gasps made in response to asphyxia in utero result in amniotic fluid being inhaled into the respiratory tract. In one study, 84% of stillborn calves had these lesions of asphyxia. It is well established that asphyxiation during birth is a major factor in intra-partum stillbirth in piglets and contributes to early postnatal mortality. Froth may be present in the caudal trachea of some calves that die within 10 to 20 minutes after birth.

Varying degrees of subcutaneous edema of the head and/or bruising of the rib cage are also common. Fractures of the ribs are common, accompanied by intrathoracic hemorrhage. Vertebral body fractures occur commonly at the thoracolumbar region and may be accompanied by intraabdominal hemorrhage. The lungs may be inflated normally, partially inflated, or not inflated. Severe bruising and hemorrhage occur around the costochondral junctions, at the sternal extremities of the costal cartilages, and over the sternum and shoulder regions. In some cases, the traumatic lesions are severe and may involve primarily the right side of the rib cage. Severe subcutaneous hemorrhage and edema may be present over the carpal and fetlock joints as a result of the pressure applied by the obstetric chains or ropes.

In the syndrome described in the United States, the lesions either appeared at birth or developed in the first few weeks of life. At necropsy the prominent lesions are marked edema and hemorrhages of the subcutaneous tissues over the carpal and tarsal joints

and extending distally down the limbs. The synovial fluid may be tinged with blood and contain fibrinous deposits. Erosions or ulceration of the gastrointestinal tract, petechial hemorrhage of internal organs, involution of the thymus gland, and hemorrhages in skeletal muscle have also been present.

The weak-calf syndrome described in Japanese Black calves was associated with atrophy of the red bone marrow and thymic hypoplasia.<sup>9</sup> Degeneration of brainstem nerve cells, attributed to protracted hypoxia, was also noticed.

Samples for confirmation of diagnosis include the following:

- Bacteriology—fetal liver, lung, stomach content, adrenal gland; placenta (culture); special detection techniques for *Leptospira* antigens
- Histology—fixed placenta, lung, spleen, brain, liver, kidney; maternal caruncle (light microscopy, Immunohistochemistry)

#### DIFFERENTIAL DIAGNOSIS

Determination of the cause of weak-calf syndrome in a herd is often difficult because the limits of the case definition cannot be determined. Several risk factors may interact to contribute to the disease. The most common definition is a calf that is alive at birth, appears normal otherwise, but either fails to breathe or breathes for less than approximately 10 minutes and then dies. If they survive for several hours or a few days, affected calves are usually in sternal recumbency, depressed, reluctant to stand unassisted, reluctant to walk, and not interested in sucking. They may not respond favorably to supportive therapy.

#### Case definition

When an epidemic of the disease is encountered, an epidemiologic investigation of the herd is necessary in an attempt to identify possible risk factors.

The patterns of occurrence should be determined:

- Is the problem more common in calves born to heifers than cows? In some situations, the owner may provide more surveillance for the calving heifers and less for the mature cows, with a consequent greater incidence of weak calves born from the cows.
- Is there any evidence that parturition is prolonged in the heifers or the cows? If so, what are the possible reasons?
- How long are heifers and cows in the herd allowed to calve unassisted before obstetric assistance is provided?
- Is it possible that some nutritional, management, or environmental factor is interfering with normal parturition?
- Is the condition more common in male or female calves, and what are the relative birth weights?

- How soon after birth are the calves affected?
- What is the course of the illness after the first clinical abnormalities are noted?
- Is the serologic herd status regarding specific infectious diseases known (e.g., *leptospirosis*, BVD, bluetongue)?
- The veterinarian should make every effort to clinically examine a representative number of affected calves.

#### TREATMENT

Calves born weak, unable to stand, lacking the instinct to seek the teat, or lacking a suck reflex need intensive care, including force-feeding of colostrum and the provision of warm surroundings to prevent hypothermia and other complications. Affected calves must be assisted to suck the dam normally. Bottle feeding for a few days may be necessary until the calf becomes strong enough to suck the dam on its own.

#### CONTROL AND PREVENTION

Control and prevention of weak-calf syndrome is based on empirical observations, beginning with insuring **adequate nutrition of the dam** to avoid any possible nutritional factors affecting neonatal calf vitality. The provision of **adequate surveillance at calving time** and competent obstetric assistance when necessary is also crucial to avoid prolonged parturition and fetal hypoxia in calves.

When epidemics of the disease are occurring, the surveillance of calving must be intensified, and it may be necessary to intervene with obstetric assistance earlier than usual. Determination of the cause may require that the veterinarian attend several calvings, make detailed clinical examinations of the length of parturition, and observe the parturition process and the health of the calves at birth.

## DISEASES OF CLONED OFFSPRING

The successful cloning of domestic animals using somatic-cell nuclear transfer has resulted in birth of offspring with a high frequency of clinical abnormalities. Cloning of livestock and horses is achieved by transfer of nuclear material from the cell of an adult animal to the enucleated egg of an animal of the same species (somatic-cell nuclear transfer), with subsequent implantation of the resulting embryo in a surrogate dam and birth of a live, viable offspring. However, the use of nuclear material from somatic cells of adult animals, and from fetal cells, frequently does not result in normal development of the embryo and placenta.

The abnormal development in cloned embryos is a consequence of altered methylation of the genome in transferred nuclear material. This applies particularly for imprinted genes, which are those genes for which only one copy is expressed in the embryo, compared with nonimprinted genes for which both parental copies of the gene are expressed. The lower frequency of expression of imprinted genes (i.e., only one copy, paternal or maternal) is a result of methylation of DNA or chromatin proteins that makes the DNA inaccessible for transcription.<sup>1</sup> Imprinting is a form of epigenetic control of gene expression. To date, 132 imprinted genes have been identified in mice, but only 25, 21, and 14 in cattle, pigs, and sheep, respectively.<sup>1</sup> Imprinted genes encode proteins involved in regulation of many cell processes, including embryonic and neonatal growth and development.<sup>1,2</sup>

In normal reproduction, the paternal genome is demethylated during passage through the oocyte and fusion with the maternal genome. Consequently, the methylation marks of the two genomes (paternal and maternal) are different at the end of the cleavage process. Transfer of somatic nuclear material into an enucleated oocyte results in exposure of both genomes to the active demethylating process in the cytoplasm of the oocyte and uniform or variable demethylation of both genomes. The loss of these parent-specific epigenetic markers results in widespread dysregulation of imprinted genes and subsequent abnormalities in the placenta, fetus, and newborn. Imprinting marks (methylation) are erased during early development, and reprogramming of somatic-cell nuclei used in cloning and these abnormalities in epigenetic control of expression of imprinted genes result in biallelic expression of imprinted genes.<sup>3</sup> The loss of epigenetic control of imprinted genes causes at least some of the abnormalities common in cloned ruminants, including large-offspring syndrome (LOS).<sup>3</sup>

A small proportion of transferred blastocysts develop in viable animals. For cattle, of 134 recipients that received blastocysts, 50

were pregnant 40 days after blastocyst transfer, and 23 had full-term pregnancies. For all species studied, fewer than 3% of cloned embryos result in birth of viable animals. Abnormalities in the placenta and newborn cloned animals are reported for cattle and sheep, but are less frequently reported, if at all, for pigs and equids (horses and mules). Factors influencing the risks of abnormalities in newborns include the source of the nuclear material, type of in vitro culture media, coculture with somatic cells, hormonal treatments, and manipulation of the embryo.<sup>1,4</sup> The frequency of birth of live animals born after somatic-cell nuclear transfer from well-differentiated tissue (e.g., fibroblasts) or fetal somatic cells is lower than after nuclear transfer from embryonic cells (7%, 15%, and 34%, respectively).

The cause of placental, fetal, and neonatal abnormalities is abnormal expression of imprinted genes as a consequence of transfer of nuclear material from differentiated somatic cells,<sup>5</sup> conditions and media used for maintenance and culture of cytoplasts and blastocysts, and techniques used for handling cells.<sup>3,6-8</sup> The key abnormality is loss of methylation of imprinted genes contributed by each parent, with subsequent biallelic expression of these genes. There is debate about which epigenetic or genetic abnormalities underlay the development of placental and fetal abnormalities. Aberrant hypomethylation of IGF-2 and CDK1C genes has been identified in calves with LOS and results in biallelic expression in the liver and placenta of affected animals.<sup>1</sup> Abnormalities in embryologic development of vasculature is identifiable early during embryogenesis in calves and might be the defect underlying pulmonary, circulatory, and umbilical abnormalities in cloned calves.<sup>9</sup> Furthermore, there is decreased expression of genes in the lungs of cloned goats that do not survive compared with those of healthy kids. Compared with normal goats of the same age from conventional reproduction, expression of 13 genes (BMP4, FGF10, GHR, HGFR, PDGFR, RABP, VEGF, H19, CDKN1C, PCAF, MeCP2, HDAC1, and Dnmt3b) decreased in transgenic cloned goats that died at or shortly after birth.<sup>6</sup> Expression of eight genes (FGF10, PDGFR, RABP, VEGF, PCAF, HDAC1, MeCP2, and Dnmt3b) decreased in fetal death of transgenic cloned goats.<sup>6</sup> A comprehensive list of genes known to be involved in embryogenesis and fetal and placental growth and a description of the effect of decreased expression of these genes are available.<sup>10</sup>

**Clinical findings** in cloned calves and lambs include abortion, placental abnormalities, large birth size, poor extrauterine viability, respiratory disease, cardiovascular abnormalities, and neurologic disease compatible with neonatal encephalopathy. LOS is confined to ruminants and is characterized by overgrowth, evident as abnormally high birth weight, enlarged tongue, umbilical

hernias, and hypoglycemia.<sup>3</sup> Abortion occurs after day 90 of gestation in 30% to 50% of pregnancies in cattle, resulting from transfer blastocysts containing transferred nuclear material. Abnormalities, including hydroallantois, are present in approximately 25% of advanced pregnancies. **Placental abnormalities** include hydroallantois, a reduction in the number of placentomes (from a normal value of approximately 100 to as few as 26 to 70 in cloned calves), abnormally large placentomes (140 g in cloned calves versus 33 g in conventional calves), and edema of the placenta.<sup>10</sup> Maternal retention of the placenta is common and occurs in most cows. Duration of gestation is probably longer in cloned calves, although the frequent delivery of cloned calves by cesarean section makes assessment of gestational duration difficult. Cloned calves are heavier than conventional calves, often by as much as 25%, a well-recognized part of the **large-offspring syndrome** that affects calves born as a result of reproductive manipulation, including in vitro fertilization. Viability of cloned calves that are born alive (commonly by cesarean section) is less than that of conventional calves; only approximately two-thirds of cloned calves born alive survive more than 1 month, although others have reported better survival. Similar results are reported for horses.

A high proportion of cloned calves have **clinically detectable abnormalities** at or soon after birth, including sepsis, neonatal encephalopathy, respiratory failure, umbilical abnormalities, anemia, flexure contracture, abdominal distension, and renal dysfunction. Respiratory failure is a common finding and might reflect persistent fetal circulation or inadequate surfactant production, as evidenced by the high pulmonary artery pressures and signs consistent with patent ductus arteriosus.<sup>11</sup> Left heart failure, which can also cause pulmonary hypertension, is reported in cloned calves. Umbilical abnormalities are evident as abnormal umbilical cord structure (multiple arteries and veins) and large size, with a high risk of hemorrhage from the umbilical cord after birth. Cloned calves have higher body temperatures than do conventional calves.

Of 27 cloned calves delivered alive, 7 were bradypneic or apneic at birth, 5 had flexural limb deformities, and at least 23 had enlarged umbilical cords. The calves were acidotic at birth as a result of both respiratory and lactic acidosis. Calves had normocytic hypochromic anemia, stress leukogram (leukocytosis, neutrophilia, and lymphopenia), and hypoproteinemia (with both hypoalbuminemia and hypoglobulinemia) and had increased serum creatinine concentration.<sup>12</sup> Three of the calves did not develop other clinical signs and were considered healthy after birth, whereas 22 had at least one important clinical abnormality detected during the week

after birth. Twelve of the calves developed omphalitis. Fourteen of the calves died or were euthanized.<sup>12</sup>

Hematologic abnormalities include anemia and decreased mean corpuscular volume. Biochemical abnormalities include hypoxemia, azotemia, and hypoglycemia. Plasma leptin and IGF-2 concentrations are higher, and thyroxine lower, in cloned calves. Serum cortisol and adrenocorticotrophic hormone (ACTH) stimulation tests do not differ between cloned and conventional calves. Cloned calves can mount normal immune responses.<sup>13</sup> Failure of transfer of passive immunity can occur if calves are unable to suckle or are not administered colostrum or plasma.<sup>12</sup>

**Necropsy** examination reveals placentomegaly, presence of excess pleural and peritoneal fluid, hepatomegaly, interstitial pneumonia or pulmonary consolidation and alveolar proteinosis, right ventricular dilation, and hepatocellular vacuolation.

**Treatment** is supportive and directed toward correcting hypoxemia and providing nutritional, fluid, and environmental support (see earlier discussion).

There are currently no recognized methods for preventing these abnormalities, but incremental improvements in methodology and culture techniques will continue to result in fewer cloned offspring with these abnormalities.

## EQUINE NEONATAL MALADJUSTMENT SYNDROME (NEONATAL ENCEPHALOPATHY, DUMMY FOAL, BARKERS, AND WANDERERS)

This is a syndrome of foals less than 36 hours of age characterized by a spectrum of changes in mentation ranging from failure

to suckle, abnormal behavior, and seizures through coma in otherwise apparently healthy foals. The syndrome is defined by the clinical abnormalities and not by a common etiology.

## ETIOLOGY

The clinical signs associated with this syndrome can be produced by a number of diseases, each of which has its particular etiology. Diseases that contribute to this syndrome include antenatal, natal, or postnatal hypoxia;<sup>1</sup> a range of congenital abnormalities (hydrocephalus, hydrancephalus,<sup>2</sup> and such); metabolic disorders;<sup>3</sup> placental abnormalities;<sup>4</sup> intracranial hemorrhage; prematurity; and thoracic trauma. Fetal or perinatal hypoxia has achieved some prominence as a cause of neonatal maladjustment syndrome in the absence of consistent demonstration of lesions of hypoxia on histopathologic examination of foals. There are isolated cases in which histologic evidence of hypoxia exists, but these are the exception rather than the rule. Finally, most foals with neonatal maladjustment syndrome improve rapidly and completely recover within several days—a clinical course not expected with neonatal or perinatal asphyxia in other species.

Recent evidence implicates a role of neuroactive progesterone derivatives in the etiology of neonatal maladjustment syndrome.<sup>5,6</sup> Plasma concentrations of these neuroactive steroids in foals are high immediately after birth and decline rapidly in healthy foals, but not in foals with neonatal maladjustment syndrome.<sup>5</sup> Foals with neonatal maladjustment syndrome and foals with other illness have higher concentrations of progesterone derivatives than do healthy foals.<sup>7</sup> Plasma concentrations of progesterone derivatives decline in sick foals that do not have neonatal maladjustment syndrome, but not in foals with the syndrome.<sup>5</sup> Progesterone derivatives include progesterone, pregnenolone, androstenedione, dehydroepiandrosterone, and epitestosterone.<sup>5</sup> Evidence from other species and limited experimental evidence in foals indicate that allopregnanolone infusion induces changes in mental status that mimic those seen in foals with neonatal maladjustment syndrome.<sup>6</sup> It is proposed that a subset of foals with signs of neonatal maladjustment syndrome have disease attributable to persistence of the fetal hypothalamic–pituitary–adrenal axis after birth.

## EPIDEMIOLOGY

The disease is sporadic and occurs worldwide, with an annual **incidence** in foals of less than 1%.<sup>7</sup> Foals of either sex and of any breed born to mares of any age or reproductive history can be affected. The **case fatality rate** is very low for appropriately treated foals without other systemic illness.

## PATHOGENESIS

Hypoxia resulting from intracranial vascular accidents, asphyxia at birth, or placental insufficiency before birth damages the central nervous system, causing a wide variety of signs of neurologic dysfunction.

A proposed pathogenesis for foals with persistently high plasma concentrations of progesterone derivatives after birth is failure of the foal's hypothalamic–pituitary–adrenal axis to rapidly adjust to extrauterine life.<sup>6</sup> In utero, foal movement and activity is suppressed, presumably at least in part by high concentrations of neuroactive progesterones. At birth in healthy foals there is a rapid reduction in concentration of these hormones coincident with increases in activity of the foal. Progesterone derivatives, some of which can cross the blood–brain barrier, modulate the activity of the GABA<sub>A</sub> receptor and at high concentrations completely inhibit its activity, providing a potential explanation for the somnolence and other signs displayed by foals with neonatal maladjustment syndrome and high plasma progesterone concentrations.<sup>5</sup>

Neurologic abnormalities and a failure to nurse result in a failure of the transfer of maternal immunoglobulins, which predisposes the foal to septicemia and hypoglycemia. Failure to nurse also results in hypoglycemia and malnutrition.

## CLINICAL SIGNS

**Foals that are abnormal at birth** can display a range of behavioral abnormalities, from lack of suckle reflex to convulsions with extensor rigidity. The placenta of affected foals is often abnormal, or there is a history of prolonged parturition. Affected foals either do not develop or lose the suck reflex, have no affinity for the mare, and are unable to locate the udder or teat. Aimless wandering and a characteristic “barking” vocalization are sometimes present. Recumbent foals struggle wildly and in an uncoordinated fashion to stand. Convulsing foals usually display opisthotonus with extensor rigidity. Other signs of convulsive activity include facial twitching and grimacing, nystagmus, rapid blinking, sucking, chewing, and drooling. Between episodes foals are usually depressed or somnolent. Affected foals display little or no interest in the mare. Convulsing foals are tachypneic, tachycardic (>180 bpm), and hyperthermic (>39°C, 102°F) during and immediately after convulsions. It is important to recognize that the severity of clinical signs varies from very mild (foals are often described by owners as being a bit slow or dimwitted) through to grand mal seizures.

**Foals that are normal at birth** can develop signs by 24 hours of age. The signs are similar to those described previously, with the exception that the foals are initially able to ambulate. It is important to realize that healthy newborn foals lack a menace reflex, have a hypermetric gait and intention

tremor, and become flaccid when restrained. The reflex response of healthy foals to restraint by a handler placing one arm under the foal's neck and another around the buttocks and squeezing is to become “floppy” and somnolent.<sup>6</sup> Foals restrained in this way become immobile, lie down, and have an increased pain threshold during restraint.<sup>6</sup>

Affected foals can take days to weeks to recover completely. Blind foals that do not have ocular lesions can take as long as 4 to 6 weeks to regain vision.

Ancillary testing is not usually indicated unless the foal fails to respond after approximately 7 days. At that time, CT or MRI examination of the brain might be indicated to detect congenital anomalies such as hydrocephalus. Examination of CSF should be performed in any foal with signs of central nervous system dysfunction in the presence of fever or other signs of sepsis.

## CLINICAL PATHOLOGY

There are no routine hematologic or serum biochemical abnormalities characteristic of the disease, although it is prudent to conduct such examinations to eliminate other diseases; common characteristics are as follows<sup>3</sup>:

- Affected foals usually have **failure of transfer** of maternal immunoglobulins (serum IgG < 400 mg/dL).
- They may be **hypoglycemic** (<80 mg/dL, 4 mmol/L).
- **Cerebrospinal fluid** is often normal, although it may contain red blood cells or appear xanthochromic as a result of bleeding.

Detection of **biomarkers of brain injury** has been investigated. Plasma concentrations of **ubiquitin C-terminal hydrolase** (UCHL1) are higher (6.57, range 2.35 to 11.9 ng/mL) in foals with signs of neonatal maladjustment syndrome (defined as neonatal hypoxic-ischemic encephalopathy in the study) than in healthy foals (2.52, range 1.4 to 4.01 ng/mL).<sup>8</sup> The sensitivity and specificity for diagnosis of neonatal maladjustment syndrome based on a cutoff of ubiquitin C-terminal hydrolase concentrations in plasma of 4.01 ng/mL were 70% and 94%, respectively.<sup>8</sup>

Measurement of **plasma progesterone concentrations** of foals with signs of neonatal maladjustment syndrome might prove to be useful in diagnosis of the disease. Foals with high concentrations of progesterone could be treated appropriately, and those with low or normal concentrations could be further investigated for other diseases such as intracranial hemorrhages or hydrocephalus.

## DIAGNOSTIC CONFIRMATION

**Definitive diagnosis** of the disease is difficult and is based on exclusion of other diseases that can cause similar signs and, at necropsy, demonstration of intracranial lesions consistent with the disease.

## NECROPSY FINDINGS

Gross changes are typically limited to diffuse pulmonary congestion with a variable degree of atelectasis. In cases in which dystocia has been a contributing factor, fractured ribs and foci of subcutaneous edema and hemorrhage are sometimes noted. Occasionally, macroscopic cerebral hemorrhages are visible. Histologically, the key findings are hemorrhagic foci within the brain and areas of ischemic necrosis in the cerebral cortex. Meconium and other components of aspirated amniotic fluid accompanied by atelectasis and a mild inflammatory response may be present within the lung. In less affected foals the brain lesions are restricted to hemorrhage, cerebral swelling, and edema. Some affected foals subject to necropsy examination have evidence of intracranial vascular accidents, but it must be recognized that this is a biased sample; many foals recover from the disorder. Affected foals that are euthanized for financial or management reasons often have no detectable lesions in the brain.

## Samples for Postmortem Diagnostic Confirmation

Samples for postmortem diagnostic confirmation include formalin-fixed brain, including cerebral cortex, cerebellum, and brainstem, and lung for light microscopic examination.

### DIFFERENTIAL DIAGNOSIS

The disease must be differentiated from other diseases that cause neurologic or behavioral abnormalities in foals, including sepsis; renal, hepatic, or gastrointestinal disease, which can occur secondary to fetal hypoxia; hydrocephalus; hypoglycemia; meningitis; neonatal isoimmune hemolytic anemia; and prematurity, dysmaturity, or immaturity (Table 19-10).

## TREATMENT

The principles of treatment are as follows:

- Control of convulsions
- Treatment of cerebral edema and hemorrhage

- Correction of FTPI
- Nutritional support and general nursing care

The management of affected foals is mainly supportive and is a time-consuming and labor-intensive endeavor. Provision of nutritional support, treatment of failure of transfer of maternal immunoglobulins, and nursing care are discussed in detail in the section "Principles of Care of the Critically Ill Neonate."

For other than emergency treatment of seizures, in which **diazepam** (0.1 to 0.4 mg/kg, intravenously, as required) or **midazolam** (0.05 to 0.1 mg/kg IV, as required) are useful, **phenobarbital** (phenobarbitone), **phenytoin**, and **primidone** are the drugs of choice for long-term control of seizure activity. Phenobarbital is administered initially at a dose of 9–20 mg/kg intravenously in 30 mL of isotonic saline infused over 15 to 30 minutes. Maintenance therapy is a similar dose intravenously (7–9 mg/kg IV over 20 min every 8–12 hours) or a lower dose (1–5 mg/kg) orally, every 8 hours, and the dose is adjusted

**Table 19-10** Differential diagnosis of comatose ("sleeper") neonatal foals

Disease	Epidemiology	Clinical findings	Clinical pathology	Lesions	Treatment and prognosis
Septicemia	<i>E. coli</i> , <i>Klebsiella</i> spp., <i>Streptococcus</i> spp., <i>Salmonella</i> spp., <i>Actinobacillus suis</i> , Equine herpesvirus-1. Failure of transfer of passive immunity.	Abrupt onset of depression, fever, failure to nurse, and recumbency. Later diarrhea, pneumonia, and joint distension.	Culture of organism from blood or lesions (joints, lungs, feces).	Consistent with septicemia. Pneumonia. Septic synovitis, arthritis, and osteomyelitis.	Broad-spectrum antibiotics, supportive care (see "Principles of Providing Care to the Critically Ill Neonates"). Guarded to poor prognosis.
Isoimmune hemolytic anemia	Incompatible mating of Aa + or Qa + stallion with negative mare.	Normal at birth. Subsequent depression, cessation of nursing, exercise intolerance, icterus, and anemia. Hemoglobinuria in severe cases.	Positive Coombs' test to demonstrate immunoglobulin on foal's red cells. Dam's colostrum agglutinates or lyses foal red cells.	Anemia, icterus. Death from anemic hypoxia.	Transfusion of washed dam's red blood cells or of compatible donor (check dam's plasma with donor's red cells). Fair prognosis.
Uroperitoneum	Ruptured bladder, urachus or ureteral defect. Colts 1–3 days of age. Foals of either sex with other systemic diseases.	Normal at birth. Onset of abdominal distension, mild colic, depression, and recumbency. May urinate small volumes.	Peritoneal fluid has high creatinine concentration. Hyperkalemia, hyponatremia, and hypochloremia.	Uroperitoneum. Rupture bladder, urachus or ureter.	Surgical correction AFTER drainage of abdomen and resolution of hyperkalemia with intravenous dextrose or 0.9% NaCl. Good prognosis with appropriate care.
Hypoglycemia	Failure to nurse. Rejection by mare. Mare has no milk (agalactia).	Normal at birth, repeated attempts to nurse. Gradual onset (hours) of weakness and depression.	Low blood glucose concentration (<60 mg/dL, 3 mmol/L).	None. No food in stomach.	Excellent response to feeding or intravenous glucose.
Neonatal maladjustment syndrome	Sporadic.	Onset of abnormal behavior, recumbency, failure to nurse or orient to mare. Aimless wandering and vocalization.	None characteristic. Frequently failure of transfer of passive immunity.	Usually none apparent. Occasional intracranial vascular accidents.	Supportive care (see "Principles of Providing Care to Critically Ill Neonates"). Good prognosis.
Congenital defects	Sporadic.	Depends on nature of cardiac, gastrointestinal, or central nervous system defect.	None.	Consistent with defect.	Usually no treatment. Poor prognosis depending on defect.

to provide control of seizures while minimizing the degree of sedation. Because of the long elimination half-life of phenobarbital in foals (~200 hours) and the transient nature of the disease, once seizure control is achieved, administration of phenobarbital can be discontinued. Drug concentrations will be at or above the target concentration (5 to 30 µg/mL) for several days after the final dose. **Phenytoin** (5 to 10 mg/kg intravenously or orally initially, then 1 to 5 mg/kg every 4 hours) or **primidone** (20 to 40 mg/kg orally every 12 to 24 hours, to effect) are also used to control convulsions.

Definitive demonstration of the presence of cerebral edema or intracranial hemorrhage is impossible without sophisticated imaging devices, such as MRI or CT. However, treatment is often initiated on the basis of clinical signs. None of the treatments has demonstrated efficacy, and some are controversial. **Dimethyl sulfoxide** (DMSO) is given intravenously at 0.5 to 1 mg/kg once or twice daily for 3 days as a 10% solution. **Mannitol** (0.25 g/kg, intravenously as a 20% solution) may be effective in treating cerebral edema, but it is contraindicated if intracranial hemorrhage is present. **Glucocorticoids** (dexamethasone, 0.2 to 1 mg/kg, or prednisone, 1 to 2 mg/kg) might reduce intracranial inflammation and swelling. They might be contraindicated in foals with sepsis.

**Magnesium sulfate** (0.05 mg/kg per hour for 1 hour, then 0.025 mg/kg/h intravenously for up to 48 hours) is often administered to foals with suspected hypoxic encephalopathy in an attempt to minimize neuronal damage. There is no objective evidence of its efficacy in foals.

Foals with respiratory depression can be administered **caffeine** (10 mg/kg orally once and then 3.0 mg/kg orally q 24 hours). There is objective evidence of the lack of efficacy of this treatment in improving survival or decreasing arterial carbon dioxide tension in foals with a diagnosis of neonatal hypoxia-ischemia.<sup>9</sup> Adverse effects include agitation, hyperesthesia, tachycardia, and convulsions.

**Good nursing care** is critical in affected foals, and a concerted and persistent effort should be made to encourage the foal to nurse the mare. Encouraging the foal to nurse can be frustrating for the handler and mare, but should be done regularly, about every 4 hours, and preferably when the foal is hungry. Affected foals often begin to nurse quite suddenly. Foals should be provided with nutritional support, such as with mare's milk administered by indwelling nasogastric tube, until they are able to suckle.

Affected foals can require up to 4 to 6 weeks to recover completely, although most do so within 1 week of birth, and hasty decisions regarding euthanasia should not be made without recognition of the sometimes long time required for complete recovery.

## CONTROL

Prevention of hypoxia in neonates by close monitoring of the health of the mare and of parturition may reduce the incidence of the disease.

## Neonatal Infectious Diseases

### SYNOPSIS

**Etiology** Common infections for each animal species are listed under "Etiology" in the discussion. Most etiologies are bacterial, but some are viral.

**Epidemiology** Commonly predisposed by management and environmental factors and difficult delivery that increase the exposure risk and load and decrease the resistance of the neonate.

**Clinical findings** Depending on the pathogen and portal of entry, local infection or septicemia with following localization can occur; signs can be specific for the agent and the affected organ(s).

**Clinical pathology** White blood cell and differential counts, toxic change, serum immunoglobulin concentrations, blood gas analysis, acute-phase protein concentrations, blood culture.

**Necropsy findings** Specific to disease.

**Diagnostic confirmation** Specific to disease.

**Treatment** Treatment may include antimicrobial therapy, correction of acid-base disturbance, fluid and electrolyte therapy, blood or plasma transfusion, antiinflammatory therapy, and other supportive treatment.

Infection is a common cause of morbidity and mortality in neonates. There are a number of specific infectious pathogens that can cause disease. Other microorganisms normally present in the neonate's environment can become opportunistic pathogens whenever the immunologic status of the neonate is impaired. Maternal immunoglobulins are not transferred transplacentally in ungulates, and the newborns rely on the

acquisition of immunoglobulins from colostrum for passive antibody protection.

## ETIOLOGY

In domestic farm animals the common infections that can produce disease during the neonatal period are described in the following subsections. (Relative importance and prevalence statistics are not given because these vary from area to area and with differing management systems.)

### Calves

- Enteritis associated with enterotoxigenic *Escherichia coli*; *Salmonella* spp.; rotavirus and coronavirus;
- *Cryptosporidium parvum*; *Clostridium perfringens* types A, B, and C; and occasionally by the virus of infectious bovine rhinotracheitis and bovine viral diarrhea
- Bacteremia and septicemia associated with *E. coli*, *Listeria monocytogenes*, *Pasteurella* spp., streptococci, or *Salmonella* spp.

### Pigs

- Septicemia with or without localization in joints, endocardium, and meninges associated with *Streptococcus suis*, *Streptococcus equisimilis*, *Streptococcus zooepidemicus*, and *L. monocytogenes*
- Bacteremia, septicemia, and enteritis associated with *E. coli*
- Transmissible gastroenteritis, Aujeszky's disease, swine pox, enterovirus infections, and vomiting and wasting disease associated with viruses
- Enteritis associated with *C. perfringens*, *Campylobacter* spp., rotavirus, and *Coccidia* spp.
- Arthritis and septicemia associated with *Erysipelothrix rhusiopathiae*

### Foals

- Septicemia with localization associated with *E. coli*, *Actinobacillus equuli*, *Klebsiella pneumoniae*,  $\alpha$ -hemolytic streptococci, *S. zooepidemicus*, *L. monocytogenes*, *Rhodococcus equi*, and *Salmonella typhimurium*
- Enteritis associated with *C. perfringens* types A, B, and C; *Clostridium difficile*; *R. equi*; *Salmonella* spp.; *Strongyloides westeri*; *C. parvum*; and rotavirus.

### Lambs

- Septicemia or bacteremia with localization in joints and/or synovia and/or leptomeninges associated with *E. coli*, *L. monocytogenes*, streptococci, micrococci, *E. rhusiopathiae*, and *Chlamydomphila* spp.
- Enteritis associated with enterotoxigenic *E. coli*, *Salmonella* spp., rotavirus and coronavirus, and *C. parvum*
- Lamb dysentery associated with *C. perfringens* types B and C

- Gas gangrene of the navel associated with *Clostridium septicum*, *Clostridium novyi*, and *Clostridium chauvoei*
- Pyemia associated with *Staphylococcus aureus*, *Fusobacterium necrophorum*, and *Trueperella* (formerly *Arcanobacterium*) *pyogenes*
- Pneumonia, polyserositis, and peritonitis associated with *Pasteurella multocida* and *Mannheimia hemolytica*

The agents listed in the following subsections are recorded as causing neonatal infections but are less common than those listed in the previous subsections and not of as great importance.

### Calves

*Pseudomonas aeruginosa*, *Streptococcus pyogenes*, *Streptococcus faecalis*, *S. zooepidemicus*, *Pneumococcus* spp.; enteritis resulting from *Providencia stuartii*, *Chlamydia* spp., *A. equuli*.

### Lambs

*S. aureus* (tick pyemia); enteritis resulting from *E. coli*, rotavirus; pneumonia resulting from *Salmonella abortus-ovis*.

### Foals

*Enterobacter cloacae*, *S. aureus*, *Pasteurella multocida*, *P. aeruginosa*, *T. pyogenes*, *Serratia marcescens*.

### All Species

Nonspecific infections are associated with pyogenic organisms, including *T.* (formerly *Arcanobacterium*) *pyogenes* and *Fusobacterium necrophorum*; *S. faecalis*, *S. zooepidemicus*, *Micrococcus* spp., and *Pasteurella* spp. occur in all species.

## EPIDEMIOLOGY

The occurrence of neonatal disease is broadly influenced by two main factors: the exposure or infection pressure of the infectious agent to the neonate and the ability of the neonate to modulate the infection so that disease does not occur. Some agents are sufficiently virulent in their own right that an exposure can lead to disease. With others, the majority, the defenses of the host must be compromised or the infection challenge must be very high before clinical disease occurs. Management of the neonate has a great influence on both of these factors, and the recognition and correction of these risks is the key to the prevention of neonatal disease in both the individual and the group.

## Sources of Infection

### Postnatal Infection

The vast majority of infections are acquired by the neonate after birth, directly from the environment into which it is born. The source of infection can be any adult animal present in the maternity area, an infected neonate housed in close proximity, contamination of the environment, or an animal

caretaker functioning as mechanical or biological vector. Details for the common neonatal diseases are given under the individual disease headings.

### Prenatal Infection

Some bacterial and viral infections that manifest with neonatal disease are acquired in utero and are associated with bacteremia/viremia in the neonate.<sup>1</sup> The majority of these are agents that cause abortion, and neonatal septicemia is only part of the disease spectrum associated with these pathogens. Examples include many of the agents producing abortion in sheep.

Some septicemic infections in **foals**, particularly those associated with *A. equuli*, *S. zooepidemicus*, *Salmonella abortus equi*, and possibly some *E. coli* septicemic infections, are acquired by prenatal infection. If the disease is intrauterine in origin, it reaches the foal's organism via the placenta, probably by means of placentitis resulting from a blood-borne infection or endometritis of the mare.

**Viral** infections that are acquired in utero are listed in the section on congenital disease.

## Routes of Transmission

The **portal of infection** is commonly by oral ingestion, but infection may also occur via aerosol inhalation. Invasive organisms capable of producing bacteremia and septicemia invade through the nasopharynx or through the intestinal epithelium. An alternate route of infection and invasion is via the umbilicus. Routes of **excretion** are via the feces in enteric disease and the nasal secretions, urine, and sometimes the feces in septicemic disease, resulting in contamination of the neonatal environment.

Where neonates are in groups or in close contact, direct transmission by fecal, respiratory secretion, and urine aerosols are common routes for transmission of infection. Neonatal bull calves that are group-housed and that suck one another's navels can transmit infection by this activity.

## Risk Factors and Modulation of Infection

### Immunity

Neonates are generally more susceptible to infection than their adult counterparts. The calf, lamb, piglet, and foal are born without significant levels of immunoglobulins and possess almost no resistance to certain diseases until after they have ingested colostrum and absorbed sufficient quantities of immunoglobulins from the colostrum. **Failure of transfer of passive immunity** is a major determinant and is discussed under that heading.

### Immune Responsiveness

All components of the immune system are present in foals and calves at birth, but the immune system of the newborn animal is less mature than its adult counterpart, at

least for the first 30 days of life, and does not respond as effectively to an antigen stimulus.

Immune responsiveness is age-dependent but also varies with the antigen. In colostrum-fed animals, part of the inefficiency of the newborn to produce humoral antibodies following exposure to antigens is the interference from circulating colostrum antibody and the downregulation by colostrum of endogenous immunoglobulin production.

Colostrum-deprived calves respond actively to injected antigens and are thought to be immunologically competent at birth with respect to most antigens. Immune competence begins during fetal life, and the age of gestation at which this occurs varies according to the nature of the antigen. The bovine fetus will produce antibodies to some viruses, beginning at 90 to 120 days, and by the third trimester of gestation it will respond to a variety of viruses and bacteria. The lamb will respond to some antigens beginning as early as 41 days and not until 120 days for others. The piglet at 55 days and the fetal foal also respond to injected antigens.

The presence of high levels of antibodies in the precolostral serum of newborn animals suggests that an in utero infection was present, which is useful for diagnostic purposes. The detection of immunoglobulins and specific antibodies in aborted fetuses can be a useful aid in the diagnosis of abortion in cattle.

## Exposure Pressure

The exposure pressure is a factor of the cleanliness of the environment of the neonate. The phenomenon of a "buildup of infection" in continual-throughput housing for neonatal animals has been recognized for decades and has been translated to many observations of risk for neonatal disease associated with suboptimal hygiene and stocking density in both pen and paddock birthing areas. Details for the individual species are provided in the section on perinatal disease.

## Age at Exposure

With several agents that produce neonatal disease, the age of the neonate at infection and the infecting dose have a significant influence on the outcome. Examples are the importance of age with respect to susceptibility to disease associated with some enteric infections. Disease associated with enteropathogenic *E. coli* and with *C. perfringens* types B and C occurs only in young animals, and if infection can be avoided by hygiene in this critical period, disease will not occur regardless of subsequent exposure. Colostrum-deprived calves show significant resistance to challenge at 7 days of age with strains of *E. coli* that invariably produce septicemic disease if challenged at the time of birth, and isolation of

an immunocompromised neonate is an important factor in its survival. Thus the management of the neonate and its environment is a critical determinant of its health. Age at exposure also varies with the epidemiology of the pathogen, and segregated early weaning is used to reduce transmission of and infection with certain pathogens in pigs.

### Animal Risk Factors

Animal risk factors that predispose to infection include those that interfere with sucking drive and colostrum intake, such as cold stress and dystocia. These are detailed in the preceding section on perinatal disease.

### PATHOGENESIS

The pathogenesis varies with the neonatal infectious disease under consideration and is given for each of these in the special medicine section.

An infection can remain localized at the initial site of infection, as is the case with uncomplicated omphalitis or enterotoxigenic *E. coli* infection, or it can spread by invading the organism (e.g., via the nasopharynx, the gastrointestinal tract, or the umbilical vein or urachus). In the latter case the usual pattern of development is bacteremia followed by **septicemia** with severe systemic signs, or **bacteremia** with few or no systemic signs followed by **localization** in various organs.<sup>2</sup> **Localization** is most common in the joints, producing a suppurative or nonsuppurative arthritis. Less commonly there is localization in the eye to produce panophthalmitis, in the heart valves to cause valvular endocarditis, or in the meninges to produce meningitis.

Secondary lesions often take time to develop, and signs usually appear at 1 to 2 weeks of age. This is especially true with some of the streptococcal infections, in which bacteremia may be present for several days before localization in the joints and meninges produces clinical signs. Bacterial meningitis in newborn ungulates is preceded by bacteremia followed by a fibrinopurulent inflammation of the leptomeninges, choroid plexuses, and ventricle walls, but it does not affect the neuraxial parenchyma. It is proposed that the bacteria are transported in monocytes, which do not normally invade the neuraxial parenchyma.

Dehydration and acid-base and electrolyte imbalance can occur very quickly in newborn animals, whether diarrhea and vomiting (pigs) are present or not, but obviously are more severe when there is fluid loss into the gastrointestinal tract. In gram-negative sepsis the prominent signs are those of endotoxemia.

### CLINICAL FINDINGS

The clinical findings depend on which organ systems are affected, the rapidity of growth of the organism, its propensity to localize,

and its potential to produce toxemia. Clinical signs are often vague and unspecific in the initial phase of septicemia until the infection localizes and affects one or several organs.<sup>1,2</sup> Organisms that have a low propensity for toxemia present with fever, depression, anorexia, and signs referable to localization. These include endocarditis with a heart murmur; panophthalmitis with pus in the anterior chamber of the eye; meningitis with rigidity, pain, and convulsions; and polyarthritis with lameness and swollen joints. With more virulent organisms there are clinical signs of toxemia and bacteremia, including fever, and advanced stages result in hypothermia, severe depression, obtundation, coma, petechiation of mucosae, dehydration, acidemia, and rapid death.

The clinical and clinicopathologic characteristics of the septicemic foal were detailed in an outbreak of septicemia in colostrum-deprived foals and in the clinical records of 38 septicemic foals admitted to a referral clinic. The major clinical findings included lethargy, unwillingness to suck, inability to stand without assistance but remaining conscious, unawareness of environment and thrashing or convulsing, diarrhea, respiratory distress, joint distension, central nervous system abnormalities, uveitis, and colic. Fever was not a consistent finding.

A **sepsis score** has been developed for foals based on 14 measures related to historical, clinical, and laboratory data (Table 19-11). The score derived from the collective differential scoring of these data has been found to be more sensitive and specific for infection than any parameter taken individually. However, a subsequent study of 168 foals presented to a university hospital found that the sepsis score correctly predicted sepsis in 58 out of 86 foals and nonsepsis in 24 out of 45 foals, resulting in a sensitivity of 67%, a specificity of 75%, a positive predictive value of 84%, and a negative predictive value of 55%, and it was suggested that the score system should be used with care because the low negative predictive value limited its clinical utility.

A sepsis score for calves, based on fecal consistency, hydration, behavior, ability to stand, state of the umbilicus and degree of injection of scleral vessels, and presence of hypoglycemia and abnormal neutrophil cell count, was found to have reasonable predictive value.<sup>3</sup>

The clinical findings specific to individual etiologic agents are given under their specific headings in the special medicine section of this book.

### CLINICAL PATHOLOGY

Clinical pathology is used as an integral part of the evaluation of a sick neonate and to help formulate a treatment plan. A major evaluation is to attempt to confirm the presence or absence of sepsis, and this type of evaluation has been developed most successfully in the

foal. **Blood culture** is part of this examination, but the time for a positive result limits its value in the acutely ill neonate. Laboratory findings in foals with neonatal sepsis are variable and depend on the severity, stage, and site of infection. **Serial examinations** are commonly used. In examinations relating to the possible presence of septicemia, particular emphasis is placed on the results of the white blood cell and differential counts, the presence of toxic change (toxic granulation and vacuolization), serum immunoglobulin concentrations, arterial oxygen concentrations, the presence of metabolic acidosis, abnormal blood glucose concentrations, and elevated fibrinogen levels.<sup>1,4</sup>

### DIFFERENTIAL DIAGNOSIS

- The principles of diagnosis of infectious disease in newborn animals are the same as for older animals. However, in outbreaks of suspected infectious disease in young animals, there is usually a need for more diagnostic microbiology and pathology.
- With outbreaks, owners should be encouraged to submit all dead neonates as soon as possible for a meaningful necropsy examination.
- In addition to postmortem examination, it is necessary to identify the factors that may have contributed to an outbreak of disease in newborn calves, piglets, or lambs, and only detailed epidemiologic investigation will reveal these.

### TREATMENT

The first principle is to obtain an etiologic diagnosis if possible. Ideally a drug sensitivity of the causative bacteria should be obtained before treatment is given, but this is not always possible. It may be necessary to choose an **antibiotic** based on the tentative diagnosis and previous experience with treatment of similar cases.

Outbreaks of infectious disease are common in litters of piglets and groups of calves and lambs, and individual treatment is often necessary to maximize survival rate. Supportive fluid and electrolyte therapy and correction of acid-base disturbances are described in detail under "Disturbances of Free Water, Electrolytes, and Acid-Base Balance."

The provision of **antibodies** to sick and weak newborn animals through the use of blood transfusions or serum is often practiced, especially in newborn calves in which the immunoglobulin status is unknown. Whole blood given at the rate of 10 to 20 mL/kg body weight, preferably by the intravenous route, will often save a calf that appears to be in shock associated with neonatal diarrhea. The blood is usually followed by fluid therapy. Serum or plasma can also be given at half the dose rate. The blood should not be taken from a cow near parturition because the circulating immunoglobulins

**Table 19-11** Worksheet for calculating a sepsis score for foals less than 12 days of age

Variable	NUMBER OF POINTS TO ASSIGN					Score for this case
	4	3	2	1	0	
1. Historical data						
a. Placentitis, vulvar discharge before delivery, dystocia, sick dam, induced parturition		Present			Absent	
b. Gestation length (days)		<300	300–310	311–330	>330	
2. Clinical examination						
a. Petechiation or scleral injection (nontraumatic)		Marked	Moderate	Mild	None	
b. Rectal temperature (°C)			>38.9	<37.8	37.9–38.7	
c. Hypotonia, convulsions, coma, depression			Marked	Moderate	Mild	
d. Anterior uveitis, diarrhea, respiratory distress, swollen joints or open wounds		Present			Absent	
3. Hemogram						
a. Neutrophil count (cells × 10 <sup>9</sup> /L)		<2.0	2.0–4.0 or 8.0–12.0	4.0–8.0		
b. Band neutrophils (cells × 10 <sup>9</sup> /L)		>0.2	0.05–0.2		<0.05	
c. Toxic changes in neutrophils	Marked	Moderate	Slight		None	
d. Fibrinogen concentration (g/L)			>6.0	4.1–6.0	4.0	
4. Laboratory data						
a. Blood glucose (mmol/L)			<2.7	2.7–4.4	>4.4	
b. IgG concentration (g/L)	<2.0	2.0–4.0	4.1–8.0		>8.0	
c. Arterial oxygen tension (Torr)		<40	40–50	51–70	>70	
d. Metabolic acidosis (base excess < 0)				Present	Absent	
Total points for this foal						

To calculate the sepsis score, assign foal a score corresponding to the historical physical examination and laboratory data included in the table. A score of 11 or less predicts the absence of sepsis correctly in 88% of cases, whereas a score of 12 or higher predicts sepsis correctly in 93% of cases. For foals less than 12 hours of age that have nursed or received colostrum, assign a value of 2 for the serum immunoglobulin score. If the foal has not nursed, assign a value of 4.

will be low from the transfer into the mammary gland.

**Plasma** is often incorporated into the therapeutic regimen in foals, both for its immunoglobulin content and for its effect on blood volume and osmotic pressure. Stored plasma can be used. A dose of 20 mL plasma/kg body weight given slowly intravenously is often used, but significantly higher doses are required to elevate circulating immunoglobulins by an appreciable amount. Blood may be collected, the red blood cells allowed to settle, and the plasma removed and stored frozen. The donor plasma should be prescreened for compatibility. Lyophilized hyperimmune equine serum as a source of antibodies may also be fed to foals within 4 hours after birth. Good nursing care is also essential.

Further information on treatment is given in the section on critical care for the newborn later in this chapter.

## CONTROL

Methods for avoidance of failure of transfer of passive immunity and the principles for prevention of infectious disease in newborn farm animals follow in this chapter. The control of individual diseases is given under specific disease headings elsewhere in this book.

## PRINCIPLES OF CONTROL AND PREVENTION OF NEONATAL INFECTIOUS DISEASES

The four principles of control and prevention of infectious diseases of newborn farm animals are as follows:

- Reduction of risk of acquisition of infection from the environment
- Removal of the newborn from the infectious environment if necessary
- Increasing and maintaining the nonspecific resistance of the newborn
- Increasing the specific resistance of the newborn through the use of vaccines

The application of each of these principles will vary depending on the species, the spectrum of diseases that are common on that farm, the management system, and the success achieved with any particular preventive method used previously.

## REDUCTION OF RISK OF ACQUISITION OF INFECTION FROM THE ENVIRONMENT

The animal should be born in an environment that is clean, dry, sheltered, and conducive for the animal to get up after birth, suck the dam, and establish bonding.<sup>1,2</sup> Calving

and lambing stalls or grounds, farrowing crates, and foaling stalls should be prepared in advance for parturition. No conventional animal area can be sterilized, but it can be made reasonably clean to minimize the infection rate before colostrum is ingested and during the first few weeks of life when the newborn animal is very susceptible to infectious disease.

With seasonal calving or lambing there can be buildup of infection in the birth area, and animals born later in the season are at greater risk of disease. In these circumstances it may be necessary to move to secondary lambing or calving areas. In northern climates snow may constrict the effective calving area and result in a significant buildup of infection. Buildup of infection pressure must be minimized by a change to a fresh calving/lambing area and by the frequent movement of feed bunks or feed areas. Any system that concentrates large numbers of cattle in a small area increases environmental contamination, and close confinement of heifers and cows around calving time is a known risk factor for calf mortality. With large herds both the cow herd and heifer herd should be broken into as many subgroups as is practical. Extensive systems where cows calve out over large paddocks are optimal, and with more intense systems a group size no larger than 50 has been suggested.

Lambing sheds and calving areas for beef cattle should be kept free of animal traffic during the months preceding the period of

parturition. In dairy herds, maternity pens separate from other housing functions should be provided and cleaned and freshly bedded between calvings. Certainly they should not also be used as hospital pens.

In swine herds, the practice of batch farrowing, with all-in all-out systems of management and disinfection of the farrowing rooms, is essential. Sows should be washed before entry to the farrowing area, and the floor of the farrowing crate should be of the type that minimizes exposure of the piglet to fecal material at birth.

The swabbing of the **navel** with tincture of iodine or chlorhexidine solutions to prevent entry of infection is commonly practiced by some producers and seldom by others. In a heavily contaminated environment it is recommended, although hard evidence supporting the efficacy of this procedure is currently lacking.<sup>1</sup> Severance of the umbilical cord too quickly during the birth of foals can deprive the animal of large quantities of blood, which can lead to neonatal maladjustment syndrome.

When deemed necessary, some **surveillance** should be provided for pregnant animals that are expected to give birth, and assistance provided if necessary. The major objective is to avoid or minimize the adverse effects of a difficult or slow parturition on the newborn and the dam. Physical injuries, hypoxia, and edema of parts of the newborn will reduce the vigor and viability of the newborn and, depending on the circumstances and the environment in which it is born, may lead to disease or even death soon after birth.

When possible, every effort should be made to minimize exposure of the neonate to extremes of temperature (heat, cold, snow). Shelter sheds should be built if necessary.

In beef herds, the practice of purchasing male dairy calves to foster on to cows whose calves have died should be discouraged. If calves are purchased, they should be from a herd whose health status is known to the veterinarian and certainly never through a market. Similarly, colostrum should be obtained from cows within the herd and stored frozen for future use. Colostrum obtained from a different herd presents a biosecurity risk because it can transmit diseases such as bovine enzootic leukemia or Johne's disease. Furthermore, purchased dairy colostrum is commonly second- or third-milking colostrum and of limited immunologic value. The use of a commercial colostrum supplement or replacer is possible, although they have significant limitations.

### REMOVAL OF THE NEWBORN FROM THE INFECTIOUS ENVIRONMENT

In some cases of high animal population density (e.g., a crowded dairy barn) and in

the presence of known disease, it may be necessary to transfer the newborn to a noninfectious environment temporarily or permanently. Adult cows shedding enteric pathogens are a risk for calf infection. Thus dairy calves are often removed from the dam at birth and placed in individual pens inside or outdoors in hutches and reared in these pens separately from the main herd. This reduces the severity of neonatal diarrhea and pneumonia and risk for mortality compared with calves allowed to remain with the dam.

**Individual housing** in hutches is preferred because this avoids navel sucking and other methods of direct-contact transmission of disease. Humans entering these hutches should also practice interhutch hygiene. The prevalence of disease is higher in enclosed artificially heated barns than in hutches. However, despite the well-established value of individual rearing of calves, animal welfare regulations in several countries require that there be visual and tactile contact between calves. The removal of the cow-calf pair from the main calving grounds to a "nursery pasture" after the cow-calf relationship (neonatal bond) is well established, at 2 to 3 days of age, has proved to be a successful management practice in beef herds. This system moves the newborn calf away from the main calving ground, which may be heavily contaminated because of limited space. It necessitates that the producer must plan the location of the calving grounds and nursery pastures well in advance of calving time. Calves that develop diarrhea in the calving grounds or nursery pasture are removed with their dams to a "**hospital pasture**" during treatment and convalescence. The all-in all-out principle of successive population and depopulation of farrowing quarters and calf barns is an effective method of maintaining a low level of contamination pressure for the neonate.

### INCREASING THE NONSPECIFIC RESISTANCE OF THE NEWBORN

Following a successful birth, the next important method of preventing neonatal disease is to ensure that the newborn ingests colostrum as soon as possible. With natural sucking the amount of colostrum ingested by the neonate will depend on the amount available, the vigor of the animal, the acceptance by the dam, and the management system used, which may encourage or discourage the ingestion of liberal quantities of colostrum. Beef cows that calve at a condition score lower than 4 (out of 10) are at higher risk of having calves that develop failure of transfer of passive immunity, and the ideal condition score at calving is 5 to 6.

The method of colostrum delivery that is needed to optimize transfer of passive immunity to the dairy calf will vary with the breed of cow, the management level of the farm, and the priority given to calf health. Owner

acceptance of alternate feeding systems to natural sucking also is a consideration. The success of the farm policy for the feeding of colostrum is easily monitored by one of the tests described earlier, as is the effect of an intervention strategy.

Newborn male dairy calves are commonly assembled and transported to market or to calf-rearing units within a few days of birth. Studies have repeatedly shown high rates of FTPI in this class of calf. The high rates occur either because the original owner does not bother to feed colostrum to the calf, knowing it is to be sold, or because calves are purchased off the farm before colostrum feeding is completed. The effects of the transportation can have a further deleterious effect on the defense mechanism of the calves, and they are at high risk of disease.

Calf-rearing units should preferably purchase calves directly from a farm with an established policy of feeding colostrum before the calf leaves the farm, and every effort should be made to reduce the stress of transportation by providing adequate bedding, avoiding long distances without a break, and attempting to transport only calves that are healthy. In some countries there is now legislation requiring the feeding of colostrum and limiting the transport of newborn calves.

The honesty of the stated farm colostrum feeding policy can be monitored by testing the calves for their immunoglobulin concentration in serum. Where this is not possible and market calves must be used, the entry immunoglobulin concentration should be tested; the incidence of infectious disease in low-testing calves will be high unless hygiene, housing, ventilation, management and nutrition are excellent. The entry immunoglobulin concentration of calves entering veal or other calf-rearing units is a prime determinant of subsequent health and performance. The "alert" cut-point can be established for an individual farm by monitoring of individual immunoglobulin concentrations and subsequent calf fate.

Following the successful ingestion of colostrum and establishment of the neonatal bond, emphasis can then be given to provision, if necessary, of any special nutritional and housing requirements. Newborn piglets need supplemental heat, and attention must be given to the special problems of intensive pig husbandry. Orphan and weak piglets can now be reared successfully under normal farm conditions with the use of milk replacers containing added porcine immunoglobulins. Heat is often provided to lambs for the first day in pen lambing systems.

**Milk replacers** for the newborn must contain high-quality ingredients. Calves younger than 3 weeks are less able to digest nonmilk proteins, and the fats best used by the calf are high-quality animal source fats and slightly unsaturated vegetable oils. A 22% crude protein is recommended for milk

replacers comprised only of milk proteins and 24% to 26% in replacers that contain nonmilk protein sources. The level of fat should be at least 15%; higher fat concentration will provide additional energy, which may be required in colder climates. Feeding utensils must be cleaned and disinfected between each feeding if disease transmission is to be minimized.

With animals at pasture, the mustering and close contact associated with management procedures such as castration and docking pose a risk for disease transmission. These procedures should be performed in yards prepared for the purpose—preferably temporary yards erected for this sole purpose in a clean area.

### INCREASING THE SPECIFIC RESISTANCE OF THE NEWBORN

The specific resistance of the newborn to infectious disease may be enhanced by vaccination of the dam during pregnancy to stimulate the production of specific antibodies that are concentrated in the colostrum and transferred to the newborn after birth. Vaccination of the dam can provide protection for the neonate against enteric and respiratory disease. Details are given under the specific disease headings in this text. The vaccination of the late fetus in utero stimulates the production of antibody but its practical application has yet to be determined.

## COLIBACILLOSIS OF NEWBORN CALVES, PIGLETS, LAMBS, KIDS, AND FOALS

### SYNOPSIS

**Etiology** Pathogenic serotypes of *Escherichia coli*: septicemic, enterotoxigenic (ETEC); enteropathogenic (EPEC); enterohemorrhagic (EHEC), also referred to as verocytotoxin-producing (VTEC) or Shiga-toxin-

producing (STEC); and necrotoxicogenic *E. coli* (NTEC).

**Epidemiology** Affects newborn calves, piglets, lambs, and goat kids. Risk factors include colostrum deprivation, overcrowding, adverse climatic conditions, and inferior milk replacers. Prevalence of ETEC varies between herds. EHEC (O157:H7) in cattle is not normally associated with clinical disease, but it presents a major zoonotic concern.

**Signs** Weakness and collapse (septicemia), diarrhea, and dehydration; complications such as meningitis or polyarthritis.

**Clinical pathology** Isolation of organism from feces or blood; hematology and serum biochemistry to evaluate inflammation and acid-base and electrolyte imbalance.

**Lesions** Septicemic lesions, dehydration, enteritis.

**Diagnostic confirmation** Culture of organism and serotyping.

**Treatment** Antimicrobials, antiinflammatory drugs, fluid and electrolyte therapy.

**Control** Reduce infection pressure on neonates. Ensure adequate transfer of passive immunity, and vaccinate pregnant dams to induce specific colostrum antibody. Minimize stressors and their effect on neonates.

### ETIOLOGY

Colibacillosis is associated with pathogenic serotypes of *E. coli*. For the most part, *E. coli* is a group of harmless bacteria that serve as indicator organisms for fecal contamination and breaches in hygiene. However, several strains have acquired virulence factors, turning them into potentially dangerous pathogens.<sup>1</sup> The prevalence of the different pathogenic serotypes of *E. coli* in farm animals has remained relatively constant for many years. Certain serotypes cause diarrhea and others cause septicemia. Serotypes include the following:

- **Enterotoxigenic *E. coli* (ETEC)** is the most common enteropathogen that causes diarrhea in newborn farm animals. The bacteria cause diarrhea by adhering to enterocytes, colonizing the intestinal mucosa, and **producing enterotoxins**. Enterotoxins cause hypersecretion of electrolytes and water into the small intestine without causing significant morphologic damage or invading tissue.<sup>2</sup>
- **Enteropathogenic *E. coli* (EPEC)** are the “**attaching and effacing**” strains that colonize the small intestine, where they attach tightly to the epithelial cells of the villus and cause typical **attaching and effacing lesions**. They do not produce toxins and seldom invade the intestinal mucosa.

- **Enterohemorrhagic *E. coli* (EHEC)** also cause attaching and effacing lesions and are among the *E. coli* strains capable of producing toxins similar to the one produced by *Shigella dysenteriae* type I. They are therefore also referred to as **Shiga-toxin-producing *E. coli* (STEC)**. Because Shiga toxins are detected with the Vero cell-toxicity test, STEC are also known as **verotoxin or verocytotoxin-producing *E. coli* (VTEC)**. Shiga toxins may cause anything from mild diarrhea to severe hemorrhagic colitis. In humans EHEC is responsible for the highly fatal hemolytic-uremic syndrome in children.<sup>3</sup> **EHEC are highly prevalent in cattle** but in general do not cause clinical disease in this species, although some Shiga-toxin-producing *E. coli* have been associated with diarrhea in calves. Cattle are the main reservoir of *E. coli* O157:H7, one of the important EHEC strains, causing a broad range of clinical disease in humans (see the section on enterohemorrhagic *E. coli* in farm animals and zoonotic implications). Shiga-toxin-producing *E. coli* strains have been associated with edema disease in swine.<sup>2</sup>
- **Necrotoxicogenic *E. coli* (NTEC)** strains produce cytotoxic necrotizing factor (CNF)1 or 2. NTEC2 isolates are restricted to ruminants, particularly calves and lambs with diarrhea and septicemia.
- **Septicemic *E. coli*** strains of serogroup O78 are invasive and cause septicemia in calves, piglets, and lambs. Their powerful endotoxins cause endotoxic shock, with a high case fatality rate.

### EPIDEMIOLOGY

#### Occurrence and Prevalence of Infection

The prevalence of colibacillosis has increased in recent years. There are several possible reasons for this, including size of herds, shortage of qualified labor, automated livestock-rearing systems, and increased population density.

Colibacillosis occurs most commonly in newborn farm animals and is a significant cause of economic loss in raising livestock. It is a complex disease in which several different risk factors interact with certain pathogens, resulting in the disease. There are at least two different types of the disease: **enteric colibacillosis** is characterized by varying degrees of diarrhea, dehydration, acidosis, and death in a few days if not treated; **coli-form septicemia** is characterized by severe illness and rapid death within hours.

#### Cattle and Calves

The infection prevalence of **enterohemorrhagic *E. coli***, particularly the *E. coli* O157:H7 strain, has been studied extensively because of concerns with beef and raw milk as source

of foodborne disease in humans. In the United States *E. coli* O157:H7 infection prevalence rates based on positive fecal samples were between 0.2% and 8.4% for cows, 1.6% and 3.0% for heifers, and 0.4% to 40% for calves. Infection prevalence rates reported from Canada, Italy, Japan, and the United Kingdom were 0.3% to 16.1% for cows, 10.0% to 14.1% for heifers, and 1.7% to 48.8% for calves.<sup>4</sup> These numbers underscore the obvious effect of animal age on the epidemiology of infection with *E. coli* O157:H7. The **considerable prevalence of this EHEC strain** in cattle has little impact on animal health because EHEC infection in this species is normally not associated with clinical disease, but it presents a **serious public health concern**.

The prevalence of **enterotoxigenic *E. coli* (ETEC)** in diarrheic calves varies widely geographically, between herds, and depending on the age of the animals. The prevalence can be as high as 50% to 60% in diarrheic calves under 3 days of age and only 5% to 10% in diarrheic calves 8 days of age. In some countries the prevalence is only 5% to 8% in diarrheic calves under 3 days of age. Thus **enterotoxigenic colibacillosis is a major cause of diarrhea in calves less than 3 days of age** and is not associated with outbreaks of diarrhea in calves older than 3 days. ETEC infection in calves older than 2 to 3 days will in most cases be associated with a viral infection. The prevalence of ETEC infection is very low or nil in clinically normal calves in herds that have not had a problem with diarrhea. In some beef herds affected with diarrhea in young calves there may be little evidence of infection with enterotoxigenic *E. coli*, and other factors need to be examined.

### Piglets

The prevalence of ETEC in diarrheic piglets varies geographically and with herds. In some areas the F5 (K99) pilus was found more frequently than F4 (K88) or F6 (987P), whereas in other regions the F4 pilus is more common. The F4 and F18 pilus adhesins are most commonly associated with postweaning diarrhea of pigs.

### Morbidity and Mortality Rates Calves

In dairy calves raised under intensive and poorly managed conditions the morbidity rate of infection with ETEC may reach 75%, but it is usually about 30%. Case fatality rates vary from 10% to 50% depending on the level of clinical management.

In beef calves the morbidity rates vary from 10% to 50% and the case fatality rates from 5% to 25% or even higher in some years. The population mortality rate in both beef and dairy calves can vary from a low of 3% in well-managed herds to a high of 60% in problem herds in certain years.

### Piglets

In piglets the morbidity rate of preweaning diarrhea varies widely between herds, but it averages about 6% of litters, mostly in the first week of life. The morbidity rates increase with increased litter size and decrease with increasing parity of the sow. Losses as a result of stillbirths, traumatic injuries, starvation, and undersize at birth account for a much greater combined total preweaning loss, but colibacillosis accounts for approximately 50% of the gastroenteropathies encountered during the preweaning period.

Postweaning diarrhea (PWD) occurring in the 2 weeks following weaning is one of the economically most important diarrheal diseases in piglets in which colibacillosis plays an important etiologic role.<sup>5</sup> ETEC associated PWD commonly occurs in the immediate postweaning period. Outbreaks can occur suddenly, with mortality rates of 50% and higher. Affected animals can die acutely or show profuse diarrhea for up to 4 days. In uncomplicated cases mortality rates rarely exceed 10%.<sup>5</sup> Postweaning diarrhea of pigs is covered in detail under this heading.

### Risk Factors

Several risk factors influence the occurrence of the disease, each one of which must be considered, evaluated, and modified or removed if necessary when investigating the cause of an outbreak so that effective clinical management and control of the disease may be achieved.

### Animal Risk Factors

#### Animal Species

The pathogenesis of colibacillosis involves a number of host factors, of which the presence of specific receptors for adhesins and enterotoxins is probably among the most important.<sup>6</sup> Clinical disease associated with *E. coli* infection is largely dependent on the presence of specific receptors that usually only occur in one or few animal species, because of this receptor specificity of adhesins and enterotoxins, **ETEC strains have considerable species specificity**.<sup>7</sup>

#### Age and Birth Weight

Diarrhea associated with ETEC occurs in calves mainly during the first few days of life, rarely in older calves, and never in adults. Epidemiologic studies of both beef and dairy calves indicate that more than 80% of clinical cases associated with ETEC F5 (K99) occur in calves younger than 4 days of age. The ability of the F5 ETEC to adhere to the small intestinal epithelium of calves decreases continuously from 12 hours of age to 2 weeks of age.<sup>8</sup> The mechanism of this age-related resistance is not well understood, but it may be related to development of resistance to colonization of the small intestine as the calf becomes older. This could be associated with the replacement of villous

epithelial cells that occurs in the first few days after birth.

The disease is more common in **piglets** born from gilts than from sows, which suggests that immunity develops with developing age in the sow and is transferred to the piglets. In a survey of approximately 4400 litters of piglets over a period of 4 years in a large piggery, 64% of the litters were treated for diarrhea before weaning, and piglets born to sows under parity 2 were 1.7 times more likely to develop diarrhea before weaning than litters born to sows over parity 3. The susceptibility or resistance to *E. coli* diarrhea in piglets has an inherited basis. The cell surface receptor for the F4 (K88) antigen is inherited in a simple mendelian way, with adherence (S) dominant over nonadherence (s). Homozygous dominants (SS) and heterozygotes (Ss) possess the receptor and are susceptible, whereas in the homozygous recessive (ss) the receptor is absent and the pigs are resistant. The highest incidence of diarrhea occurs in susceptible progeny born from resistant dams and sired by susceptible sires. Most if not all pigs have intestinal receptors for F5 (K99<sup>+</sup>) pili and an inheritance pattern similar to F4 (K88) receptors does not exist for F5 receptors.

### Immunity and Colostrum

Newborn farm animals are agammaglobulinemic and must ingest colostrum and absorb colostral immunoglobulin within hours of birth to obtain protection against septicemic and enteric colibacillosis. The transfer of immunoglobulin from the dam to the neonate is termed *transfer of passive immunity*. **Failure of transfer of passive immunity** predisposes the neonate to development of infectious diseases (see also the section "**Failure of Transfer of Passive Immunity**").

Transfer of maternal immunoglobulin to calves depends on three successive processes:

- Formation of colostrum with a high concentration of immunoglobulin by the dam
- Ingestion of an adequate volume of colostrum by the calf
- Efficient absorption of colostral immunoglobulin by the calf

Colostral immunoglobulin is absorbed for up to 24 hours after birth in calves and up to 48 hours in piglets. However, in calves the maximum efficiency of absorption occurs during the first 6 to 12 hours after birth and decreases rapidly from 12 to 24 hours after birth. Following absorption, transfer to the intestinal lumen is a major means of IgG clearance in calves, and this transfer results in antigen-binding antibody in the intestinal lumen. Both blood-derived antibody and lactogenic antibody are significant sources of passive antibodies in the intestinal lumen of the neonatal calf. Maintenance of high concentrations of

milk-derived antibodies in the small intestinal lumen may require more than twice-a-day feedings because antibodies derived from a milk diet are predominantly cleared from the intestinal lumen by 12 hours after feeding. Transfer of passively acquired antibodies from the circulation to the small intestinal lumen is therefore a reasonable hypothesis to explain the strong association between high serum passive immunoglobulin concentrations and reduced morbidity in neonatal calves.

Newborn dairy calves should ingest 80 to 100 g of colostral IgG, and ideally up to 150 g, within a few hours after birth to achieve serum immunoglobulin of 1000 mg/dL.

### Environmental and Management Risk Factors

#### *Meteorologic Influences*

Although few epidemiologic data are available to support the claim, many veterinarians have observed a relationship between adverse climatic conditions and colibacillosis in both calves and piglets. During inclement weather, such as a snowstorm, a common practice in beef herds is to confine the calving cows in a small area, where they can be fed and watered more easily. The overcrowding is commonly followed by an outbreak of acute calf diarrhea. There is evidence that cold, wet, and windy weather during the winter months and hot, dry weather during the summer months have a significant effect on the incidence of dairy calf mortality.

The risk factors for mortality from diarrhea in beef calves in Alberta, Canada, have been examined. The odds of mortality were increased when the cows and heifers were wintered on the same grounds, when the herd was wintered and calved on the same grounds, and if the cows and heifers were calved on the same grounds. The morbidity and mortality rates from diarrhea during the first 30 days of life increased with an increasing percentage of heifers calving in the herd. Heifers are commonly more closely confined during the calving season for more effective observation and assistance at parturition. This may lead to increased contamination of the environment and the abdominal wall and udder of the heifers. Additional factors in heifers include a higher incidence of dystocia and maternal misbehavior and lower volume and quality of colostrum, all of which can result in weak calves that may not acquire sufficient colostral immunity.

#### *Nutrition and Feeding Methods*

Dairy calves fed milk substitutes may be more susceptible to acute undifferentiated diarrhea, some of which may be a result of enteric colibacillosis, compared with those fed cows' whole milk. Extreme heat treatment of the liquid skim milk in the processing of dried skim milk for use as milk

substitutes for calves results in denaturation of the whey protein, which interferes with digestibility of the nutrients and causes destruction of any lactoglobulins that are present and may have a protective effect in the young calf.

Irregular feeding practices resulting in dietetic diarrhea may contribute to a higher incidence of enteric colibacillosis in calves. The person feeding and caring for the calves is an important factor influencing calf mortality a result of diarrhea. Although it is generally thought that general or specific nutritional deficiencies, such as a lack of energy, protein, or vitamin A, in the maternal diet predispose to colibacillosis, particularly in calves and piglets, there is no direct evidence that specific nutritional deficiencies are risk factors. However, they probably are, at least in indirect ways, for example, by having an effect on the amount of colostrum available at the first milking after parturition in first-calf heifers underfed during pregnancy.

#### *Standard of Housing and Hygiene*

Housing and hygienic practices are probably the most important environmental risk factors influencing the incidence of colibacillosis in calves and piglets, but they have received the least amount of research effort compared with other aspects, for example, control of the disease through vaccination. As the size of herds has increased, and as livestock production has become more intensified, the quality of hygiene and sanitation, particularly in housed animals, has assumed major importance. The disease is much less common when calves are run at pasture or are individually tethered, or penned, on grass.

#### *Source of the Organism and Its Ecology and Transmission*

Ingestion is the most likely portal of infection in calves, piglets, and lambs, although infection via the umbilical vessels and nasopharyngeal mucosa can occur. It has been suggested that certain serotypes of *E. coli* may enter by the latter route and lead to the development of meningitis.

In most species, it is assumed that the primary source of the infection is the feces of infected animals, including the healthy dams and neonates, and diarrheic newborn animals, which act as multipliers of the organisms. In some cases, the organism may be cultured from the vagina or uterus of sows whose litters become affected. In pig herds the total number of organisms on each sow is highest in the farrowing barn, decreases when the sow is returned to the breeding barn, and is lowest when the sow is in the gestation barn.

Calves acquire the infection from contaminated bedding and calf pails, dirty calf pens, nearby diarrheic calves, overcrowded calving grounds, and the skin of the perineum

and udder of the cow. The organism is spread within a herd through the feces of infected animals and all the inanimate objects that can be contaminated by feces, including bedding, pails, boots, tools, clothing, and feed and water supplies. The organism is one of the first encountered by newborn farm animals, usually within minutes after birth. In cattle, the tonsil can be a reservoir for STEC in healthy animals. It is possible that virulent *E. coli* can be present and may be transferred to calves when they are licked by their dams at birth. The high population density of animals that occurs in overcrowded calving grounds in beef herds and heavily used calving pens in dairy herds and the continuous successive use of farrowing crates without a break for cleanup contribute to a large dynamic population of *E. coli*. The population of bacteria in an animal barn will continue to increase with the length of time the barn is occupied by animals without depopulation, clean-out, disinfection, and a period of vacancy. In some countries where lambing must be done in buildings to avoid exposure to cold weather, the lambing sheds may become heavily contaminated within a few weeks, resulting in outbreaks of septicemic and enteric colibacillosis.

Infected animals are the main reservoir for ETEC, and their feces are the major source of environmental contamination with the bacteria. Passage of the *E. coli* through animals causes a "multiplier effect"; each infected animal excretes many more bacteria than it originally ingested. Diarrheic calves are the most extreme multipliers because they often pass 1 L or more of liquid feces containing  $10^{10}$ /g ETEC within 12 hours, and recovered calves can continue to shed bacteria for several months.

Normal calves and adult cows can serve as reservoirs of infection, and the bacteria can persist in a herd by circulating through animals of all ages. Carrier animals introduced to an uninfected herd are thought to be one of the main causes of natural outbreaks. The duration and amount of shedding probably depend on the degree of confinement, resulting population density, herd immunity, environmental conditions, and perhaps the serotype of the organism.

### Pathogen Risk Factors

#### *Virulence Factors of E. coli*

Virulence factors of *E. coli* include *pili* (*fimbriae*), *enterotoxins* (*exotoxins*), *endotoxins*, and *capsules*. The adhesins in the pili of ETEC allow them to adhere to intestinal villous epithelial cells and prevent peristaltic elimination by the gut and to produce enterotoxins.

The virulence factors are relevant to vaccine efficacy. The species-specific adhesin antigens must be identified and incorporated into vaccines, which are given to pregnant females in an attempt to stimulate the production of specific antibody in the

colostrum, which will provide protection against enterotoxigenic colibacillosis. An essential element of vaccine development is the detection of common fimbrial antigens occurring among most pathogenic isolates and able to induce antibodies that block bacterial adhesion. The great diversity of potential pathogenic serotypes encountered in colisepticemia and the failure of serotype-specific antibody to cross-protect against a heterologous challenge in experimental infection have made it difficult to develop vaccines against septicemic colibacillosis.

The major virulence factors of ETEC in calves are the F5 (K99) adhesin antigen and the heat-stable enterotoxin (ST). The colonization in the small intestine of calves by F5 ETEC appears to be site specific, having a predilection for the ileum. Some serogroups also elaborate the F41 adhesin to the F5. Other surface-adhesive antigens, such as Att 25 and F17, have been identified on bovine enteropathogenic and septicemic *E. coli*. The F17a-positive ETEC strains are no longer isolated from diarrheic calves in some countries. It is postulated that the use of a vaccine including O101, K32, and H9 antigens in addition to F5 explains the strongly reduced incidence of the O101:K32:H9, F5 *E. coli* clone. A F4-related fimbrial antigen occurs on some enterotoxigenic and septicemic strains.

Enterotoxins are plasmid-regulated secreted peptides of ETEC bacteria that affect the intestinal epithelium. Two types of enterotoxins are differentiated, large-molecular-weight (88 kDa) heat-labile enterotoxins (LT) and small-molecular-weight heat-stable enterotoxins (ST).<sup>7</sup> LT enterotoxins are predominantly produced by human and porcine ETEC strains, whereas ST enterotoxins are produced by human, porcine, and bovine ETEC strains. The heat-stable enterotoxin from bovine ETEC has been purified and characterized. There is evidence of a form of ST enterotoxin that is common to bovine, porcine, and human strains of ETEC.

Most strains of **septicemic *E. coli*** belong to certain serogroups with virulence properties that enable them to resist the defense mechanisms that would normally eliminate other *E. coli*. **Septicemic strains produce endotoxin**, which results in shock and rapid death, usually in calves that are less than 5 days of age and with FTPI. Isolates of *E. coli* from the blood of critically ill bacteremic calves on a calf-rearing farm in California constituted a heterogeneous group and were found to be aerobactin positive and often resistant to the bactericidal effects of serum. The relative importance of individual serogroups varies between countries. However, it has been established that typeable isolates of *E. coli* from septic calves belong to a relatively small number of serogroups.<sup>9</sup> Strains commonly isolated from calves with septicemia belong to serogroups O78 and O15.<sup>9,10</sup>

**Enterohemorrhagic *E. coli* (EHEC) and Shiga-toxin-producing *E. coli* (STEC)** are recognized in humans and animals with increased frequency and constitute a major zoonotic concern (see the discussion of enterohemorrhagic *E. coli* in farm animals and zoonotic implications). These organisms are members of O111, O103, O5, and O26 serogroups, and none produces enterotoxin, nor do they possess the F5 pili. They produce the potent Shiga toxins or verotoxins SLT1 and SLT2; and some strains, the **attaching and effacing *E. coli* (AEEC)**, attach to and efface the microvilli of the enterocytes, causing diarrhea and dysentery as a result of hemorrhagic colitis in calves 2 to 5 weeks of age. The effacing (*eae*) gene and the gene coding for the Shiga toxin 1 (*SLT1*) are associated with most isolates of AEEC in cattle. They have been isolated from both diarrheic and healthy sheep and goats.

A study of the onset and subsequent pattern of shedding of STEC O26, O103, O111, O145, and O157 in a cohort of beef calves on a mixed cattle and sheep farm in Scotland found that O26 was shed by 94% of the calves and that 90% of the O26 isolates carried the *vtx1*, *eae*, and *ehf* genes. *E. coli* O103 was the second most commonly shed serogroup of the tested calves, and the pattern of shedding was sporadic and random. There was an absence of shedding of *E. coli* O111, and the prevalence of shedding of O145 was low. Although some shedding of O157 occurred, shedding in calves was sporadic and infrequent. For O26, O103, and O157, there was no association between shedding by calves and shedding by dams within 1 week of birth. For O26 and O103, there was no association between shedding and diarrhea and no significant change in shedding following housing. In a sample of Australian dairy farms, calves as young as 48 to 72 hours had evidence of fecal excretion of STEC, indicating that dairy cattle are exposed to STEC from birth. Calves at weaning are most likely to shed STEC O26 or *E. coli* O157, similar to the prevalence surveys in the northern hemispheres.

Naturally occurring cases of attaching and effacing lesions of the intestines in calves with diarrhea and dysentery and infected with *E. coli* O126:H11, the predominant STEC strain in humans, have been described in the United Kingdom. STEC and *eae*-positive non-STEC have been isolated from diarrheic dairy calves 1 to 30 days of age.

*E. coli* O157 has been isolated from neonatal calves and has been implicated as a cause of diarrhea in calves. The isolates carried various virulence genes, such as *Ehly*, *eae*, *stx1*, and *stx2*. The *Ehly* gene may be a virulence marker for bovine enterohemorrhagic *E. coli* O157 strains. Similar findings have been reported in dairy cattle herds in Brazil. Strains of *E. coli* possessing a subtype beta intimin, normally found in human

enteropathogenic *E. coli*, have been found in diarrheic calves in Brazil.

Non-O157 STEC have been isolated from diarrheic calves in Argentina, and the serotypes carried virulence traits associated with increased pathogenicity in humans and cattle. Severe clinical syndromes associated with non-O157 STEC are common in children under 4 years of age and may be associated with diarrheic calves, which shed highly virulent STEC strains and could act as a reservoir and contamination source in these areas.

*E. coli* O116, a serogroup previously associated with cases of hemolytic-uremic syndrome in humans, has been associated with an outbreak of diarrhea and dysentery in 1- to 16-week-old calves in India. *E. coli* O103:H2, an STEC strain causing disease in humans, has been isolated from calves with dysentery and from a sheep in Australia.

**Necrotoxicogenic *E. coli* (NTEC)**, which produce **cytotoxic necrotizing factor (CNF)**, have been isolated from cattle in Northern Ireland and Spain and from diarrheic piglets in England. NTEC1 strains from cattle, pigs, and humans can belong to the same serogroups/biogroups, carry genes coding for adhesions belonging to the same families, and possess other identical virulence-associated properties, and they therefore do not exclude the possibility of cross-infection between humans and farm animals in some cases. In Spain NTEC were detected by tissue culture and PCR in 15.8% of diarrheic dairy calves from 1 to 90 days of age; the majority were NTEC producing CNF2, and the risk increased with age. There was also a strong association between CNF2 and F17 fimbriae. The NTEC, with their associated adhesins and toxins, were present in diarrheic and septicemic calves as early as 1958, and their prevalence seems to be increasing. Their role in causing disease needs further examination.

Most ETEC from **neonatal pigs** belong to the so-called "classical serogroups": O8:K87, O45, O138:K81, O141:K85, O147:K89, O149:K91, and O157:KXVX17. Strains of these serogroups usually express and produce F4 (K88), F5 (K99), F6 (987P), F18 and F41 pilus antigens. With the exception of F18, these pilus antigens mediate adhesion of *E. coli* to ileal villi in neonates, causing profuse diarrhea in unweaned pigs. The F4 and F5 pilated strains are the most common cause of enteric disease in piglets under 2 weeks of age. ETEC strains that produce F6 pili colonize the small intestines and cause diarrhea in neonatal pigs under 6 days of age, but not older pigs. F18, in contrast, is not associated with neonatal colibacillosis in piglets, but together with F4 is the most common adhesin associated with postweaning colibacillosis. There are also some ETEC strains that produce none of the antigens mentioned previously.

F4 produces heat-labile enterotoxin (LT), F5 and F6 do not produce LT, and all three

types produce heat-stable enterotoxin STa in infant mice. Some isolates produce neither LT nor STa but produce enterotoxin in ligated intestinal loops of pigs (STb). Other “nonclassical” strains colonize the small intestine to a certain extent, do not strongly adhere to the intestinal epithelium, and produce enterotoxin and diarrhea in neonatal piglets.

The porcine ETEC strains that induce diarrhea in piglets less than 2 weeks of age but not in older pigs are designated class 2, whereas those strains that induce diarrhea in older pigs are class 1 ETEC. The bovine ETEC strains have several features in common with the porcine class 2 organisms, which include the possession of the 0 antigens 8, 9, 20, or 101; characterization as mucoid colonies; possession of F5 pili; and production of heat-stable enterotoxin. Most ETEC strains of pigs belong to a restricted number of serogroups.

### Lambs

Enterotoxigenic strains of *E. coli* can be isolated from the feces of approximately 35% of diarrheic lambs. ETEC strains have also been isolated from the blood of a small percentage of diarrheic lambs. F5 (K99) piliated *E. coli* are associated with outbreaks of diarrhea in lambs under a few days of age. F17 fimbriae *E. coli* have been isolated from diarrheic lambs and kids, but none of the isolates produced any of the toxins normally associated with ETEC strains. Attaching and effacing *E. coli* negative for Shiga toxin but positive for *eae* have been isolated from goat kids affected with severe diarrhea, with a high case fatality rate.

### Zoonotic Implications of *E. coli*

Cattle are a major source of EHEC strain O157:H7, which is associated with food-borne disease in humans. (See “Enterohemorrhagic *Escherichia coli* in Farm Animals and Zoonotic Implications.”)

### PATHOGENESIS

The factors important in understanding the pathogenesis of colibacillosis are the affected species, the age and the immune status of the animal, and the virulence factors of the strain of *E. coli*, particularly its capacity to invade tissues and produce septicemia or to produce an enterotoxin. Diarrhea, dehydration, metabolic acidosis, bacteremia, and septicemia are the major pathogenetic events in the various forms of colibacillosis.

### Septicemic Colibacillosis (Coliform Septicemia)

Septicemic colibacillosis occurs in all species as a result of invasive strains of *E. coli* invading the tissues and systemic circulation via the intestinal lumen, nasopharyngeal mucosa, and tonsillar crypts, or umbilical vessels. The intestinal permeability to macromolecules in the newborn piglet may

predispose to the invasion of septicemia-inducing *E. coli*. These strains are able to invade extraintestinal tissues, to resist the bactericidal effect of complement in blood, to survive and multiply in body fluids, to escape phagocytosis and intracellular killing by phagocytes, and to induce tissue damage by the release of cytotoxins. Calves and piglets that are deficient in colostral immunoglobulins are highly susceptible to septicemia. Colostrum provides protection against colisepticemia, but it may not prevent diarrhea associated with *E. coli*. Also, colostrum-fed calves are much more resistant to endotoxin than colostrum-deprived calves. Calves, piglets, and lambs that have normal levels of serum immunoglobulins are generally protected from septicemia. The clinical findings and lesions in septicemic colibacillosis are attributable to the effects of endotoxin, which causes shock. The general effects of endotoxin in cattle include hypothermia, decreased systemic blood pressure, tachycardia and decreased cardiac output, changes in WBC counts, alterations in blood coagulation, hyperglycemia followed by hypoglycemia, and depletion of liver glycogen. Animals that recover from septicemia may later develop lesions as a result of local infection of other organs at varying periods of time. Arthritis is a common associated finding in calves, foals, and lambs. Meningitis is common in calves and piglets. Polyserositis as a result of *E. coli* has been recorded in pigs.

### Enteric Colibacillosis

#### Enterotoxigenic Colibacillosis

Enterotoxigenic strains of *E. coli* (ETEC) colonize and proliferate in the upper small intestine and produce enterotoxins, which cause an increase in net secretion of fluid and electrolytes into the gut lumen. The adhesion of *E. coli* to the intestinal epithelial cells is mediated by bacterial pili. The enterotoxigenic form of colibacillosis occurs most commonly in calves and piglets and less commonly in lambs and kids.

The factors that allow or control the colonization and proliferation of these strains and their production of enterotoxin are not well understood. The bacterial fimbriae attach to specific receptor sites on villous epithelial cells, following which the bacteria multiply and form microcolonies that cover the surface of the villi. The capsular polysaccharide of *E. coli* may also be involved in adhesion and colonization. The fimbriae of *E. coli* are strongly immunogenic, a factor that is utilized in the production of vaccines. Because the F5 antigen is only expressed at an environmental pH above 6.5, colonization of the mucosa of the small intestinal tract starts in the ileum, where the intraluminal pH is the highest, and progresses proximally from there.<sup>8</sup> Once established in the gut, ETEC strains start producing and secreting a heat-stable enterotoxin. Similar to the

expression of F5, production of enterotoxin is pH dependent, with very limited production at an environmental pH below 7.0.<sup>8</sup> Although this does not appear to have been studied specifically, it can be hypothesized that any factor resulting in an increase of the pH in the gut lumen will facilitate the proliferation of the organism; conversely, lowering the pH may reduce the severity of colibacillosis.

### Diarrhea, Dehydration, Metabolic Acidosis, and Electrolyte Imbalance

The production of the enterotoxin results in net secretion of fluid and electrolytes from the systemic circulation into the lumen of the intestine, resulting in varying degrees of diarrhea, dehydration, electrolyte imbalances, acidemia, circulatory failure, shock, and death. The hyperkalemia that is observed in a subset of calves with severe dehydration and acidemia has been associated with cardiac arrhythmias, including bradycardia and atrial standstill.

The effect of the enterotoxin on the gut of calves, piglets, and other species is similar to the effect of cholera enterotoxin in humans and takes place through an intact mucosa. Enterotoxin stimulates mucosal adenylcyclase activity, leading to an increase in cyclic adenosine monophosphate (AMP), which increases intestinal chloride secretion. The increased intraluminal chloride content osmotically drags water into the gut to an amount that exceeds the absorptive capacity of the intestinal mucosa, thereby causing diarrhea. The secretion originates primarily in the intestinal crypts, but the villous epithelium also has a secretory function. The mucosal membrane colonized by ETEC remains morphologically intact. The fluids secreted are alkaline and, in comparison to serum, isotonic, low in protein, and high in sodium and bicarbonate ions. Distension of the abdomen of diarrheic calves may occur, which may be associated with fluid distension of the abomasum and the intestines.

When the disease is confined to the intestine, it responds reasonably well to treatment in the early stages. If death occurs, it is a result of acidemia, electrolyte imbalance, and dehydration. The acid-base and electrolyte changes in piglets 1 to 3 days of age infected naturally and experimentally with ETEC reveal severe dehydration, acidemia, and metabolic acidosis.

Severe metabolic changes can occur in calves with diarrhea. If the disease is progressive, acidemia and metabolic acidosis become more severe as lactic acidosis develops, and severe hypoglycemia may occur. If large amounts of fluid are lost, hypovolemia and shock occur.

Historically, conventional wisdom held that **metabolic acidosis** in diarrheic calves is the result of fecal bicarbonate loss and formation of L-lactate as a result of increased anaerobic glycolysis in dehydrated animals

with decreased tissue perfusion. However, accumulation of L-lactate in neonatal diarrheic calves only appears to occur in calves in their first week of life. Because the relationship between L-lactic acid accumulation and the severity of metabolic acidosis could not be confirmed in clinical cases, it was proposed that exogenous acid supply to the organism must be the major contributor to the so-called **anion-gap acidosis** typically observed in diarrheic calves.<sup>12</sup> The anion gap, defined as the sum of the major cations minus the sum of the major anions, is a measure of “unspecified organic and inorganic acids,” of which lactic acid forms a considerable part. It was not until the end of last century that **D-lactic acid accumulation** was first identified as a major contributor to elevated anion gaps in diarrheic calves. In the meantime, several studies confirmed that D-lactic but not L-lactic acidosis is a common occurrence in diarrheic calves. Furthermore D-lactic acidosis was identified as a major contributory factor in calves with high anion-gap acidosis.<sup>12</sup> It is currently assumed that D-lactic acidosis is caused by increased intestinal absorption of this compound in diarrheic calves, where malabsorption results in bacterial fermentation of unabsorbed carbohydrates to D-lactate.<sup>12</sup> Recent retrospective studies suggested that the major driving factor of the acidemia of diarrheic calves was an increase in unmeasured anions, of which lactic acid forms a considerable part. The loss of fluid through the intestinal tract with high sodium and low chloride content is likely to contribute to the so-called strong-ion acidosis. The increase of the total plasma protein concentration that is commonly observed with marked dehydration and resulting in a so-called weak-acid acidosis was found to be a minor contributor to acidemia in diarrheic calves.<sup>13</sup>

The severity and nature of the acidosis in diarrheic calves vary with the age of the calf. Younger calves tend to dehydrate more rapidly and severely than older calves, which may be related to the greater incidence of enterotoxigenic colibacillosis in the young age group. The severity of dehydration, hypothermia, and acidemia is associated with the level of obtundation. Accordingly, the degree of deterioration of the patient's demeanor in combination with the age of the calf are used to predict the severity of acidemia; the more severe the acidemia, the greater the depression.

Conventional wisdom posits that neurologic effects such as ataxia, somnolence, or even coma are primarily caused by severe acidemia or metabolic acidosis, but a series of recent studies unequivocally demonstrated that disturbed neurologic function can better be explained by the frequently observed increase in plasma D-lactate concentration than acidemia/metabolic acidosis per se.<sup>14,15</sup> Experimental studies conducted on euhydrated calves showed that neurologic

signs similar to the ones observed in severely diarrheic calves can be reproduced by inducing hyper-D-lactatemia without concomitant acidosis. In contrast, experimentally inducing severe hyperchloremic acidosis in calves did not result in noteworthy effects on the demeanor of treated calves.<sup>16,17</sup>

### Hyperkalemia in the Diarrheic Calf

Hyperkalemia is the most prominent electrolyte disturbance recognized in dehydrated diarrheic calves that are severely acidemic. It occurs despite significant net losses of potassium into the gut in diarrheic animals. A recent retrospective study conducted on patients of a teaching hospital revealed an incidence of hyperkalemia in diarrheic calves of 34%.<sup>18</sup> The predominant clinical finding associated with hyperkalemia is bradycardia and arrhythmia that can lead to atrial standstill, with fatal outcome. Although the association between hyperkalemia and acidemia is well established, the underlying mechanism is poorly understood.<sup>19</sup> The long-held mechanism responsible for hyperkalemia in diarrheic calves is directly associated with extracellular acidosis and the electrochemical exchange of  $K^+$  for  $H^+$  across the cell membrane, leading to a shift of potassium from the extracellular to the intracellular space in exchange for  $H^+$  that tends to shift into the opposite direction with increasing extracellular  $H^+$  concentrations. Although widely accepted, this proposed mechanism lacks a sound physiochemical basis because a decrease in plasma pH from 7.4 to 7.0 would increase the extracellular  $H^+$  concentration from 0.000,040 mmol/L to 0.000,100 mmol/L. An equimolar exchange of  $K^+$  for  $H^+$  can therefore only account for an increase of the serum potassium concentration of 0.000,06 mmol/L, an effect that not only is not measurable with current laboratory equipment but also is physiologically irrelevant.<sup>19</sup> An alternative mechanism that has been proposed is impaired activity of Na/K-ATPase in states of acidemia, resulting in impaired transport of potassium into the intracellular space.<sup>19</sup> The previously mentioned retrospective study found the occurrence and the degree of hyperkalemia to be more closely associated to the degree of dehydration than to the decrease in venous blood pH or base excess, suggesting that the impaired ability to excrete potassium through the urinary tract may play a more important role than metabolic acidosis/acidemia in the etiology of hyperkalemia in dehydrated calves.<sup>18</sup>

### Hypernatremia in the Diarrheic Calf

Hypernatremia is uncommon in diarrheic calves generally suffering from isotonic or mildly hypotonic dehydration. However, incidental cases of hypernatremia have been reported. It is presumed that mixing errors in the preparation of oral electrolyte solutions to treat diarrhea rather than diarrhea

itself is the cause. The experimental oral administration of 1 L of electrolyte concentrate containing 2750 mEq sodium found that calves would willingly consume the solution mixed with milk, and developed signs of hypernatremia within 6 hours of administration.

### Effect of Colostral Immunoglobulin Status

An adequate level of serum immunoglobulin can protect calves from death as a result of the effects of diarrhea, but not necessarily from diarrhea. The best protection is provided if both the immunoglobulin levels in the serum and the levels in the colostrum and milk during the first week after birth are high. The immunoglobulin subclasses in the plasma of calves that have received sufficient colostrum are IgG, IgM (and IgM is probably the more important of the two for the prevention of septicemia), and IgA. The serum IgG concentrations of calves under 3 weeks of age dying from infectious disease were much lower than those in normal calves. Of the dead calves, 50% had serum IgG levels that were more than 2 standard deviations below the normal mean, and an additional 35% had concentrations greater than 1 standard deviation below the normal mean. In the intestine, no single subclass of immunoglobulin is known to be responsible for protection against the fatal effects of diarrhea. Individually, each immunoglobulin subclass can prevent death from diarrhea even though calves may be affected with varying degrees of diarrhea. In contrast to the situation in the pig, IgA appears to be least effective.

In pigs, IgA becomes the dominant immunoglobulin in sow colostrum after the first few days of lactation, and this is the immunoglobulin that is not absorbed but is retained in, and reaches a high level in, the gut and plays a major role in providing local protection against enteric colibacillosis in piglets. Porcine colostrum IgA is more resistant to gastrointestinal proteolytic enzymes than IgG<sub>2</sub> and IgM. On the other hand, IgG is at a peak concentration in colostrum in the first day after parturition, is readily absorbed by the newborn piglet, and is vital in providing protection against septicemia. Lysozyme in sows' milk may assist in the control of the bacterial population in the gut of the unweaned piglet.

### Intestinal Mucosa

In general, ETEC exert their effects by the enterotoxin causing hypersecretion through an intact intestinal epithelium. However, the intraluminal exposure of the jejunum of 3-week-old pigs to sterile crude-culture filtrates from strains of *E. coli* known to produce two types of ST will induce microscopic alterations of the villous epithelium. Focal emigration of neutrophils, especially through the epithelium above aggregated lymphatic follicles; stunting of jejunal and

ileal villi; and adherence of bacteria to jejunal and ileal mucosae are the most consistent findings. These changes are useful in making the diagnosis of enterotoxigenic colibacillosis in calves. Although enterotoxigenic strains are considered to be noninvasive, this does not preclude the possibility that invasion into the systemic circulation may occur, resulting in septicemia, or that septicemic strains may not also be present.

Enzyme histochemistry studies of the small intestinal mucosa in experimental infections of calves with rotavirus and ETEC indicate a marked decrease in enzyme activity in dual infections and a lesser decrease in monoinfections. Increased enzyme activity occurred in parts of the intestinal mucosa that were not affected or only slightly affected by the enteropathogens, which may be an adaptation of the mucosa to maintain absorptive function. Lactose digestion is slightly impaired in calves with mild diarrhea. Calves with acute diarrhea are in a catabolic state and respond with a larger increase of plasma glucose concentration to a given amount of absorbed glucose than do healthy calves.

Fat and carbohydrate malabsorption frequently occurs in diarrheic calves over 5 days of age and contributes to the development of D-lactic acidosis, which has been associated with a strong neurotoxic effect that is presumably responsible for the impaired demeanor of diarrheic calves.

### Attaching and Effacing Colibacillosis

Attaching and effacing enteropathogenic *E. coli* can cause naturally occurring diarrhea and dysentery in calves at 18 to 21 days. They do not produce enterotoxin but adhere to the surface of the enterocytes of the large intestine. Affected calves pass bright red blood in the diarrheic feces. The lesions in experimentally infected calves are indistinguishable from those produced by some *E. coli* that are enteropathogenic for humans, rabbits, and pigs. The bovine O118:H16 EHEC strain is able to colonize the intestine of newborn calves, inducing diarrhea 24 hours after challenge and producing attaching and effacing lesions in the small and large intestines.

### Synergism Between Enteropathogens

Enterotoxigenic colibacillosis occurs naturally and can be reproduced experimentally using ETEC in calves less than 2 days of age but not in calves 1 week of age. Diarrheic calves older than 3 days of age may be infected with enterotoxigenic F5 (K99) *E. coli* and rotavirus. There is evidence that prior or simultaneous infection of the intestine with rotavirus will enable the *E. coli* to colonize in older calves. Thus there may be synergism between rotavirus and ETEC in calves older than 2 days; this may explain the fatal diarrhea that can occur in calves at 1 week of age, which normally would not be fatal with a

single infection. The rotavirus may enhance the colonization of *E. coli*.

The simultaneous experimental infection of neonatal gnotobiotic calves at 24 hours of age with rotavirus and ETEC results in a severe diarrheal disease. The same situation occurs in piglets. However, in both species the effect was considered to be additive rather than synergistic.

### Summary of Pathogenesis

Septicemic colibacillosis occurs in newborn animals, and FTPI is the major predisposing factor. Enteric colibacillosis occurs in colostrum-fed animals and is associated with the colonization and proliferation of ETEC, which produce enterotoxin and cause varying degrees of diarrhea, acidemia, and dehydration. Although single infections occur commonly, as in piglet diarrhea, and what was previously described as enteric-toxicemic colibacillosis in calves, multiple infections with ETEC and viruses and other agents are more common.

## CLINICAL FINDINGS

### Calves

#### Coliform Septicemia

Coliform septicemia is most common in calves during the first 4 days of life and is described as the systemic inflammatory response syndrome (SIRS) to an active infectious process.<sup>20</sup> Most affected calves have low levels of serum IgG because of inadequate transfer of colostral immunoglobulin.<sup>21</sup> The illness is peracute, with the course varying from 24 to 96 hours, with a survival rate of less than 12%. Early clinical signs are vague and nonspecific. Affected animals are weak and obtunded, commonly recumbent, and dehydrated; tachycardia is present, and although the temperature may be high initially, it falls rapidly to subnormal levels when the calf becomes weak and moribund. The suck reflex is weak or absent, the oral mucous membranes are dry and cool, and the capillary refill time may be prolonged. Cold extremities, weak peripheral pulse, and prolonged capillary refill time are common. Scleral injection is common. Diarrhea and dysentery may occur but are uncommon.

The involvement of multiple body systems and organs is characteristic of neonatal septicemia, and careful clinical examination is required to detect abnormalities. If a calf survives the septicemic state, clinical evidence of postsepticemic localization may appear in about 1 week. This includes arthritis, meningitis, panophthalmitis, and, less commonly, pneumonia. In a series of 32 cases of meningitis in neonatal calves, the most frequent clinical findings were lethargy, anorexia, recumbency, loss of the suck reflex, stupor, and coma. Opisthotonos, convulsions, tremors, and hyperesthesia were seen less frequently. The case fatality rate was 100% in spite of intensive therapy, and lesions of septicemia were present at necropsy.

### Predictors of Septicemia

The early clinical findings of septicemia in neonatal calves are vague and nonspecific and are often indistinguishable from the findings of noninfectious diseases or those of focal infections such as diarrhea. Positive blood cultures are required for a definitive diagnosis of septicemia, but results are not usually available for 48 to 72 hours, and false negatives are common. Laboratory parameters that have been proposed to identify potentially septic calves include hypoglycemia, left shift of neutrophils, and signs of toxicity of neutrophils.<sup>20</sup>

No single laboratory test has emerged as being completely reliable for the early diagnosis of septicemia in farm animal neonates, and therefore scoring systems and predictive models using obtainable historical, clinical, and clinicopathologic data have been developed.<sup>20</sup> The goal of these mathematical models is to identify septicemic neonates early in the course of disease when appropriate therapy would be most likely to result in a favorable outcome. In a study of diarrheic calves under 28 days of age submitted to a referral clinic for treatment, 31% of the calves were septicemic, based on blood culture. Two models to predict septicemia were used. Clinicopathologic variables associated with an increased risk of septicemia were moderate (1.99 to 5.55 mg/dL) and marked (>5.66 mg/dL) increases in serum creatinine (OR 8.63), moderate to marked toxic changes in neutrophils (OR 2.88), and FTPI (IgG concentrations  $\beta$  800 mg/dL, globulin  $\beta$  2 g/dL [OR 2.72], and total serum protein  $\beta$  5 g/dL). The clinical variables associated with an increased risk of septicemia were age under 5 days (OR 2.58), focal infection (OR 2.45), recumbency (OR 2.98), and weak suck reflex (OR 4.10).

### Enteric Colibacillosis

Enteric colibacillosis is the most common form of colibacillosis in newborn calves, primarily 3 to 5 days of age. It may occur in calves as early as 1 day of age and only rarely up to 3 weeks. The clinical severity will vary depending on the number and kind of organisms causing the disease. The presence of a single ETEC may cause a state of collapse usually designated as **enteric toxemia**. In this form of the disease the outstanding clinical signs include severe weakness, coma, subnormal temperature, cold and clammy skin, pale mucosae, wetness around the mouth, collapse of superficial veins, slowness and irregularity of the heart, mild convulsive movements, and periodic apnea. Diarrhea is usually not evident, although the abdomen may be slightly distended, and auscultation may reveal fluid-splashing sounds suggesting a fluid-filled intestine. The prognosis for these calves is poor, and they commonly die 2 to 6 hours after the onset of signs.

In the more common form of the disease in calves, there is diarrhea in which the feces

are profuse and watery to pasty, usually pale yellow to white in color, and occasionally streaked with blood flecks and very foul-smelling. The dry-matter content of the feces is commonly below 10%. Defecation is frequent and effortless, and the tail and perineum are soiled with feces. The temperature is usually normal in the initial stages but becomes subnormal as the disease worsens. Affected calves may or may not suck or drink depending on the degrees of acidosis, dehydration, and weakness. Calves under 8 days of age may be weak, primarily from the effects of rapid and severe dehydration; in calves older than 8 days the acidemia and metabolic acidosis, a considerable part of which is a result of the accumulation of D-lactic acid, tend to be more severe and make a greater contribution to obtundation and weakness. In the early stages of the disease, the abdomen may be slightly distended as a result of distension of fluid-filled intestines, which can be detected by succussion and auscultation of the abdomen. In some of these calves the diarrhea is not yet obvious but is delayed for several hours, when it can become quite profuse. Mildly to moderately affected calves may be diarrheic for a few days and recover spontaneously with or without treatment. However, 15% to 20% of calves with enteric colibacillosis become progressively worse over a period of 3 to 5 days, gradually become more weak, lose the desire to suck, and progressively appear more obviously dehydrated.

Throughout the course of the diarrhea the degree of dehydration will vary from just barely detectable clinically (4% to 6% of body weight [BW]) to up to 10% to 16% of body weight. The degree of dehydration can be estimated by “tenting” the skin of the lateral portion of the cervical region and measuring the time required for the skin fold to return to normal. In calves with 8% dehydration, 5 to 10 seconds will be required for the skin fold to return to normal; in 10% to 12% dehydration, up to 30 seconds will be required. Recession of the eyeball (enophthalmos) is an alternative method validated to reliably estimate the degree of dehydration in diarrheic calves. Slight sinking of the eyeball without an obvious space between

the eyeball and the orbit represents 6% to 8% dehydration, moderate separation of the eyeball from the orbit represents 9% to 12% dehydration, and marked separation of the eyeball from the orbit represents over 12% and up to 16% dehydration. A summary of the relationship between degree of dehydration (% BW), depth of enophthalmos (mm), cervical skin tent duration in seconds, and the state of the mucous membranes and extremities in calves with experimentally induced diarrhea is set out in Table 19-12.<sup>1</sup>

Affected calves can lose 10% to 16% of their original body weight during the first 24 to 48 hours of the diarrhea. The hyperkalemia in calves with neonatal diarrhea has been associated with cardiac rate and rhythm abnormalities, including bradycardia and atrial standstill. Herd outbreaks of the disease in beef calves may last for several weeks, during which time almost every calf will be affected within several days after birth.

**Veal calf hemorrhagic enteritis** is a fatal syndrome of veal calves characterized by anorexia, fever, diarrhea with mucus-containing feces that become bloody in the later stages, and hemorrhagic diathesis on the conjunctivae and mucous membranes of the mouth and nose. The etiology is unknown; the *E. coli* strains isolated from the feces of affected calves produced enterotoxins and Shiga toxins, but their significance is uncertain.

In some calves between 10 and 20 days of age with a history of diarrhea in the previous several days, from which they have recovered, there will be metabolic acidosis without clinical signs of dehydration. Affected calves are depressed, weak, ataxic, and sometimes recumbent, and they appear comatose. Affected calves respond quickly to treatment with intravenous sodium bicarbonate. A similar syndrome occurs in goat kids.

### Lambs and Goat Kids

Although some cases manifest enteric signs, and chronic cases may occur, colibacillosis in lambs is commonly septicemic and peracute. Two age groups appear to be susceptible: lambs 1 to 2 days of age and lambs 3 to 8 weeks old. Peracute cases are found dead

without premonitory signs. Acute cases show collapse and occasionally signs of acute meningitis manifested by a stiff gait in the early stages, followed by recumbency with hyperesthesia and tetanic convulsions. Chronic cases are usually manifested by arthritis. The disease in goat kids is similar to that in lambs.

### Piglets

#### Coliform Septicemia

Coliform septicemia is uncommon but occurs in piglets within 24 to 48 hours of birth. Some are found dead without any premonitory signs. Usually more than one piglet, and sometimes the entire litter, will be affected. Severely affected piglets seen clinically are weak and almost comatose, appear cyanotic, feel cold and clammy, and have a subnormal temperature. Usually there is no diarrhea. The prognosis for these piglets is poor, and most will die in spite of therapy.

**Edema disease** is a unique form of colibacillosis occurring in piglets between a few days after birth to well after weaning. It is caused by Shiga-toxin-producing *E. coli* strains that induce degenerative angiopathy of small arteries and arterioles.

### Enterotoxigenic Colibacillosis

#### Newborn Piglet Diarrhea

Newborn piglet diarrhea, a form of colibacillosis in piglets, occurs from 12 hours of age up to several days of age, with a peak incidence at 3 days of age. As with the septicemic form, usually more than one pig or the entire litter is affected. The first sign usually noticed is the fecal puddles on the floor. Affected piglets may still nurse in the early stages, but they gradually lose their appetite as the disease progresses. The feces vary from a pasty to watery consistency and are usually yellow to brown in color. When the diarrhea is profuse and watery, there will be no obvious staining of the perineum and hindquarters with feces, but the tails of the piglets will be straight and wet. Sick piglets occasionally vomit, although vomiting is not as prominent as with transmissible gastroenteritis. The temperature is usually normal or subnormal. The disease is progressive; diarrhea and dehydration continue, and the piglets become very weak and lie in lateral recumbency and make weak paddling movements. Within several hours they appear very dehydrated and shrunk, and they commonly die within 24 hours after the onset of signs if not treated. In severe outbreaks the entire litter may be affected and die within a few hours of birth. The prognosis is favorable if treatment is started early, before significant dehydration and acidosis occur.

#### Postweaning Diarrhea

The postweaning diarrhea (PWD) form of colibacillosis in piglets presents an economically important cause of death of weaned piglets. It is commonly seen within days of

**Table 19-12** Degree of dehydration in calves with experimentally induced diarrhea

Degree of dehydration (% BW)	Depth of enophthalmos (mm)	Cervical skin-tent duration (s)	Mucous membranes and extremities
0	None	Less than 2	Moist
2	1	3	Dry
4	2	4	Dry
6	3	5	Dry
8	4	6	Cool extremities
10	6	7	Cool extremities
12	7	>8	Cool extremities
>14	>8	>10	White mucous membranes

weaning. In peracute cases piglets are found dead with an obviously dehydrated appearance, deeply sunken eyes, and cyanotic extremities. In less acute cases the first sign may be a loss in condition that is largely a result of dehydration. Diarrhea may not be apparent in all cases because fluid may just accumulate in the gut in some animals. If present, diarrhea can be watery to pasty, may contain blood in some instances, and may last between 1 and 5 days (see also "Post-weaning Diarrhea of Pigs").

## CLINICAL PATHOLOGY

### Culture and Detection of Organism

If septicemia is suspected, blood should be submitted for isolation of the organism and determination of its drug sensitivity. Blood for culture must be taken aseptically and inoculated directly into brain–heart infusion broth. Because of the limited sensitivity to detect bacteremia by a single culture, the blood sample should be repeated a few hours later to enhance recovery rate and confirm septicemia.

The **definitive etiologic diagnosis of enteric colibacillosis** depends on the isolation and characterization of *E. coli* from the intestines and the feces of affected animals. The best opportunity of making a diagnosis is when untreated representative affected animals are submitted for pathologic and microbiological examination. The distribution of the organism in the intestine; determination of the presence of F4 (K88), F5(K99), or F6 (987P) antigens; and the histopathologic appearance of the mucosa contribute to the diagnosis.

The routine culture of feces and intestinal contents for *E. coli* without determining their virulence determinants is of limited value. The laboratory tests used to identify enterotoxigenic F4 (K99) *E. coli* include a direct fluorescent antibody technique with conventional culturing methods and the ELISA, with or without monoclonal antibody, to detect the organism or the enterotoxin in the feces. DNA gene probes specific for genes encoding enterotoxin and adhesins are available and are being used to evaluate *E. coli* isolated from diarrheic animals. Isolates of the organism can also be examined for the presence of toxins using an enzyme immune assay test and latex agglutination test.

Detection of STEC in feces has relied on cytotoxicity testing and DNA hybridization. Several ELISAs are available, and monoclonal antibodies to the Shiga toxins ST1 and ST2 have been used to examine feces from animals. The isolation of *E. coli* O157:H7 has relied on its ability to ferment sorbitol. A sandwich ELISA using monoclonal antibodies to *E. coli* Shiga toxins 1 and 2 for capture and detection is available for detection of STEC in animal feces. A PCR test is also available for detection of ST genes in *E. coli* isolated from cattle, sheep, and pigs affected with diarrhea.

The determination of drug sensitivity of the *E. coli* isolated from the feces of diarrheic calves and piglets is commonly done, but it is of limited value without determining which isolate is enteropathogenic.

### Hematology and Serum Biochemistry

A total and differential leukocyte count and remarkable changes in the fibrinogen concentration may indicate the presence of septicemia or severe intestinal infection. However, severely affected calves may not have grossly abnormal hemograms.<sup>21</sup> In enteric disease, the major changes in plasma composition are dehydration, electrolyte imbalance, and metabolic acidosis/acidemia. The total plasma osmolality tends to be decreased.

The packed cell volume and the total protein concentration of the blood will indicate the degree of dehydration, although the increase of total protein in calves with FTPI may underestimate the degree of dehydration. The blood urea nitrogen (BUN) concentration may be increased in severe cases because of inadequate renal perfusion. The blood bicarbonate concentration is markedly reduced, indicating the presence of metabolic acidosis. Decreased blood pH values represent acidemia. Calves with a venous blood pH below 7.0 require immediate parenteral therapy for acidemia. Other serum electrolytes are variable, but there may be a slight decrease in serum sodium and a slight increase in serum chloride. In severely dehydrated animals hyperkalemia may occur, which may result in bradyarrhythmia.<sup>18</sup>

Hematologic abnormalities associated with **septicemia** vary with the stage and severity of the disease. Abnormal neutrophil counts (neutrophilia or neutropenia), a left shift of neutrophils, and signs of toxicity in neutrophils are commonly seen in septic animals.<sup>11,20,21</sup> Hypoglycemia is another common, although certainly not pathognomonic, finding in septic calves.

### NECROPSY FINDINGS

In **coliform septicemia** there may be no gross lesions, and the diagnosis may depend on the isolation of the organism from the filtering organs. In less severe cases there may be subserosal and submucosal hemorrhages. A degree of enteritis and gastritis may be present. Occasionally, fibrinous exudates are found in the joints and serous cavities, and there may be omphalophlebitis, pneumonia, and meningitis. The histologic features of such presentations of colibacillosis are those of septicemia and toxemia.

In **enteric colibacillosis** of piglets and calves the carcass appears dehydrated, but the intestine is flaccid and filled with fluid. In calves, the abomasum is usually distended with fluid and may contain a milk clot. Clots are typically absent in calves fed whey milk replacers that do not contain casein. The abomasal mucosa may contain numerous

small hemorrhages. In both calves and pigs, the intestinal mucosae may appear normal or hyperemic, and there may be edema of the mesenteric lymph nodes. Mild atrophy or even fusion of jejunal and ileal villi is often seen, but the key microscopic observation is the **presence of bacilli adherent to the brush borders of enterocytes**. Ultrastructurally, there is increased epithelial cell loss from the villus about 12 hours after experimental inoculation of calves with an ETEC.

In calves affected with attaching and effacing *E. coli* there is pseudomembranous ileitis, mucohemorrhagic colitis, and proctitis. Microscopic examination of well-preserved gut segments reveals bacterial adherence, atrophy of ileal villi, and erosion of enterocytes.

In addition to traditional bacteriologic culture techniques, the ETEC may be identified by several tests, including indirect fluorescent antibody (IFA) tests specific for F4 (K88), F5 (K99), and F6 (987P) pilus antigens. The IFA tests can be performed on impression smears or frozen sections of ileal tissue, and the results are available within a few hours. Newer techniques such as DNA gene probes, enzyme immune assays, and latex agglutination tests are now available to identify those isolates that are enterotoxin producers and have adhesin properties.

During severe disease outbreaks it is often necessary to conduct the necropsy examination on diarrheic animals that have been killed specifically for the purpose of obtaining a definitive etiologic diagnosis. The combined use of bacteriologic, parasitologic, and virological methods, together with histologic and immunofluorescent studies of fresh intestinal tissue, will provide the most useful information about the location of the lesions and the presence of enteropathogens. Postmortem autolysis of the intestinal mucosae and invasion of the tissues by intestinal microflora occurs within minutes after death, so gut samples should be collected immediately following euthanasia of the animal.

### Samples for Confirmation of Diagnosis

#### Coliform Septicemia

- Bacteriology—chilled spleen, lung, liver, culture swabs of exudates, umbilicus, meninges (culture)
- Histology—fixed samples spleen, lung, liver, kidney, brain, and any gross lesions

#### Enteric Colibacillosis

- Bacteriology—chilled segments of ileum and colon (including content; culture and/or FAT, latex agglutination, PCR)
- Histology—fixed duodenum, jejunum, ileum, colon, and mesenteric lymph node

**Table 19-13** Possible causes of bacteremia/septicemia and acute neonatal diarrhea in farm animals

Calves	Piglets	Lambs and kids	Foals
<b>Bacteremia/septicemia</b>			
<i>Escherichia coli</i>	<i>E. coli</i>	<i>E. coli</i>	<i>E. coli</i>
<i>Salmonella</i> spp.	<i>Streptococcus</i>	<i>Salmonella</i> spp.	<i>Actinobacillus equuli</i>
<i>Listeria monocytogenes</i>	<i>L. monocytogenes</i>	<i>L. monocytogenes</i>	<i>Salmonella abortusovae</i>
<i>Pasteurella</i> spp.		<i>Erysipelothrix rhusiopathiae</i>	<i>Salmonella typhimurium</i>
<i>Streptococcus</i> spp.			<i>Streptococcus pyogenes</i>
<i>Pneumococcus</i> spp.			<i>L. monocytogenes</i>
<b>Acute neonatal diarrhea</b>			
Enteropathogenic and enterotoxigenic <i>E. coli</i>	Enteropathogenic <i>E. coli</i>	<i>Clostridium perfringens</i> type C	Foal-heat diarrhea
Rotavirus	<i>Salmonella</i> spp.	<i>C. perfringens</i> type B	Rotavirus
Coronavirus	Transmissible	(lamb dysentery)	<i>C. perfringens</i> type B
Bovine coronavirus (Breda virus)	gastroenteritis virus	Rotavirus	
Bovine calicivirus	<i>C. perfringens</i> type C	Caprine herpesvirus	
Bovine norovirus	(rarely A)		
<i>Cryptosporidium</i> spp.	<i>Clostridium difficile</i>		
<i>Giardia</i> spp.	Rotavirus		
<i>Salmonella</i> spp.	PRRSV		
<i>Eimeria</i> spp. (calves at least 3 weeks old)	<i>Isospora</i> spp.		
<i>C. perfringens</i> type C			

PRRSV, porcine reproductive and respiratory syndrome virus.

## DIFFERENTIAL DIAGNOSIS

The definitive etiologic diagnosis of septicemic colibacillosis is dependent on the laboratory isolation of the causative agent, which is usually a single species or organism. The septicemias of the newborn cannot be distinguished from one another clinically. The definitive etiologic diagnosis of enteric colibacillosis in newborn calves and piglets may be difficult and often inconclusive because the significance of other organisms in the intestinal tract and feces of diarrheic animals cannot be easily determined.

Table 19-13 lists the possible causative agents of diarrhea and septicemia in newborn farm animals. Using the combined diagnostic approach of detection of enteropathogens in the feces before death and in the intestinal mucosa after death, it is possible to identify where ETEC, rotavirus, coronavirus, *Salmonella* spp., and *Cryptosporidium* spp. appear to be the only or principal causative agents. However, mixed infections are more common than single infections.

Every effort that is economically possible should be made to obtain an etiologic diagnosis. This is especially important when outbreaks of diarrhea occur in a herd or when the disease appears to be endemic. The use of an interdisciplinary approach will increase the success of diagnosis. This includes making a visit to the farm or herd and making a detailed epidemiologic investigation of the problem. The diagnosis depends heavily on the epidemiologic findings, the microbiological and pathologic findings, and sometimes on the results of treatment.

The major difficulty is to determine whether or not the diarrhea is infectious in origin and to differentiate it from dietetic diarrhea, which is most common in hand-fed

calves and in all newborn species that are sucking high-producing dams. In dietetic diarrhea the feces are voluminous and pasty to gelatinous in consistency; the animal is bright and alert and is usually still sucking, but some may be inappetent.

## TREATMENT

### Coliform Septicemia

**Intensive critical care** is required for the treatment of neonatal coliform septicemia. Early identification of animals suspected of being septicemic and early therapeutic intervention are important determinants of the treatment success. Evidence from human medicine indicates that the survival rate must be expected to decrease by 10% for every hour antimicrobial therapy is delayed in patients in septic shock.<sup>22</sup> A recent consensus statement in human medicine recommends initiation of intravenous antimicrobial therapy within the first hour after having recognized severe septicemia.<sup>23</sup> Thus, in most cases antimicrobial therapy has to be initiated before confirmatory culture results are available.

Although *E. coli* may be cultured from the blood of septicemic foals and calves, a significant percentage of isolates are gram-positive, which justifies the use of antimicrobials that have a broad spectrum. Antimicrobials are given parenterally and may be given continuously intravenously, more than once daily and daily until recovery is apparent. Isolation of the organisms from blood and determination of drug sensitivity constitute the ideal protocol. Intravenous fluid and electrolyte therapy are administered continuously until recovery is apparent

(see “Principles of Fluid and Electrolyte Therapy”). Whole blood transfusions are used in calves and foals, especially when immunoglobulin deficiency is suspected from the history or is determined by measurement of serum immunoglobulins of blood. In one series on neonatal septicemia in calves, in which *E. coli* accounted for 50% of the bacterial isolates, the survival rate was only 12%.

### Enteric Colibacillosis

The considerations for treatment of enteric colibacillosis include the following:

- Fluid and electrolyte replacement
- Antimicrobial and immunoglobulin therapy
- Antiinflammatory therapy
- Antimotility drugs
- Intestinal protectants
- Alteration of the diet
- Probiotics
- Clinical management of outbreaks

### Fluid and Electrolyte Replacement

The dehydration, acidosis, and electrolyte imbalance are corrected by the parenteral and oral use of simple or balanced electrolyte solutions. The provision of fluid therapy in diarrheic dehydrated calves under field conditions in veterinary practice has been described. It is important to obtain an adequate history of the case, including age of the calf, duration of the diarrhea, and all treatments already given by the owner. The physical examination of the calf includes a standard clinical examination with emphasis on evaluating the degree of dehydration and acidosis.

**Dehydration** is evaluated by two clinical observations:

- **Skin elasticity.** The skin of the middle of the neck is better than the eyelid. A portion of the skin is tented and twisted for 1 second, and then the time to return to the initial position is measured—less than 2 seconds in the normal calf, 6 seconds in moderate (8%) dehydration, and more than 8 seconds in severe (12%) dehydration (Table 19-12).
- **Position of eyeball in the orbit and extent of enophthalmos.** This is determined by measuring the distance between the globe and the orbit. The eyeball is not sunken in healthy calves. Degrees of dehydration of 4%, 8%, and 12% are represented by 2-mm, 4-mm, and 7-mm enophthalmos, respectively (Table 19-12).

The degree of metabolic acidosis can be evaluated by determining the degree of obtundation, muscular tone, ability to stand, intensity of the sucking reflex, temperature of the inside of the oral cavity, and age of the calf that correlate with an estimate of the **base deficit**. The following categories for diarrheic calves are being used under field conditions:

1. Calves with good muscular tone and the ability to stand, strong suck reflex, and warm oral cavity have no base deficit if younger than 8 days of age and up to 5 mEq/L if older than 5 days.
2. Calves that can stand, have a slightly cool oral cavity, and have a weak suck reflex have a base deficit of 5 mEq/L if under 8 days of age and 10 mEq/L if older than 8 days.
3. Calves in sternal recumbency with a cool oral cavity and no suck reflex have a base deficit of 10 mEq/L if under 8 days of age and 15 mEq/L if older than 8 days.
4. Calves in lateral recumbency that lack a suck reflex and have a cold oral cavity have a base deficit of 10 mEq/L if under 8 days of age and 20 mEq/L if older than 8 days.

### Categorizing Diarrheic Calves Into Treatment Groups

Based on the history and clinical findings, affected calves can be divided into the following categories according to the type of therapy required and which is most economical:

1. **Oral fluid therapy**—calves with a history of acute diarrhea, less than 7% dehydrated, slightly dry oral mucosa, good suck reflex, good muscle tone, alert, able to stand, and warm mouth. These can be treated with oral fluids and electrolytes.
2. **Oral fluid therapy and hypertonic saline solution**—calves with 7% to 9% dehydration and slight acidosis, weak suck reflex, good muscular tone, and warm mouth. Administer hypertonic

saline solution (7.5% NaCl) intravenously at 3 to 4 mL/kg BW in 5 minutes. Assure voluntary intake of oral fluids, or administer oral fluids and electrolytes by stomach tube at 40 to 60 mL/kg BW. Reevaluate in 6 to 8 hours.

3. **Intravenous fluid therapy with alkalinizing agents**—calves that are more than 9% dehydrated, have dry and cool oral mucous membranes, are recumbent, have no suck reflex, and are very depressed. Provide intravenous replacement and maintenance fluid and electrolyte therapy including an alkalinizing agent for a period of 6 to 8 hours and up to 24 to 36 hours if necessary.

The details for parenteral and oral fluid and electrolyte therapy are described under “Principles of Fluid and Electrolyte Therapy.”

### Antimicrobial Therapy

Antimicrobials have been used extensively for the specific treatment of colibacillosis in calves and piglets because it was assumed that an infectious enteritis was present. It has been difficult to evaluate the efficacy of antimicrobials for the treatment of enteric colibacillosis because of the complex nature of the interactive factors that affect the outcome in naturally occurring cases. These include the presence of mixed infections, the effects of whether or not milk is withheld from the diarrheic calves, the effects of the immune status of individual calves, the variable times after the onset of diarrhea when the drugs are given, the possible presence of antimicrobial resistance, and the confounding effects of supportive treatment such as electrolyte and fluid therapy.

### Change in Small Intestinal Bacterial Flora in Calves With Diarrhea

There has been a paradigm shift in the last 40 years toward categorizing an episode of calf diarrhea as being the result of a specific etiologic agent, such as rotavirus, coronavirus, cryptosporidia, *Salmonella* spp., or ETEC. Although the etiologic approach has correctly focused attention on preventive programs, including vaccination and optimizing transfer of colostral immunity, the approach has diverted attention from the universal finding of all studies, which is that calves with diarrhea of whatever etiology have coliform bacterial overgrowth of the small intestine.

Studies completed more than 70 years ago documented increased numbers of *E. coli* bacteria in the abomasum, duodenum, and jejunum of scouring calves. Moreover, calves severely affected with diarrhea had increased numbers of *E. coli* bacteria in the anterior portion of their intestinal tracts compared with mildly affected animals. More recent studies have consistently documented the fact that calves with naturally

acquired diarrhea, regardless of age and the etiologic cause for the diarrhea, have altered small intestinal bacterial flora. Specifically, *E. coli* bacterial numbers were increased 5- to 10,000-fold in the duodenum, jejunum, and ileum of calves with naturally acquired diarrhea, even when the diarrhea was not attributable to ETEC, and where rotavirus and coronavirus were identified in the feces. The largest increase in *E. coli* bacterial numbers occurs in the distal jejunum and ileum, whereas the *E. coli* or coliform bacterial numbers in the colon and feces are similar or higher for calves with diarrhea than calves without diarrhea, with *E. coli* being more numerous in the feces of colostrum-deprived than colostrum-fed calves. Small intestinal overgrowth with coliform bacteria can persist after departure of the initiating enteric pathogen.

In calves with naturally acquired diarrhea, increased small-intestinal colonization with *E. coli* has been associated with impaired glucose, xylose, and fat absorption.

Mixed infections with enteric pathogens are commonly diagnosed in calves with naturally acquired diarrhea, and the clinical signs and pathologic damage associated with rotavirus infection are more severe when *E. coli* is present than when it is absent. Primary viral morphologic damage to the small intestine also facilitates systemic invasion by normal intestinal flora, including *E. coli*.

In calves with experimentally induced ETEC diarrhea, colonization of the small intestine by *E. coli* has been associated with impaired glucose and lactose absorption, decreased serum glucose concentration, and possibly increased susceptibility to cryptosporidial infection.

In summary, calves with diarrhea have increased coliform bacterial numbers in the small intestine, regardless of etiology, and this colonization is associated with altered small-intestinal function, morphologic damage, and increased susceptibility to bacteremia. It therefore follows that administration of antimicrobials that decrease small-intestinal coliform bacterial numbers in calves with diarrhea may prevent the development of bacteremia, decrease mortality, and decrease morphologic damage to the small intestine, thereby facilitating digestion and absorption and increasing growth rate.

### Incidence of Bacteremia in Calves With Diarrhea

Calves with diarrhea are more likely to have FTPI, and this group of calves, in turn, is more likely to be bacteremic. Colostrum-deprived calves that subsequently developed diarrhea were frequently bacteremic, whereas bacteremia occurred much less frequently in colostrum-fed calves that developed diarrhea.

Based on field studies of diarrheic calves, it can be assumed that, **on average, 30% of**

**severely ill calves with diarrhea are bacteremic**, with *E. coli* being the predominantly isolated pathogen. The risk of bacteremia is higher in calves with FTPI than in calves with adequate transfer of passive immunity, and the risk of bacteremia is higher in calves 5 days of age or younger. Veterinarians should also assume that 8% to 18% of diarrheic calves with adequate transfer of passive immunity and systemic illness are bacteremic. The prevalence of bacteremia is sufficiently high in systemically ill calves that effective antimicrobial treatment for potential bacteremia should be routinely instituted, with emphasis on treating potential *E. coli* bacteremia, regardless of transfer of passive immunity status and treatment cost. Withholding an effective treatment for a life-threatening condition, such as bacteremia in calves with diarrhea, cannot be condoned on animal welfare grounds.

#### Antimicrobial Susceptibility of Fecal *Escherichia coli* Isolates

The most important determinant of antimicrobial efficacy in calf diarrhea is obtaining an effective antimicrobial concentration against bacteria at the sites of infection (small intestine and blood). The results of fecal antimicrobial susceptibility testing have traditionally been used to guide treatment decisions; however, susceptibility testing in calf diarrhea probably has clinical relevance only when applied to fecal isolates of ETEC or pathogenic *Salmonella* spp. and blood culture isolates from calves with bacteremia. Validation of susceptibility testing as being predictive of treatment outcome for calves with diarrhea is currently lacking.

The ability of fecal bacterial culture and antimicrobial susceptibility testing using the Kirby–Bauer technique to guide treatment in calf diarrhea is questionable when applied to fecal *E. coli* isolates that have not been identified as enterotoxigenic. There do not appear to be any data demonstrating that fecal bacterial flora is representative of the bacterial flora of the small intestine, which is the physiologically important site of infection in calf diarrhea. Marked changes in small-intestinal bacterial populations can occur without changes in fecal bacterial populations, and the predominant strain of *E. coli* in the feces of a diarrheic calf can change several times during the diarrhea episode. Furthermore, and most importantly, 45% of calves with diarrhea had different strains of *E. coli* isolated from the upper and lower small intestine, indicating that fecal *E. coli* strains are not always representative of small-intestinal *E. coli* strains. Marked discrepancies in antimicrobial resistance among *E. coli* strains isolated from different segments of the upper and lower intestinal tract of healthy veal calves at slaughter have also been reported in a more recent study.<sup>24</sup>

An additional bias present in most antimicrobial susceptibility studies conducted

on fecal *E. coli* isolates is that data are frequently obtained from dead calves, which are likely to be treatment failures. The time since death is also likely to be an important determinant of the value of fecal culture because such a rapid proliferation of bacteria occurs in the alimentary tract after death that the results of examinations made on dead calves received at the laboratory can have little significance. Calves that die of diarrhea are likely to have received multiple antimicrobial treatments, and preferential growth of antimicrobial-resistant *E. coli* strains starts within 3 hours of antimicrobial administration. A further concern with fecal susceptibility testing is that the Kirby–Bauer breakpoints (minimum inhibitory concentration [MIC]) are not based on typical antimicrobial concentrations in the small intestine and blood of calves. Studies documenting the antimicrobial susceptibility of *E. coli* isolates from the small intestine of untreated calves, based on achievable drug concentrations and dosage regimens, are urgently needed. Until these data are available, it appears that antimicrobial efficacy is best evaluated by the clinical response to treatment, rather than the results of in vitro antimicrobial susceptibility testing performed on fecal *E. coli* isolates. Thus, the value of antimicrobial susceptibility testing as a tool to guide the choice of an antibiotic to treat enterotoxigenic colibacillosis must currently be considered as very limited. Nonetheless, antimicrobial susceptibility testing presents an important tool to monitor the development of resistances not only of pathogens, but also of so-called indicator bacteria normally isolated in healthy animals in the field.<sup>25,26</sup> Because antimicrobial resistance can be transferred via plasmids from apathogenic bacteria to pathogens, monitoring trends in resistance patterns in the field is of critical importance.

#### Surveillance for Antimicrobial Resistance in *Escherichia coli* Isolates

The purpose of monitoring antimicrobial resistance through so-called indicator bacteria is to avoid misjudgment (overestimation) of resistance levels that would be extrapolated from resistance of pathogenic bacteria.<sup>24</sup> As mentioned earlier, pathogens isolated from sick or deceased animals have frequently been exposed to antimicrobial therapy, which is likely to alter resistance patterns. A comparison of antibiotic resistance for *E. coli* populations isolated from groups of diarrheic and control calves in the United Kingdom found a higher incidence of antibiotic-resistant *E. coli* in samples obtained from farms with calf diarrhea than from farms without the disease. Considering all samples, bacterial colonies in 84% were resistant to ampicillin, in 13% to Apramycin, and in 6% to nalidixic acid. Antibiotic resistance among ETEC from piglets and calves with diarrhea in a diagnostic laboratory survey of one

geographic area in Canada over a 13-year period found that the least resistance occurred against ceftiofur for all isolates, followed by apramycin and gentamicin for porcine and florfenicol for bovine isolates.

In a UK study over a 5-year period, *E. coli* isolates from calves with diarrhea became more resistant to furazolidone, trimethoprim-potentiated sulfonamide, clavulanic-acid-potentiated amoxicillin, and tetracycline. *E. coli* strains from outbreaks of diarrhea in lambs in Spain became increasingly resistant to nalidixic acid, enoxacin, and enrofloxacin. Some antimicrobial-resistant *E. coli* strains from diarrheic calves in the United States may possess a chromosomal *flo* gene that specifies cross-resistance to both florfenicol and chloramphenicol, and its presence among *E. coli* isolates of diverse genetic backgrounds indicates a distribution much wider than previously thought. In Spain, 5.9% of *E. coli* strains from cattle were resistant to nalidixic acid, and 4.9% were resistant to enrofloxacin and ciprofloxacin. In sheep and goats, only 0.5% and 1.4%, respectively, of the strains were resistant to nalidixic acid, and none was resistant to fluoroquinolones. Most of the quinolone-resistant strains were nonpathogenic strains isolated from cattle. Susceptibility data obtained from 10 European countries for the years 2002 to 2004 revealed that although there was a generally high prevalence of resistance of *E. coli* isolated from diarrheic calves, resistance patterns varied considerably between countries.<sup>25</sup> Generally high resistance of *E. coli* in the range of 50% or higher was reported from most countries for ampicillin, streptomycin, sulfonamides, trimethoprim, combinations of trimethoprim and sulfonamides, and tetracyclines.<sup>25</sup> Although resistance of *E. coli* isolated from diarrheic calves against fluoroquinolones was rare in several countries, resistance rates at or above 20% were reported from Spain, Belgium, and France.<sup>25</sup> In certain regions of Italy the incidence of enrofloxacin-resistant *E. coli* strains was reported to have increased from 14.2% in 2002 to over 40% in 2008.<sup>27</sup>

The CTX-M-14-like enzyme has been detected in *E. coli* recovered from the feces of diarrheic dairy calves in Wales. The enzyme is an extended-spectrum beta-lactamase (ESBL), which confers resistance to a wide range of beta-lactam (penicillin and cephalosporin) compounds. Organisms possessing ESBLs are considered to be resistant to second-, third-, and fourth-generation cephalosporins, and in vitro resistance to amoxicillin/clavulanate among producers is variable, reflecting the amount of beta-lactamase produced. In addition to this enzyme, the isolates produced a TEM-35 (IRT-4) beta-lactamase that conferred resistance to the amoxicillin/clavulanate combination. These two enzymes confer resistance to all the beta-lactamase compounds approved for veterinary use in the United

Kingdom. Thus their occurrence in animals may be an important development for both animal and public health. ESBLs in human infections have emerged as a significant and developing problem, occurring in patients in the community and in those with recent hospital contact. Spread of this form of resistance in bacteria affecting the animal population could have serious implications for animal health, rendering many therapeutic options redundant.

Antimicrobial resistance to intestinal bacteria also occurs in dairy calves fed milk from cows treated with antibiotics and has been associated with the prophylactic administration of medicated milk replacer.<sup>28</sup> The resistance increases with higher concentrations of antibiotics in the milk. Susceptibility of fecal and environmental *E. coli*, *Salmonella* spp., and *Campylobacter* spp. to tetracyclines was monitored on farms during use of medicated milk replacer and after discontinuation of this practice. Discontinuing the use of medicated milk replacer resulted in increased susceptibility of these organisms to tetracyclines within 3 months, without causing an increase of disease occurrence.<sup>28</sup>

#### Antimicrobial Susceptibility of Blood *Escherichia coli* Isolates

The Kirby–Bauer technique for antimicrobial susceptibility testing has more clinical relevance for predicting the clinical response to antimicrobial treatment when applied to blood isolates rather than fecal isolates. This is because the Kirby–Bauer breakpoints (MICs) are based on achievable antimicrobial concentrations in human plasma and MIC<sub>90</sub> values for human *E. coli* isolates, which provide a reasonable approximation to achievable MIC values in calf plasma and MIC<sub>90</sub> values for bovine *E. coli* isolates. Unfortunately, susceptibility results are not available for at least 48 hours, and very few studies have documented the antimicrobial susceptibility of blood isolates in calves with diarrhea. In a 1997 study of dairy calves in California, the antimicrobial susceptibility of isolates from the blood of calves with severe diarrhea or illness produced the following results: ceftiofur, 19/25 (76%) sensitive; potentiated sulfonamides, 14/25 (56%) sensitive; gentamicin, 12/25 (48%) sensitive; ampicillin, 11/25 (44%) sensitive; tetracycline, 3/25 (12%) sensitive, although there was a clinically significant year-to-year difference in the results of susceptibility testing that may have reflected different antimicrobial administration protocols on the farm.

#### Evidence-Based Recommendations for Antimicrobial Treatment of Diarrheic Calves

The four critical measures of success of antimicrobial therapy in calf diarrhea are as follows (in decreasing order of importance): (1) mortality rate, (2) growth rate in

survivors, (3) severity of diarrhea in survivors, and (4) duration of diarrhea in survivors.

In his review of the literature on the use of antibiotics for the treatment of calf diarrhea, Constable concluded that the statement that oral or parenteral antimicrobials should not be used is not supported by a critical evidence-based review of the literature.<sup>29</sup> The arguments used to support a nonantimicrobial treatment approach have included the following:

- Orally administered antimicrobials alter intestinal flora and function and thereby induce diarrhea, which has been documented on more than one occasion with chloramphenicol, neomycin, and penicillin.
- Antimicrobials harm the “good” bacteria in the small intestine more than the “bad” bacteria (an undocumented claim in the calf).
- Antimicrobials are not effective (a statement that is clearly not supported by the results of some published peer-reviewed studies).
- Antimicrobial administration promotes the selection of antimicrobial resistance in enteric bacteria.

In calves with diarrhea and moderate to severe systemic illness, the positive predictive value (0.65) of clinical tests (sensitivity = 0.39, specificity = 0.91) and the positive predictive value (0.77) of laboratory tests (sensitivity = 0.40, specificity = 0.95) for detecting bacteremia are too low, assuming reasonable estimates for the prevalence of bacteremia (30%). Accordingly, it is recommended that clinicians routinely assume that 30% of ill calves with diarrhea are bacteremic and that bacteremia constitutes a threat to the life of the calf. Antimicrobial treatment of diarrheic calves should therefore be practiced and focused against *E. coli* in the small intestine and blood because these constitute the two sites of infection. In addition, the antimicrobial must reach therapeutic concentrations at the site of infection for a long enough period (the treatment interval) and, ideally, have only a narrow gram-negative spectrum of activity to minimize collateral damage to other enteric bacteria. Fecal bacterial culture and antimicrobial susceptibility testing is not recommended in calves with diarrhea because fecal bacterial populations do not accurately reflect small-intestinal or blood bacterial populations, and the breakpoints for susceptibility test results have not been validated. Antimicrobial efficacy is therefore best evaluated by the clinical response to treatment.

The efficacy of antimicrobial therapy can vary with the route of administration and when given orally, whether the antimicrobial is dissolved in milk, oral electrolyte solutions, or water. Oral antimicrobials administered as a bolus or contained in a gelatin capsule are deposited into the rumen and

therefore have a different serum concentration–time profile than antimicrobials dissolved in milk replacer that are suckled by the calf. Antimicrobials that bypass the rumen are not thought to alter rumen microflora, potentially permitting bacterial recolonization of the small intestine from the rumen. Finally, when oral antimicrobials are administered to calves with diarrhea, the antimicrobial concentration in the lumen of the small intestine is lower and the rate of antimicrobial elimination faster than in healthy calves.

In the United States parenterally administered oxytetracycline and sulfachloropyridazine and orally administered amoxicillin, chlortetracycline, neomycin, oxytetracycline, streptomycin, sulfachloropyridazine, and sulfamethazine are currently labeled for the treatment of calf diarrhea. Unfortunately, there is little published data supporting their efficacy in treating calves with diarrhea. Extralabel antimicrobial use (excluding prohibited antimicrobials) is therefore justified in treating calf diarrhea because of the apparent lack of published studies documenting clinical efficacy of antimicrobials with a label claim and because the health of the animal is threatened; suffering or death may result from failure to treat systemically ill calves.

#### Administration of Oral Antimicrobials to Treat *Escherichia coli* Overgrowth of the Small Intestine

Based on published evidence for the oral administration of these antimicrobial agents, only amoxicillin can be recommended for the treatment of diarrhea; dosage recommendations are amoxicillin trihydrate (10 mg/kg every 12 h) or amoxicillin trihydrate–clavulanate potassium (10 mg/kg amoxicillin trihydrate and 2.5 mg/kg clavulanate potassium every 12 h) for at least 3 days; the latter constitutes extralabel drug use. Concurrent feeding of milk and amoxicillin does not change the bioavailability of amoxicillin, although amoxicillin is absorbed faster when dissolved in an oral electrolyte solution than in milk replacer, and absorption is slowed during endotoxemia, presumably because of a decrease in abomasal emptying rate. Amoxicillin trihydrate is preferred to ampicillin trihydrate for oral administration in calves because it is labeled for the treatment of calf diarrhea in the United States and is absorbed to a much greater extent. However, a field study comparing oral amoxicillin (400 mg every 12 h) and ampicillin (400 mg every 12 h) treatments for diarrhea reported similar proportions of calves with a good to excellent clinical response (79%, 49/62 for amoxicillin bolus; 80%, 59/74 for amoxicillin powder; 65%, 47/65 for ampicillin bolus;  $p > 0.30$  for all comparisons). The addition of clavulanate potassium to amoxicillin trihydrate is recommended because clavulanate potassium, although not having a direct antimicrobial

effect, is a potent irreversible inhibitor of beta-lactamase, increasing the antimicrobial spectrum of activity.

Oral administration of potentiated sulfonamides is not recommended for treating calf diarrhea because of the lack of efficacy studies. Gentamicin (50 mg/calf orally every 12 h) markedly decreased *E. coli* bacterial concentrations in the feces of healthy calves, and treatment with gentamicin has been shown to improve stool consistency in calves with experimentally induced *E. coli* diarrhea. However, oral administration of gentamicin is not recommended because antimicrobials administered to calves with diarrhea should have both local and systemic effects, and orally administered gentamicin is poorly absorbed.

Colistin administered orally is frequently used in calves in piglets to treat enterotoxigenic colibacillosis. Oral colistin will decrease the number of *E. coli* bacteria in the intestinal lumen and thereby the amount of enterotoxin affecting the intestinal mucosa and can present an effective treatment of uncomplicated cases of enteric colibacillosis. Because colistin is poorly absorbed from the alimentary tract, this treatment is not indicated in cases of suspected septicemia.

Oxytetracycline and chlortetracycline are not recommended for the oral treatment of bacteremia, although tetracyclines may have some efficacy for treating *E. coli* bacterial overgrowth of the small intestine. Tetracyclines are bound to calcium, and oral bioavailability when administered with milk is 46% for oxytetracycline and 24% for chlortetracycline.

Florfenicol achieves high concentrations in the lumen of the small intestine and is 89% absorbed when orally administered to milk-fed calves; however, florfenicol does not provide the most appropriate antimicrobial for treating calf diarrhea, because the MIC<sub>90</sub> for *E. coli* is very high at 25 µg/mL and florfenicol (11 mg/kg orally) was shown to fail to reach the MIC<sub>90</sub> value in plasma.

Fluoroquinolones clearly have proven efficacy in treating calf diarrhea, and a label indication exists in Europe for oral and parenteral enrofloxacin and oral marbofloxacin for the treatment of calf diarrhea. Oral fluoroquinolones have a high oral bioavailability. However, it must be emphasized that extralabel use of the fluoroquinolone class of antimicrobials in food-producing animals in the United States is illegal and obviously not recommended. Also, in other countries it may be illegal to use some of the antimicrobials mentioned here because of the regulations regarding their use in food-producing animals.

The indiscriminate use of antibiotics in milk replacers for the treatment of newborn calves and piglets is widespread and must be viewed with concern when the problem of drug-resistance transfer from animal to animal and to humans is considered.

In calves with diarrhea and no systemic illness (normal appetite for milk or milk replacer, no fever), it is recommended that the clinician should monitor the health of the calf and should not administer oral antimicrobials.

#### Administration of Parenteral Antimicrobials to Treat *Escherichia coli* Bacteremia

A common and widely recommended treatment is ceftiofur (2.2 mg/kg intramuscularly/subcutaneously every 12 h) for at least 3 days. Ceftiofur is a broad-spectrum third-generation cephalosporin and beta-lactam antimicrobial that is resistant to the action of beta-lactamase; the MIC<sub>90</sub> for *E. coli* is less than 0.25 µg/mL; the recommended dosage schedule maintains free plasma antimicrobial concentrations at the desired value of four times the MIC<sub>90</sub> value for the duration of treatment in 7-day-old calves, and 30% of the active metabolite of ceftiofur (desfuroyl-ceftiofur) is excreted into the intestinal tract of cattle, providing antimicrobial activity in both the blood and the small intestine. Parenteral (2 mg/kg, intramuscularly once) administration of ceftiofur hydrochloride decreased mortality rate and the severity of diarrhea in pigs with experimentally induced enteric colibacillosis, although these pigs were not suspected to be bacteremic. The beneficial effects of parenteral ceftiofur in these pigs was attributed to decreasing intestinal luminal concentration of pathogenic *E. coli*. Administration of ceftiofur to treat bacteremia and diarrhea in calves constitutes extralabel drug use.

In those countries where the use of fluoroquinolones in food-producing animals is permitted for this indication, parenteral administration to calves with diarrhea has been recommended because of their broad-spectrum bactericidal activity, particularly against gram-negative bacteria. It must be emphasized that extralabel use of the fluoroquinolone class of antimicrobials in food-producing animals in the United States and other countries is illegal and obviously not recommended.

Cephalosporins and fluoroquinolones are among the most commonly used antimicrobials to treat colibacillosis in farm animals because of their proven efficacy and because they have largely maintained their activity against *E. coli*. Recent trends of decreasing susceptibility of *E. coli* and other pathogens mainly to fluoroquinolones and to a lesser degree to third- and fourth-generation cephalosporins have, however, been reported and present a serious public health issue (see following discussion under “Use of Antimicrobials That Are of Critical Importance for Human and Veterinary Medicine”).<sup>25-27</sup>

Another recommended treatment is parenteral amoxicillin trihydrate or ampicillin trihydrate (10 mg/kg intramuscularly every 12 h) for at least 3 days. Although par-

enteral ampicillin has proven efficacy in treating naturally acquired diarrhea, whereas ceftiofur has unproven efficacy, the broad-spectrum beta-lactam antimicrobials amoxicillin and ampicillin are theoretically inferior to ceftiofur because parenterally administered ampicillin and amoxicillin reach lower plasma concentrations and require a higher MIC than ceftiofur, and they are not beta-lactamase-resistant. The intramuscular administration of amoxicillin and ampicillin is preferable over subcutaneous administration because the rate and extent of absorption are superior after intramuscular injection.

Parenteral treatment with potentiated sulfonamides (20 mg/kg sulfadiazine with 5 mg/kg trimethoprim, intravenously or intramuscularly depending on the formulation characteristics, every 24 h for 5 d) is also widely used. The efficacy of potentiated sulfonamides has only been proved when treatment commenced before clinical signs of diarrhea were present. It is therefore unknown whether potentiated sulfonamides are efficacious when administered to calves with diarrhea and depression, although it is likely that potentiated sulfonamides are efficacious in the treatment of salmonellosis.

Parenteral administration of gentamicin and other aminoglycosides (amikacin, kanamycin) cannot currently be recommended as part of the treatment for calf diarrhea because of the lack of published efficacy studies, prolonged slaughter withdrawal times (15 to 18 months), potential for nephrotoxicity in dehydrated animals, and availability of amoxicillin, ampicillin, and ceftiofur.

Chloramphenicol had proven efficacy in treating calf diarrhea resulting from *Salmonella enterica* serotypes Bredeney and Dublin, but it is now illegal for use in food-producing animals in the United States and in many other countries. The related antimicrobial florfenicol (20 mg/kg intramuscularly) failed to reach the MIC<sub>90</sub> value in plasma and only exceeded the MIC<sub>90</sub> value for less than 60 minutes when administered intravenously (11 to 20 mg/kg IV).

In calves with diarrhea and no systemic illness (normal appetite for milk or milk replacer, no fever), the clinician should monitor the health of the calf and refrain from administering oral or parenteral antimicrobials.

#### Use of Antimicrobials That Are of Critical Importance for Human and Veterinary Medicine

Antimicrobials commonly used for the treatment of colibacillosis in food-producing animals include third- and fourth-generation cephalosporins and fluoroquinolones, some of which have a label for the treatment of septicemia caused by *E. coli* in calves in some European and other countries and some of which can be used in an extralabel

manner in certain countries.<sup>30</sup> These classes of antimicrobials are considered to be **critically important for human and animal health**, and thus recent reports of increasing prevalence of resistance of *E. coli*, *Salmonella* spp., and *Enterobacter* spp. against these classes of antimicrobials are very concerning.<sup>25-27</sup> Although there appears to be general consensus that these antimicrobials should be used restrictively in veterinary medicine, there is currently no harmonized approach on prudent use of cephalosporins and fluoroquinolones in animals. Guidance on prudent use of antimicrobials for animals have been published in many countries, but most are on a general level, and cephalosporins and fluoroquinolones are not always specially addressed.<sup>30</sup>

The World Organization for Animal Health (OIE) issued the following recommendations for these classes of antimicrobials:<sup>31</sup>

- They are not to be used as preventive treatment applied by feed or water in the absence of clinical signs.
- They are not to be used as first-line treatment unless justified. When used in a second-line treatment, such use should ideally be based on the results of bacteriologic tests.
- Extralabel/off-label use should be limited and reserved for instances in which no alternatives are available. Such use should be in agreement with the national legislature in force.

### Immunoglobulin Therapy

One of the important factors determining whether or not an animal will survive enteric colibacillosis is the serum immunoglobulin status of the animal before it develops the disease. The prognosis is unfavorable if the level of immunoglobulin is low at the onset of diarrhea, regardless of intensive fluid and antimicrobial therapy. Most of the literature on therapy omits this information and is therefore difficult to assess. There is ample evidence that the mortality rate will be high in diarrheic calves that are deficient in serum immunoglobulin, particularly IgG, in spite of exhaustive antimicrobial and fluid therapy. This has stimulated interest in the possible use of purified solutions of bovine gamma-globulin in diarrheic calves that are hypogammaglobulinemic. However, they must be given by the intravenous route and in large amounts, the cost of which would be prohibitive. In addition, they are unlikely to be of value once the calf is affected with diarrhea; they are protective and probably not curative. Whole blood transfusion to severely affected calves may be used as a source of gammaglobulin, but unless given in large quantities will not significantly elevate serum immunoglobulin concentrations in deficient calves. Limited controlled trials indicate that there is no significant difference in the survival rate of diarrheic calves treated with

either a blood transfusion daily for 3 days; fluid therapy given orally, subcutaneously, or intravenously, depending on the severity of the dehydration; or fluid therapy with antibiotics. Those calves that survived, regardless of the type of therapy, had high immunoglobulin concentrations before they developed diarrhea. This emphasizes the importance of the calf ingesting liberal quantities of colostrum within the first few hours after birth.

### Analgesic and Antiinflammatory Therapy

Pain in sick farm animals has become an important issue for veterinarians and producers and is perceived as important animal welfare issue by the public. Adequate pain management should be part of any state-of-the-art treatment approach.

Diarrhea can be accompanied by abdominal pain as a result of intestinal inflammation and cramping. In addition to controlling pain, the main objectives of antiinflammatory therapy in animals with colibacillosis are to control the inflammatory process in the intestinal tract and to ameliorate the effects of endotoxemia and septicemia.<sup>32</sup> Several field studies reported that diarrheic calves receiving nonsteroidal antiinflammatory drugs (NSAIDs) in conjunction with fluid therapy showed less signs of pain, made a faster recovery, and had better weight gains in the convalescent period.<sup>33</sup> Although the underlying mechanisms do not appear to have been studied in detail, the proven beneficial effects of several NSAIDs have been attributed to their analgesic, antiinflammatory, antipyretic, and antisecretory properties.

Two broad categories of antiinflammatory agents that are available are the corticosteroids and the NSAIDs. Little evidence documenting the efficacy of corticosteroids for the treatment of calf diarrhea is available, but the use of this class of antiinflammatory drugs has been discouraged on the theoretical grounds that diarrheic calves already tend to have higher concentrations of plasma cortisol of endogenous origin and because of the immunosuppressive effect of these compounds.<sup>32</sup>

The efficacy of different NSAIDs such as meloxicam, ketoprofen, or flunixin meglumine in diarrheic calves that were systemically ill has been investigated in several studies.<sup>32</sup> A single treatment with meloxicam (0.5 mg/kg intravenously [IV]) and treatment with ketoprofen (6 mg/kg IV) twice, 4 hours apart, were both found to improve general attitude, the fecal score, and the feed intake of systemically affected calves with diarrhea.<sup>32</sup> Flunixin meglumine (2.2 mg/kg IV) hastened clinical recovery, but only for animals that had visible amounts of blood in feces.<sup>34</sup>

Because treatment with NSAIDs in diarrheic animals bears the risk of causing renal

damage by further decreasing renal perfusion in already dehydrated animals, adequate oral and/or parenteral fluid therapy must be assured. An empirical guideline posits that treatment with NSAIDs should be limited to a single treatment whenever possible but should not exceed three treatments, a recommendation that has been justified by the risk of abomasal ulceration that is associated with prolonged use of these antiinflammatory agents.<sup>32</sup>

### Antimotility Drugs

Administration of substances reducing intestinal motility to treat diarrhea in farm animals is advocated by some veterinarians. Compounds such as hyoscine-N-butylbromide and atropine have a proven inhibitory effect on intestinal motility, which undisputedly results in a rapid decrease of the fecal output in diarrheic patients. Although reducing fecal production may be interpreted as positive treatment outcome, it can also be seen as sequestration of gut fluid in the intestinal tract. Delaying the excretion of intestinal contents in patients suffering from malabsorptive diarrhea bears the risk of enhanced fermentation of unabsorbed carbohydrates and other nutrients. This could not only exacerbate enteric dysbiosis, but also the accumulation of D-lactic acid, which was found to markedly contribute to the clinical symptoms observed in diarrheic calves.<sup>12</sup> There does not appear to be any hard evidence in favor or against the use of antimotility drugs in diarrheic animals. Their use is nonetheless discouraged based on the possible negative effects that certainly outweigh the subjective perception of clinical improvement that is based on the apparent reduction of feces production.<sup>32,35</sup>

### Intestinal Protectants

Intestinal protectants such as kaolin and pectin are in general use for diarrheic animals; however, as with antimotility drugs, their value is uncertain. When they are used, the feces become bulky, but intestinal protectants do not have any known effect on the pathogenesis of the disease.

### Alteration of the Diet

Whether or not diarrheic newborn animals should be deprived of milk during the period of diarrhea is under controversial debate. Diarrheic piglets are usually treated with an antimicrobial orally and left to nurse on the sow. Diarrheic beef calves are commonly treated with oral fluids and electrolytes and left with the cow. However, in dairy calves it is a common practice to reduce the milk intake of diarrheic animals for up to 24 hours or until there is clinical evidence of improvement. The withholding of milk from diarrheic calves has been advocated based on the consideration that lactose digestion is impaired and that "resting" the intestine for a few days will consequently minimize

additional osmotic diarrhea caused by fermentation of undigested lactose in the large intestine. In contrast, the argument in favor of continuous feeding of milk is that the intestinal tract requires a constant source of nutrition, which it receives from the ingesta in the lumen of the intestine. To date, there is no scientific evidence available confirming that transiently starving diarrheic animals has any beneficial effects on the clinical outcome. Studies exploring the effect of continuous milk feeding in diarrheic calves failed to confirm any deleterious effect, such as prolonged morbidity time, higher mortality rate, or higher treatment frequency. To the contrary, calves kept on milk had higher weight gains during the period of reconvalescence.<sup>32,36</sup> Although diarrheic animals clearly should be supplemented with oral electrolyte solutions to assist the compensation of excessive fluid and electrolyte loss, the currently available evidence is clearly in favor of maintaining the animal on milk or milk replacer. Calves should be offered reduced quantities of whole milk per feeding with higher feeding frequency. Milk should not be diluted with water because this may interfere with the clotting mechanism in the abomasum. In contrast to oral electrolyte solutions, milk should not be force-fed with an esophageal tube feeder because this will prevent closure of the reticular groove and thus foster accumulation of milk in the rumen, where it would be subject to bacterial fermentation.

### Probiotics

The use of so-called probiotics for treatment and prevention of diarrhea has become increasingly popular over the past decades. Probiotics are defined as live microorganisms that, when administered in adequate amounts, confer a beneficial effect on the health of the host.<sup>37</sup> Most probiotics intended for veterinary use belong to the broad class of lactic acid bacteria, which include *Lactobacillus*, *Bifidobacterium*, *Enterococcus*, and *Streptococcus* spp. Probiotics have been claimed to promote gastrointestinal health and immunity, to reduce the shedding of potential pathogens in feces, and to reduce the need for therapeutic intervention.<sup>38</sup> Most importantly, probiotics are widely considered not to be present any health risk for the patient. Unfortunately, to date there are no published clinical data obtained in animals supporting any of these claims. Of particular concern is that the use of probiotics in humans has been associated with *Lactobacillus* bacteremia in several immunocompromised patients, and deleterious effects with some commercial products have been observed in neonatal foals.<sup>39</sup> In veterinary medicine concerns have been voiced about the uncritical use of probiotics, particularly in neonates with systemic disease or with a compromised intestinal mucosa.<sup>40,41</sup> With the current knowledge, the use of probiotics

cannot be recommended for treatment or prevention of neonatal diarrhea.

### Clinical Management of Outbreaks

Veterinarians should consider the following principles when outbreaks of colibacillosis in neonatal farm animals are encountered:

- Visit the farm and conduct an epidemiologic investigation to identify risk factors.
- Examine each risk factor and how it can be minimized.
- Examine affected animals.
- Identify and isolate all affected animals if possible.
- Treat all affected animals as necessary.
- Take laboratory samples from affected and normal animals.
- Make recommendations for the control of diarrhea in animals to be born in the near future.
- Prepare and submit a report to the owner describing the clinical and laboratory results and how the disease can be prevented in the future.

### TREATMENT

#### Calf enterotoxigenic colibacillosis

##### Fluid therapy (highest priority)

Parenteral fluid therapy to correct acid-base and water and electrolyte imbalances\* (R-1)  
Oral rehydration solution\* (R-1)

##### Antimicrobial therapy

Amoxicillin (10 mg/kg IM/PO every 12h for at least 3 days) (R-2)  
Amoxicillin-clavulanate (12 mg combined/kg PO/IM every 12h for at least 3 days) (R-2)  
Ampicillin (10 mg/kg PO/IM every 12h for at least 3 days) (R-2)  
Colistin (100,000 IU/kg PO every 24h for at least 3 days) (R-2)  
Enrofloxacin (2.5 to 5 mg/kg IV/IM/SC/PO every 24h for at least 3 days) (R-2)  
Neomycin (10 mg/kg PO q12h) (R-2)  
Trimethoprim-sulfonamide (25 mg combined/kg IV/IM/PO every 12h for at least 3 days) (R-2)

##### Antiphlogistic therapy

Flunixin meglumine (2.2 mg/kg IV once) (R-2)  
Ketoprofen (6 mg/kg IM once) (R-2)  
Meloxicam (0.5 mg/kg IV/SC once) (R-2)

##### Antimotility drugs (R-3)

##### Probiotics (R-3)

#### Calf septicemic colibacillosis

##### Antimicrobial therapy

Amoxicillin-clavulanate (25 mg/kg IV/IM every 6–8h) (R-2)  
Ampicillin-sodium (10 mg/kg IV/IM every 8h) (R-2)  
Cefquinome (2 mg/kg IM every 24h) (R-2)  
Ceftiofur (2.2 mg/kg IM/SC every 12 h) (R-2)  
Enrofloxacin (5 mg/kg IV/IM every 24 h) (R-2)  
Florfenicol (20 mg/kg IM every 24h) (R-2)  
Trimethoprim-sulfonamide (25 mg combined/kg IV every 8–12h) (R-2)

#### Piglet enterotoxigenic colibacillosis

##### Fluid therapy (highest priority)

Oral rehydration solution\* (R-1)

Amoxicillin (10 mg/kg PO/IM every 12h for at least 3 days) (R-2)  
Amoxicillin-clavulanate (12 mg combined/kg PO/IM every 12h for at least 3 days) (R-2)  
Ampicillin (10 mg/kg PO/IM every 12h for at least 3 days) (R-2)  
Ceftiofur (1.1 to 2.2 mg/kg IM every 24h for at least 3 days) (R-2)  
Chlortetracycline (20 mg/kg PO every 24h for at least 3 days) (R-2)  
Enrofloxacin (2.5 to 5 mg/kg IV/IM/SC/PO every 24h for at least 3 days) (R-2)  
Colistin (100,000 IU/kg PO every 24h for at least 3 days) (R-2)  
Oxytetracycline (10 mg/kg IM every 24h for at least 3 days) (R-2)  
Neomycin (10 mg/kg PO every 12h for at least 3 days) (R-2)  
Trimethoprim-sulfonamide (25 mg combined/kg IV/IM/PO every 12h for at least 3 days) (R-2)

\*See "Principles of Fluid and Electrolyte Therapy."

### CONTROL

Because of the complex nature of the disease, it is unrealistic to expect total prevention, and control at an economical level should be the major goal. Effective control of colibacillosis can be accomplished by the application of three principles:

- Reduce the degree of exposure of the newborn to the infectious agents.
- Provide maximum nonspecific resistance with adequate colostrum and optimum animal management.
- Increase the specific resistance of the newborn by vaccination of the dam or the newborn.

### Reduction of the Degree of Exposure of the Newborn to the Infectious Agents

The emphasis is on ensuring that newborns are born into a clean environment. Barns, confinement pens, and paddocks used as parturition areas must be clean and should preferably have been left vacant for several days before the pregnant dams are placed in them.

### Dairy Calves

The following comments are directed particularly at calves born indoors, where contamination is higher than outdoors:

- Greatest attention must be paid to maternity pen hygiene. Calves should be born in well-bedded clean and dry box stalls.
- Obstetric intervention and assistance to calving should be provided by adequately trained personnel in a calm and hygienic manner.

- Immediately after birth the umbilicus of the calf should be swabbed or dipped 2% iodine tincture or chlorhexidine solution.
- In herds with high disease incidence the residence time of calves in the maternity pen should be kept as short as possible and calves moved to clean, dry, and well-bedded individual calf pens or hutches as soon as possible after birth.
- Calves affected with diarrhea should be removed from the main calf barn if possible and treated in isolation.

### Beef Calves

Beef calves are usually born on pasture or on confined calving grounds, and the following guidelines apply:

- Calving grounds should have been free of animals previous to the calving period; the grounds should be well drained, dry, and scraped free of snow if possible. Each cow–calf pair should be provided with at least 2000 sq ft of space. Calving on pasture with adequate protection from wind is ideal. Covering the calving grounds with straw or wood shavings provides a comfortable calving environment.
- In large beef herds, in a few days following birth when the calf is nursing successfully, the cow–calf pair should be moved to a nursery pasture to avoid overcrowding in the calving grounds.

In beef herds, breeding plans should ensure that heifers calve at least 2 weeks before the mature cows. Limiting the breeding and therefore the calving season to 45 days or less for heifers also offers several advantages. A short calving season allows the producer to more effectively and economically concentrate personnel resources on calving management compared with a longer calving season. Calving heifers earlier allows them additional time required before the next breeding season to be on an increasing plane of nutrition necessary to maintain a high conception rate. The earlier calving of heifers also provides less exposure of their calves to infection pressure from the mature animals in the herd.

The incidence and severity of neonatal disease will typically increase, and the age at disease onset will decrease, as the calving season progresses. This phenomenon is common in beef herds because of the effect of the calf as a biological amplifier. The more the calving season is shortened, the more the biological amplification effect is negated.

For beef herds, it is necessary to have a plan for cattle movement throughout the calving season. This requires a minimum of four or five separate pastures: a gestation pasture, a calving pasture, and a series of nursery pastures. To ensure that beef calves are born in a sanitary environment, the herd should be moved from the gestation pasture to the calving pasture 1 to 2 weeks before

calving. One day after birth, the cow or heifer and her calf should be moved to a nursery pasture. Cow–calf pairs should be added to a single nursery pasture until the appropriate number of pairs has been reached. Thereafter, cow–calf pairs can be added to a second nursery pasture. The difference in age between the oldest and youngest calf in a nursery pasture should never exceed 30 days, and smaller differences are preferable. This negates the biological amplification effect. The longer the calving season, the greater the need for a large number of nursery pastures. Calves that develop diarrhea should be removed immediately to an area away from healthy calves, treated, and not returned until all calves in the group are at low risk for developing diarrhea (>30 days of age).

The nutrition of the pregnant cows, and particularly the first-calf heifers, must be monitored throughout gestation to ensure an adequate body condition and sufficient resources to provide an adequate supply of good-quality colostrum.

### Veal Calves

Veal calves are usually obtained from several different sources, and 25% to 30% or higher may be deficient in serum immunoglobulin. The following guidelines apply to veal calves:

- On arrival, calves should be placed in their individual calf pens, which were previously cleaned, disinfected, and left vacant to dry.
- Feeding utensils are a frequent source of pathogenic *E. coli* and should be cleaned and air-dried daily.
- Calves affected with diarrhea should be removed and isolated immediately.

### Lambs and Kids

The principles described earlier for calves apply to lambs and kids. Lambing sheds can be a source of heavy contamination and must be managed accordingly to reduce infection pressure on newborn lambs.

### Piglets

Piglets born in a total-confinement system may be exposed to a high infection rate. The following guidelines apply to piglets:

- The all-in/all-out system of batch farrowing, in which groups of sows farrow within a week, is recommended. This system will allow the herdsman to wean the piglets from a group of sows in a day or two and clean, disinfect, and leave vacant a battery of farrowing crates for the next group of sows. This system will reduce the total occupation time and the infection rate. The continuous farrowing system without regular breaks is not recommended.
- Before being placed in the farrowing crate, sows should be washed with a suitable disinfectant to reduce the bacterial population of the skin.

### Provision of Maximum Nonspecific Resistance With Adequate Colostrum and Optimum Animal Management

The first step of fostering maximum nonspecific resistance is the provision of optimal nutrition to the pregnant dam, which will result in a vigorous newborn animal and adequate quantities of colostrum. At the time of parturition, surveillance of the dams and the provision of any obstetric assistance required will ensure that newborns are born with as much vigor as possible. Parturition injuries and intrapartum hypoxemia must be minimized as much as possible.

### Colostrum Management

The next most important control measure is to ensure that liberal quantities of good-quality colostrum are available and ingested within minutes and no later than a few hours after birth. Although the optimum amount of colostrum that should be ingested by a certain time after birth is well known, the major difficulty with all species under practical conditions is to know how much colostrum a particular neonate has ingested. Because modern livestock production has become so intensive, it is imperative that the animal attendants make every effort to ensure that sufficient colostrum is ingested by that particular species. In a recent national survey in the United States, the estimated prevalence of failure of passive immunity transfer in female dairy calves was 19.2%.<sup>41</sup>

**Failure of transfer of passive immunity (FTPI)**, as determined by calf serum immunoglobulin IgG<sub>1</sub> concentration below 1000 mg/dL at 48 hours of age, occurred in 61.4% of calves from a dairy in which calves were nursed by their dams, 19.3% of calves from a dairy using nipple bottle feeding, and 10.8% of calves from a dairy using tube feeding. A higher prevalence of FTPI in dairy calves can occur because an insufficient volume of colostrum is ingested by the calf. When artificial feeding is used, inadequate immunoglobulin concentration in the colostrum fed is the most important factor resulting in FTPI. The prevalence of FTPI in dairy herds can be minimized by artificially feeding all newborn calves large volumes (3 to 4 L) of fresh or refrigerated first-milking colostrum from cows that had nonlactating intervals of normal duration. This volume is considerably greater than the intake that Holstein calves usually achieve by sucking and also exceeds the voluntary intake of most calves fed colostrum by nipple bottle.

Calves need to ingest at least 100 g of IgG<sub>1</sub> in the first colostrum feeding to ensure adequate transfer of passive immunity. Thus the routine force-feeding of a sufficient amount of pooled colostrum immediately after birth results in high serum levels of colostrum immunoglobulin in dairy calves and is becoming a common practice in dairy herds.

Encouraging and assisting the calf to suck within 1 hour after birth is also effective. The

provision of early assisted sucking of colostrum to satiation within 1 hour after birth will result in high concentrations of absorbed immunoglobulin in the majority of calves. The ingestion of 100 g or more of colostrum immunoglobulin within a few hours after birth is more effective in achieving high levels of colostrum immunoglobulin in calves than either leaving the calf with the cow for the next 12 to 24 hours or encouraging the calf to suck again at 12 hours, which will not result in a significant increase in absorbed immunoglobulin.

Despite early assisted sucking, a small proportion of calves will remain hypogammaglobulinemic because of low concentrations of immunoglobulin in their dams' colostrum, usually associated with leakage of colostrum from the udder before calving.

In large herds where economics permit, a laboratory surveillance system may be used on batches of calves to determine the serum levels of immunoglobulin acquired. An accurate analysis may be done by electrophoresis or an estimation using the zinc sulfate turbidity test. Blood should be collected from calves at 24 hours of age. Samples taken a few days later may not be a true reflection of the original serum immunoglobulin concentrations. The information obtained from determination of serum immunoglobulin in calves at 24 hours of age can be used to improve management practices, particularly the early ingestion of colostrum.

### Quality of Colostrum

#### *Specific Gravity*

Differentiating high-immunoglobulin-concentration colostrum from low-immunoglobulin-concentration is problematic. Measurement of the specific gravity of the colostrum of dairy cows with a commercially available hydrometer (Colostrometer) has been explored. Originally it was claimed that measurement of specific gravity provided an inexpensive and practical method for estimating colostrum immunoglobulin concentration. However, the specific gravity of colostrum is more correlated with its protein concentration than immunoglobulin concentration and varies with colostrum temperature, thus limiting the predictive accuracy of the test. In addition, different relationships between specific gravity and immunoglobulin concentration of colostrum have been observed for different populations of Holstein Friesian and Jersey cows and between herds. Specific gravity may also vary considerably according to season of the year. Specific gravity was measured in 1085 first-milking colostrum samples from 608 dairy cows of four breeds on a single farm during a 5-year period. The specific gravity more closely reflected protein concentration than IgG concentration and was markedly affected by month of calving. Colostrum specific gravity values were highest for Holstein and Jersey cows, cows in third or later

lactation, and cows calving in autumn. They were lowest in Brown Swiss and Ayrshire cows, cows in first or second lactation, and cows calving in summer. Thus using the specific gravity of colostrum as an indicator of IgG concentration has potential limitations.

#### *Frozen and Thawed Colostrum*

Colostrum can be banked as frozen colostrum for future use. Excess colostrum can be stored frozen and thawed as necessary to provide an IgG source when administration of dam colostrum is impractical or insufficient. Experience has shown that the composition of frozen colostrum remains constant throughout storage. No significant changes in pH, percentage acidity, milk fat, total solids, total nitrogen, or nonprotein resulted from colostrum being stored. Feeding 4 L of frozen thawed colostrum (which had been frozen at  $-20^{\circ}\text{C}$  ( $-4^{\circ}\text{F}$ ) for 24 h) to calves by orogastric tube at 3 hours after birth did not result in a significant difference in IgG absorption compared with calves receiving fresh colostrum.

#### *Pasteurization of Colostrum*

There are several indications for pasteurization of colostrum. This procedure can be a suitable instrument in a program for the control of specific infectious diseases, such as paratuberculosis, salmonellosis, or *M. bovis* infection, but it can also be useful to ameliorate calf health by improving colostrum quality and reducing the exposure of the neonate to pathogens. On-farm pasteurization of bovine colostrum for 60 min at  $60^{\circ}\text{C}$  ( $140^{\circ}\text{F}$ ) results in elimination or at least significant reduction of bacterial contamination without impairing fluid characteristics or availability of IgG for intestinal absorption.<sup>7</sup> One recent study reported significantly higher serum IgG concentrations at 24 hours of life when calves were fed pasteurized colostrum compared with calves receiving the same quality and amount of raw colostrum.<sup>42</sup> The authors attributed this effect to reduced bacterial interference with intestinal IgG absorption. Pasteurization extends the shelf life of refrigerated colostrum without additives to 8 to 10 days when stored in clean, sealed containers.

### Colostrum Supplements and Replacers

Some colostrum-derived oral supplements containing immunoglobulin are available for newborn calves in which colostrum intake is suspected or known to be inadequate. **Colostrum supplement** products have been developed to provide exogenous IgG to calves when the dam's fresh colostrum is of low IgG concentration. Many producers also use these products to replace colostrum when it is unavailable as a result of maternal agalactia, acute mastitis, or other causes of inadequate colostrum supply. However, they contain low immunoglobulin concentrations

compared with those found in high-quality first-milking colostrum. Most colostrum supplements provide only 25 to 45 g of IgG/dose of 454 g, which is reconstituted in 2 L of water. Feeding one or even two doses of such supplements is insufficient to provide a mass of 100 g of IgG within the first 12 hours after birth. **Colostrum replacers** are intended to provide the sole source of IgG and thus must provide at least 100 g of IgG. Newborn colostrum-deprived dairy calves fed spray-dried colostrum containing 126 g of immunoglobulin in 3 L of water as their sole source of immunoglobulin achieved normal mean serum immunoglobulin concentrations. Whey protein concentrate as a colostrum substitute, administered to calves as a single feeding, was ineffective in preventing neonatal morbidity and mortality compared with a single feeding of pooled colostrum.

The IgG derived from bovine serum or immunoglobulin concentrates from bovine plasma are well absorbed by neonatal calves when given in adequate amounts. The serum concentration of IgG in calves at 2 days of age force-fed a colostrum supplement containing spray-dried serum (total of 90 g immunoglobulin protein) within 3 hours after birth was much lower than in calves fed 4 L of fresh colostrum. The mass of IgG and the method of processing are critical. Products providing less than 100 g of IgG/dose should not be used to replace colostrum.

To be successful, colostrum supplements and replacers must provide enough IgG mass to result in 24-hour calf serum IgG concentrations of more than 10 g/L.

### Purified Bovine Immunoglobulin

The administration of purified bovine gammaglobulin to calves that are deficient appears to be a logical approach, but the results have been unsuccessful. Large doses (30 to 50 g) of gammaglobulin given intravenously would be required to increase the level of serum gammaglobulin from 0.5 g/dL to 1.5 g/dL of serum, which is considered an adequate level. The cost would be prohibitive. The administration of gammaglobulin by any parenteral route other than the intravenous route does not result in a significant increase in serum levels of the immunoglobulin.

To be effective, infusion of immunoglobulin derived from blood must increase serum IgG concentrations and reduce morbidity and mortality before weaning without affecting later production. Parenteral infusions of immunoglobulin will increase the concentrations of serum IgG in calves, but may not necessarily have an effect on morbidity or mortality. High levels of specific circulating immunoglobulin can serve as a reservoir of antibodies to move into the intestine and prevent enteric infection. Thus immunoglobulin sources other than colostrum may not provide immunoglobulins that are specific for antigens present in the environment

or might be insufficient when calves are exposed to a heavy infection pressure.

### Beef Calves

The management strategies to decrease calf death losses in beef herds have been described. The role of management intervention in the prevention of neonatal deaths includes measures to improve host defenses and environmental hygiene to minimize outbreaks of neonatal disease. Specific attention is centered on preventing dystocia, improving transfer of colostrum immunoglobulin, and limiting environmental contamination.

The following practices should be implemented:

- Management of the beef herd must emphasize prevention of dystocia, which involves limiting calf size and ensuring adequate pelvic area of the dams.
- Beef calves should be assisted at birth, if necessary, to avoid exhaustion and weakness from a prolonged parturition.
- Normally beef calves will make attempts to get up and suck within 20 minutes after birth, but this may be delayed for up to 8 hours or longer. Beef calves that do not suck within 2 hours should be fed colostrum by nipple bottle or stomach tube. Whenever possible, they should be encouraged and assisted to suck to satiation within 1 hour after birth. The dam can be restrained and the calf assisted to suck. If the calf is unable or unwilling to suck, the dam should be restrained and milked out by hand, and the calf should be fed the colostrum with a nipple bottle or stomach tube. The mean volume of colostrum and colostrum immunoglobulin produced in beef cows and the absorption of colostrum immunoglobulin by their calves can vary widely. Beef calves deserted by indifferent dams need special attention. FTPI is common and estimated at 10% to 40% of beef calves.
- Constant surveillance of the calving grounds is necessary to avoid overcrowding, to detect diarrheic calves that should be removed, to avoid mismothering, and to ensure that every calf is seen to nurse its dam. Although up to 25% of beef calves may not have sufficient serum levels of immunoglobulin, the provision of excellent management will minimize the incidence of colibacillosis. The recently developed practice of corticosteroid-induced parturition in cattle may result in a major mismothering problem if too many calves are born too quickly in a confined space. Every management effort must be used to establish the cow-calf herd as soon as possible after birth. This will require high-quality management to reduce the infection rate

even further and minimize any stressors in the environment.

### Lambs

Lambs require 180 to 210 mL of colostrum/kg BW during the first 18 hours after birth to provide sufficient energy for heat production. Such an intake will usually also provide enough colostral immunoglobulin. Early encouragement and assistance of the lambs to suck the ewe is important. Well-fed ewes usually have sufficient colostrum for singletons or twins. Underfed ewes may not have sufficient colostrum for one or more lambs, and supplementation from stored colostrum obtained by milking other high-producing ewes is a useful practice.

### Piglets

The following practices should be implemented for piglets:

- Every possible economical effort must be made to ensure that each newborn piglet obtains a liberal supply of colostrum within minutes of birth. The farrowing floor must be well drained, and it must be slip-proof to allow the piglets to move easily to the sow's udder. Some herdsmen provide assistance at farrowing, drying off every piglet as it is born and placing it immediately onto a teat.
- The washing of the sow's udder immediately before farrowing with warm water and soap will reduce the bacterial population and may provide relief in cases of congested and edematous udders.
- The piglet creep area must be dry, appropriately heated for the first week, and free from drafts. During farrowing, colostrum is released in discrete ejections, possibly by discrete release of oxytocin associated with parturition. Therefore, as the piglets are born they must be as close to the udder as possible to take advantage of these discrete ejections.

### Increasing Specific Resistance of the Newborn by Vaccinating the Pregnant Dam or the Newborn

The immunization of neonate farm animals against colibacillosis by vaccination of the pregnant dam or by vaccination of the fetus or the neonate has received considerable research attention in recent years, and the results appear promising.

Such vaccines are practical and effective for the following reasons:

- Most fatal ETEC infections in farm animals occur in the early neonatal period when antibody titers in colostrum and milk are highest.
- More than 90% of the ETEC in farm animals belong to a small family of fimbrial antigens.
- Fimbriae consist of good protein antigens on the bacterial surface,

where they are readily accessible to antibodies.

- Fimbriae are required for a critical step (adhesion-colonization) early in the pathogenesis of the disease.
- Novel or previously low-prevalence fimbrial antigens have not emerged to render the vaccines ineffective.

The pregnant dam is vaccinated 2 to 4 weeks before parturition to induce specific antibodies to particular strains of enteropathogenic *E. coli*, and the antibodies are then passed on to the newborn through the colostrum. The mechanism of protection is the production of antibodies against the pilus antigens, which are responsible for colonization of *E. coli* in the intestine.

**Vaccination is an aid to good management and not a replacement for good management practices.** Vaccines to prevent ETEC diarrhea in calves and piglets are based on the prevailing fimbrial antigens for colonization by ETEC in calves (F5) and newborn pigs (F4, F5, and F6). Reliable data on the efficacy of the commercial vaccines based on randomized clinical field trials are not available, but most animal health professionals perceive that the vaccines are effective and that disease occurs primarily in unvaccinated herds. There are unpublished anecdotal reports that use of the vaccine in cattle has shifted the peak occurrence of diarrhea in calves from the first week to the third and fourth week after birth. The extensive use of fimbria-based vaccines can select against the prevailing fimbrial antigen types as reflected in the vaccines, and emergence of new or previously low-prevalence fimbrial antigens may occur. Fimbriae antigenically distinct from F1, F4, F6, F41 occur among ETEC. However, these antigen types are less prevalent than those currently used in commercial vaccines. There is no evidence that ETEC with novel colonization mechanisms or new fimbrial antigens have emerged under the selection pressure of vaccination. Nor is there evidence that previously "low-prevalence" fimbrial antigen types of ETEC, not represented in the vaccines, have emerged as "common pathogens" filling an ecological niche left by the fimbrial antigen types targeted by the vaccines.

### Calves

Vaccination of pregnant cattle with either purified *E. coli* F5 (K99) pili or a whole-cell preparation containing sufficient F5 antigen can significantly reduce the incidence of enterotoxigenic colibacillosis in calves. Good protection is also possible when the dams are vaccinated with a four-strain *E. coli* whole-cell bacterin containing sufficient F5 pilus antigen and the polysaccharide capsular K antigen. Colostral antibodies specific for F5 pilus antigen and the polysaccharide capsular K antigen on the surface of the challenge exposure strain of ETEC are protective. There is a highly significant correlation

between lacteal immunity to the F5 antigen and the prevention of severe diarrhea or death in calves challenged with enterotoxigenic *E. coli*. The colostral levels of F5 antibody are highest during the first 2 days after parturition, which is the most susceptible period for enterotoxigenic colibacillosis to occur in the newborn calf. The continuous presence of the F5 antibody in the lumen of the intestine prevents adherence of the bacteria to the intestinal epithelium. The F5 antibody is also absorbed during the period of immunoglobulin absorption and may be excreted into the intestine during diarrhea. This may be one of the reasons that mortality is inversely proportional to serum immunoglobulin levels. The pregnant dams are vaccinated twice in the first year, 6 and 2 weeks before parturition. Each year thereafter they are given a single booster vaccination. An oil-emulsion *E. coli* F5 bacterin given once or twice to pregnant beef cows 6 weeks before calving elicited high levels of serum antibodies that provided protection against experimental infection of newborn calves for up to 87 weeks after vaccination.

Vaccines containing both the F5 antigen of ETEC and rotavirus, and in some cases coronavirus, have been evaluated, with variable results. The colostral antibodies to the F5 antigen are higher in vaccinated than unvaccinated dams, but the colostral antibodies to rotavirus and coronavirus may not be significantly different between vaccinated and unvaccinated dams. In these field trials vaccination had no effect on the prevalence of diarrhea, calf mortality, or the presence of the three enteropathogens. In other field trials the combined vaccine did provide some protection against outbreaks of calf diarrhea. The use of an inactivated oil-adjuvanted rotavirus *E. coli* vaccine given to beef cows in the last trimester of pregnancy decreases the mortality from diarrhea and has a positive influence on the average weight gains of the calves at weaning. To be effective the rotavirus and coronavirus antibodies must be present in the postcolostral milk for several days after parturition, during the period when calves are most susceptible to the viral infection. Vaccination of pregnant cows twice during the dry period at intervals of 4 weeks can increase the colostral antibody levels to *E. coli* F5 by 26 times on day 1 compared with controls. Much lower increases occur at the levels of coronavirus and rotavirus.

A commercially inactivated vaccine containing bovine rotavirus (serotype G6 P5), bovine coronavirus (originally isolated from a calf with diarrhea), and purified cell-free *E. coli* F5 (adsorbed on to aluminum hydroxide gel), formulated as an emulsion in a light mineral oil, has been evaluated in a herd of Ayrshire/Friesian cows vaccinated once at 31 days before the first expected calving date. Compared with control cows, a significant increase in the mean specific antibody titer against all three antigens occurred in the

serum of vaccinated animals (even in the presence of preexisting antibodies), which was accompanied by increased levels of protective antibodies to rotavirus, coronavirus, and *E. coli* F5 in their colostrum and milk for at least 28 days.

Because naturally acquired antibodies to the **J5 antigen** may have an important role in the control of neonatal disease caused by bacterial infections with associated pathogens that share antigens with *E. coli* (J5 strain), vaccination of calves with an *E. coli* O111:B4(J5) vaccine at 1 to 3 days of age and 2 weeks later has been evaluated to control morbidity and mortality in dairy calves up to 60 days of age. The use of either a killed *E. coli* O111:B4(J5) bacterin or a modified live, genetically altered (aro-) *Salmonella dublin* vaccine, or both, in neonatal calves was effective in reducing mortality resulting from colibacillosis and salmonellosis. Such a vaccine may be beneficial in controlling mortality in well-managed herds, but it is contraindicated in poorly managed herds.

Passive immunotherapy of calves under 2 days of age with J5 *E. coli* hyperimmune plasma given subcutaneously at a dose of 5 mL/kg BW has been examined. The plasma was found to be safe and potent. It was not superior to control plasma or to no treatment for calf morbidity and mortality.

The oral administration of a F5-specific monoclonal antibody to calves during the first 12 hours after birth may be an effective method of reducing the incidence of fatal enterotoxigenic colibacillosis, particularly when outbreaks of the disease occur in unvaccinated herds. Clinical trials indicate that the severity of dehydration, depression, and weight loss and the duration of diarrhea were significantly reduced in calves that had received the F5-specific monoclonal antibody. In experimentally challenged calves the mortality was 29% in the treated calves and 82% in the control calves.

The decision to vaccinate in any particular year will depend on the recognition of risk factors. Such risk factors include the following:

- A definitive diagnosis of ETEC F5 in the previous year
- A population density in the calving grounds that is conducive to the disease
- Calving during the year when the environmental conditions are wet and uncomfortable for the calves
- A large percentage of primiparous dams that do not have protective levels of F5 antibody in their colostrum

### Piglets

Piglets born from gilts are more susceptible than those from mature sows, which suggests that immunity improves with parity. On a practical basis this suggests that gilts should be mixed with older sows that have been resident on the premises for some time. The length of time required for such natural

immunization to occur is uncertain, but 1 month during late gestation seems logical.

Naturally occurring enteric colibacillosis in newborn piglets can be effectively controlled by vaccination of the pregnant dam. Field trials in large-scale farm conditions indicate that the vaccines are efficacious. Partial budget analysis of vaccinating pregnant sows with *E. coli* vaccines revealed an economic return on investment of 124% because of the decrease in morbidity and mortality resulting from diarrhea in piglets at 1 to 2 weeks of age. Three antigen types of pili, designated F4, F5, and F6, are now implicated in colonization of the small intestine of newborn piglets by ETEC. The vaccination of pregnant sows with oral or parenteral vaccines containing these antigens will provide protection against enterotoxigenic colibacillosis associated with *E. coli* bearing pili homologous to those in the vaccines. The parenteral vaccines are cell-free preparations of pili, and the oral vaccines contain live enteropathogenic *E. coli*. The oral vaccine is given 2 weeks before farrowing and is administered in the feed daily for 3 days as 200 mL per day of a broth culture containing  $10^{11}$  *E. coli*. A simple and effective method of immunization of pregnant sows is to feed live cultures of ETEC isolated from piglets affected with neonatal colibacillosis on the same farm. The oral vaccine can be given in the feed, beginning about 8 weeks after breeding and continued to parturition. The oral vaccine results in the stimulation of IgA antibody in the intestinal tract, which is then transferred to the mammary gland and into the colostrum. A combination of oral and parenteral vaccination is superior to either route alone. The parenteral vaccine is given about 2 weeks after breeding and repeated 2 to 4 weeks before parturition. The parenteral vaccination results in the production of high levels of IgM antibody for protection against both experimental and naturally occurring enterotoxigenic colibacillosis. This vaccination also reduces the number of *E. coli* excreted in the feces of vaccinated sows, which are major sources of the organism. Immunization of pregnant sows with an *E. coli* bacterin enriched with the F4 antigen results in the secretion of milk capable of preventing adhesion of F4 *E. coli* to the gut for at least 5 weeks after birth, at which time the piglet becomes naturally resistant to adhesion by the organism.

The possibility of selecting and breeding pigs that may be genetically resistant to the disease is being explored. The highest incidence of diarrhea occurs in progeny of resistant dams sired by susceptible sires. The homozygous dominants (SS) and the heterozygotes (Ss) possess the receptor and are susceptible, whereas it is absent in the homozygous recessives (ss) and the pigs are resistant. Sows that are genetically resistant may not be able to mount an immune response to the F4 antigen because of the inability of the organism to colonize the intestinal tract.

### Competitive Exclusion Culture

An alternative method of control is the use of competitive exclusion cultures. The theory of competitive exclusion technology is to colonize the neonatal gastrointestinal tract with beneficial/commensal bacteria considered to be the normal flora of the healthy animals of a particular species. The mechanism of action is not known, but hypotheses include the following: exclusion of enteropathogens by competitive attachment sites and/or for nutrients; stimulation of the local immune mechanisms, which precludes colonization/invasion by enteric pathogens; and the production of various antimicrobial substances that either have direct action on pathogenic bacteria or produce conditions within the intestine that are unfavorable for the growth and colonization by pathogens. Experimentally, the oral administration of a porcine competitive exclusion culture to piglets within 12 hours after birth resulted in significant reductions in mortality, incidence of fecal shedding, and intestinal colonization by *E. coli* compared with control values. Mortality decreased from 23% in the control group to 2.7% in the treated group.

### Lambs and Kids

Vaccination of pregnant ewes with F5 antigen will confer colostral immunity to lambs challenged with homologous ETEC. The pregnant ewes are vaccinated twice in the first year, at 8 to 10 weeks and 2 to 4 weeks before lambing; in the second year, one vaccination 2 to 4 weeks before lambing is adequate.

Immunization of pregnant goats has been used to stimulate the development of lacteal immunity against naturally occurring colibacillosis in kids. Vaccination of pregnant does 1 month before parturition with a subunit vaccine containing F4, F5, and F6 fimbrial antigens of *E. coli* and *C. perfringens* types B, C, and D toxins in an aluminum hydroxide adjuvant, along with improved management conditions, was highly successful in reducing neonatal morbidity and mortality resulting from diarrhea. Compared with two control groups, one in which no improvement in management was made and the second in which improvements were made without vaccination, in the vaccinated group with improved management conditions, neonatal morbidity and mortality were both reduced by a factor of 3 in group 1 and by factors of 9.5 and 12.5 in groups 2 and 3, respectively. Also, the duration of diarrhea was 3.7 and 12 times shorter in the kids of groups 2 and 3, respectively.

## WATERY MOUTH OF LAMBS (RATTLE BELLY, SLAVERS)

### SYNOPSIS

- Etiology** Nonenteropathogenic *E. coli* endotoxemia predisposed by failure of passive transfer.
- Epidemiology** Higher risk with intensive housing with poor hygiene.
- Clinical findings** Loss of sucking reflex, retention of meconium or feces, excessive mucoid saliva, abomasal distension.
- Lesions** None specific.
- Diagnostic confirmation** Nothing pathognomonic.
- Treatment** Fluids and energy via stomach tube; antimicrobials.
- Control** Antimicrobials at birth, pen hygiene, ensure adequate colostral transfer.

### ETIOLOGY

Watery mouth of lambs is thought to be the result of endotoxemia in young lambs. It is postulated that the neutral pH of the abomasum in newborn lambs coupled with low concentrations of colostral immunoglobulin in the gut allow rapid multiplication of non-enteropathogenic strains of *E. coli* in the gut, and to some extent systemically, which results in endotoxemia.

### EPIDEMIOLOGY

#### Occurrence

The syndrome is primarily reported in lambs in Great Britain but has also been reported in New Zealand and in goat kids in Spain and North America. A related but perhaps separate entity, termed *salivary abomasum disease*, has been reported as common in 3- to 17-day-old lambs and kids in Greece.<sup>1</sup>

### Animal and Environmental Risk Factors

Lambs 12 to 72 hours of age are affected. The disease is seen under all management systems, but it is rare in pastured flocks and occurs most commonly in lambs kept in intensive housing where there is poor hygiene of the lambing environment. Lambs from prolific ewes are at risk, and the disease is more common in triplets than twins or singles.

Delayed or poor colostral intake is a major risk factor, and situations that

predispose this may lead to outbreaks. A high prevalence has occurred in ram lambs castrated by the use of an elastic band at a very young age, and the resulting pain may have dissuaded them from feeding.

Other risk factors, all of which reduce sucking by the lamb, are inclement weather, mismothering, maternal agalactia, competition between twins or triplets, low vitality, and ewes in poor condition.

### Experimental Disease

An equivalent clinical syndrome is reproducible by administering nonenterotoxigenic strains of *E. coli* by mouth to colostrum-deprived lambs, all of whom died within 24 hours.

### Economic Importance

Watery mouth disease is a major cause of mortality of housed newborn lambs in Great Britain and is reported to be the cause of approximately 25% of all deaths of lambs in indoor intensive lambing systems. Where conditions allow, morbidity rates may approach 24%; without early treatment, case fatality rates are high.

### PATHOGENESIS

Gram-negative bacteria, nonenterotoxigenic and nonenteropathogenic *E. coli*, in the environment are ingested as a result of a contaminated environment, or from a contaminated fleece, and survive passage through the neutral pH of the abomasum to be absorbed into the systemic circulation by the natural pinocytosis that occurs in the intestinal epithelium of newborn ruminants, producing endotoxemia.

### CLINICAL FINDINGS

Affected lambs are normal at birth but become sick at 24 to 48 hours and up to 72 hours old. The disease is characterized by dullness, lethargy, a complete failure to suck, and excessive mucoid saliva around and drooling from the mouth. As the disease progresses there is hypothermia, failure to pass feces, cold extremities, depression to the point of coma, anorexia, and, in the late stages, abdominal distension and recumbency, but rarely diarrhea. The alimentary tract is full of fluid, and the lamb rattles when it is shaken. Some lambs are hypothermic, but the temperature is normal at the onset of the condition and falls to subnormal as the disease progresses. Progress is rapid, with death 6 to 24 hours after the first signs of illness. Salivary abomasum disease is reported in flocks that vaccinate against clostridial disease.<sup>2</sup>

### CLINICAL PATHOLOGY

Total protein concentrations and base excess values are significantly elevated compared with normal lambs. Blood glucose concentrations are normal but may be low in the terminal phase of the disease.

### NECROPSY FINDINGS

There are no findings specific to watery mouth syndrome. The abomasal contents are fluid and mucoid and contain small milk curds, and the intestine is filled with gas. A case series of lambs with salivary abomasum disease found pale kidneys and acute tubular necrosis in 90%. *E. coli* was cultured from only 6 of 37 abomasa in this study.<sup>2</sup>

### TREATMENT

Treatment with intramuscular amoxillin and clavulanic acid, intravenous flunixin meglumine, and oral rehydration fluid, when administered early in the clinical course, has resulted in a high recovery rate in field cases. Dextrose solution should also be given to those lambs that are hypoglycemic, and external warming should be provided. Other recommended treatments include emptying the alimentary tract by purgation or enema.

### DIFFERENTIAL DIAGNOSIS

Most neonatal disease of lambs is manifest with diarrhea, which is not present in watery mouth. The early stages of *Colisepticemia* and *Clostridium perfringens* type B or C present with similar clinical signs, but they are easily differentiated later in the clinical course or at postmortem examination. Hypothermia/starvation/cold stress can present with similar clinical findings, but the history and environmental circumstances of occurrence differ.

### CONTROL

In outbreaks the administration of antibiotics to all newborn lambs within 15 minutes to 2 hours of birth dramatically reduces the occurrence of further cases. Fresh or frozen sheep or cow colostrum should be supplemented to lambs at risk. The provision of ewe colostrum at 50 mL/kg BW within 6 hours of birth prevents the disease.

Lambing areas and associated pens and yards should be kept clean and freshly bedded. Contaminated fleece should be removed from around the udder of the ewe before lambing, and every effort should be made to ensure early and adequate colostrum intake by newborn lambs, especially for twins and triplets.

### OMPHALITIS, OMPHALOPHLEBITIS, AND URACHITIS IN NEWBORN FARM ANIMALS (NAVEL ILL)

Infection of the umbilicus and its associated structures occurs commonly in newborn farm animals and appears to be particularly common in calves. The umbilical cord

consists of the amniotic membrane, the umbilical veins, the umbilical arteries, and the urachus. The amniotic membrane of the umbilical cord is torn at birth, and gradually the umbilical vein and the urachus close, but they remain temporarily outside the umbilicus. The umbilical arteries retract as far back as the top of the bladder.

In many countries regulations govern the minimal age at which neonatal calves can be shipped or sent to market and slaughter. The wetness or dryness of the umbilicus is used as a surrogate measure of age in welfare regulations, and the requirement is that the umbilical cord at the junction with the abdominal skin should be dry and shriveled. The drying time varies from 1 to 8 days, with variation between breeds and a longer drying period in bull calves. As might be expected, this measure is only an approximate surrogate for age, but approximately 90% of calves have dry navels by 4 days of age.<sup>1</sup>

Incidence of the disease is scarcely reported. The 30-day incidence of clinically apparent omphalitis in Thoroughbred foals in the United Kingdom was 0.7%, which was not reduced by administration of antimicrobials prophylactically.<sup>2</sup> Omphalitis was considered the cause of death in 23% of 247 calves 4 to 7 days of age that died during the preslaughter period (12 to 18 hours) at abattoirs in New Zealand.<sup>1</sup> The death rate was 0.7%, of which 23% was attributable to omphalitis. Omphalitis was the cause of wastage (condemnation of the carcass) in 54% of calves examined after slaughter.<sup>1</sup>

Infection of the umbilicus occurs **soon after birth** and can result in omphalitis, omphalophlebitis, omphaloarteritis, or infection of the urachus, with possible extension to the bladder, causing cystitis. There is usually a **mixed bacterial flora** including *E. coli*, *Proteus* spp., *Staphylococcus* spp., *T. pyogenes*, *Bacteroides* spp., *F. necrophorum*, and *Klebsiella* spp. The most common, and presumed clinically important, infections in foals are by *E. coli* and *S. zooepidemicus*. Infection of umbilical remnants in foals by *Clostridium sordelli* causes peritonitis, urachitis, omphalophlebitis, and omphaloarteritis.<sup>3</sup>

Bacteremia and localization with infection may occur in joints, bone, meninges, eyes, endocardium, and end-arteries of the feet, ears, and tail. The navel can also be the source of infection, leading to septicemia, arthritis, and fever of unknown origin in neonates with FTPI. The incidence of abnormalities of the umbilicus and consequent rate of umbilical infection is high in cloned calves.<sup>2-5</sup>

### OMPHALITIS

Omphalitis is inflammation of the external aspects of the umbilicus and occurs commonly in calves and other species within 2 to 5 days of birth and often persists for several weeks. The umbilicus is enlarged, is painful on palpation, and can be closed or draining

purulent material through a small fistula. The affected umbilicus can become very large and cause subacute toxemia. The calf is moderately depressed, does not suck normally, and is febrile. Treatment consists of surgical exploration and excision. A temporary drainage channel may be necessary.

### OMPHALOPHLEBITIS

Omphalophlebitis is inflammation of the umbilical veins. It can involve only the distal parts or extend from the umbilicus to the liver. Large abscesses can develop along the course of the umbilical vein and spread to the liver, with the development of a hepatic abscess that can occupy up to one-half of the liver. Affected foals and calves are usually 1 to 3 months of age and are unthrifty because of chronic toxemia. The umbilicus is usually enlarged with purulent material; however, in some cases the external portion of the umbilicus appears normal-sized. Placing the animal in dorsal recumbency and deep palpation of the abdomen dorsal to the umbilicus in the direction of the liver might reveal a space-occupying mass. **Ultrasonographic** examination, including measurement of the size of umbilical structures, allows detection of omphalophlebitis, including any extension along the vein to the liver.

Affected calves and foals are inactive, inappetent, and unthrifty and may have a mild fever. Parenteral therapy with antibiotics is not uniformly successful and may need to be administered for prolonged times. Exploratory laparotomy and **surgical removal** of the abscess is often necessary. Large hepatic abscesses are usually incurable unless surgically removed, but the provision of a drain to the exterior and daily irrigation may be attempted if resection is not feasible.

### OMPHALOARTERITIS

In omphaloarteritis, which is less common, the abscesses occur along the course of the umbilical arteries from the umbilicus to the internal iliac arteries. The clinical findings are similar to those in omphalophlebitis: chronic toxemia, unthriftiness, and failure to respond to antibiotic therapy. An unusual presentation is that of distal aortic aneurysm secondary to ascending infection of the umbilical artery.<sup>6</sup> The affected foal was 3 months of age and was examined because of colic and frequent urination. Treatment of omphalophlebitis consists of surgical removal of the abscesses.

### URACHITIS

Infection of the urachus may occur anywhere along the urachus, from the umbilicus to the bladder. The umbilicus is usually enlarged and draining purulent material, but it can appear normal. Deep palpation of the abdomen in a dorsocaudal direction from the umbilicus may reveal a space-occupying mass. Extension of the infection to the bladder can result in cystitis and pyuria.<sup>5</sup>

**Contrast radiography** of the fistulous tract and the bladder will reveal the presence of the lesion. The treatment of choice is exploratory laparotomy and surgical removal of the abscesses. Recovery is usually uneventful.

### CONTROL

The control of umbilical infection depends primarily on **good sanitation and hygiene** at the time of birth. The application of drying agents and residual disinfectants such as tincture of iodine is widely practiced. However, there is limited evidence that chemical disinfecting is of significant value. Chlorhexidine is more efficient in reducing the number of organisms than 2% iodine or 1% povidone iodine. High concentrations of iodine (7%) are most effective, but these are damaging to tissue and should not be used.

## NEONATAL STREPTOCOCCAL INFECTION

### SYNOPSIS

**Etiology** Various *Streptococcus* spp.

**Epidemiology** Neonatal foals, calves, lambs, piglets.

**Signs** Acute painful swelling of joints, lameness, fever; signs of meningitis, omphalophlebitis, ophthalmitis; sudden death.

**Clinical pathology** Culture organism from joint fluid.

**Necropsy findings** Fibrinopurulent synovitis, purulent meningitis and omphalophlebitis.

**Diagnostic confirmation** Recovery of organism from joint fluid.

**Differential diagnosis** Other infectious causes of arthritis, meningitis, and omphalophlebitis.

**Treatment** Antimicrobials, usually penicillin.

**Control** See "Principles of Control and Prevention of Infectious Diseases of Newborn Farm Animals" in Chapter 3.

### ETIOLOGY

Streptococci are an important cause of septicemia, polyarthritis, meningitis, polyserositis, endocarditis, and unexpected death in the neonates of all farm animal species. Meningitis associated with streptococcal infection is restricted to the neonate in all species except piglets, in which outbreaks can occur in pigs after weaning, and lambs infected with *S. suis*, in which meningitis can occur as a sporadic disease at 3 to 5 months of age. Historically, there are reports of isolates

of most of the Lancefield groups of beta-hemolytic streptococci, of nonbeta-hemolytic streptococci, and of viridans group streptococci from neonatal disease in farm animals. Commensal skin streptococci can occasionally cause disease in presumably immunocompromised neonates. However, the majority of neonatal disease is associated with a limited number of streptococcal species, although there can be geographic variation in their relative prevalence within animal species.

In **foals**, *S. zooepidemicus* (*S. equi* subsp. *zooepidemicus*) is the most common streptococcal species recovered from septicemic disease and polyarthritis and is also a cause of placentitis and abortion in mares.<sup>1,2</sup> *S. equisimilis* (*S. dysgalactiae* subsp. *equisimilis*) is a less common isolate.<sup>2</sup>

*S. suis* and *S. equisimilis* are the most common species incriminated in **piglets**. *S. suis* is especially important and is presented separately in the next section. Other Lancefield groups have been associated with sporadic disease. In **calves**, *S. dysgalactiae* and *S. uberis* are the common streptococcal isolates from synovial fluid of neonatal calves with arthritis. Beta-hemolytic streptococci are isolated from approximately 16% of septicemic calves in South Africa.<sup>3</sup> *Streptococcus pluranimalium* infection is reported in a single premature calf.<sup>4</sup>

*S. dysgalactiae* is also reported to be the most common cause of outbreaks of arthritis in neonatal lambs in Great Britain. *Streptococcus bovis* biotype 1 is reported to cause meningoencephalitis in llama cria.<sup>5</sup> *Streptococcus agalactiae* causes periarticular abscesses in camel foals in Africa.<sup>6</sup>

Streptococci can also contribute to purulent infections at local sites, such as navel ill of all species or otitis media in neonatal calves, although the latter is more commonly caused by *M. bovis*.<sup>7</sup>

### EPIDEMIOLOGY

#### Occurrence and Prevalence

The importance and relative prevalence of streptococcal infections in neonatal disease varies among countries and with surveys.

Streptococci are a common cause of postnatal infections of **foals**, representing 50% of such cases in some surveys, but with a lower prevalence in others. Up to 20% of abortions in mares are a result of placentitis from streptococcal infection. Streptococcal septicemia as a result of beta-hemolytic streptococci may occur in foals under 5 days of age that have been stressed and have FTPI.

In **calves**, neonatal infections with streptococci are usually sporadic and less common than infections with gram-negative bacteria and may be predisposed by FTPI. In **lambs**, *S. dysgalactiae* is associated with outbreaks with high morbidity, and in Great Britain *S. dysgalactiae* is reported to be the cause of over 70% of cases of polyarthritis in lambs during their first 3 weeks of life. Despite the

high attack rate in these outbreaks, it is rare for more than one of twins or triplets to have disease. Streptococcal arthritis associated with *S. suis* infection in piglets is a common disease and is covered in a separate section.

### Source of Infection

The source of the infection is usually the environment, which may be contaminated by uterine discharges from infected dams or by discharges from lesions in other animals. *S. dysgalactiae* is reported to survive for up to a year on clean straw, as opposed to wood shavings, which do not support the persistence of the organism.

The portal of infection in most instances appears to be the umbilicus, and continued patency of the urachus is thought to be a contributing factor in that it delays healing of the navel. In piglets there can be high rates of infection associated with infection entering through skin abrasions such as carpal necrosis resulting from abrasive floors or facial lesions following fighting. Contaminated knives at castration and tail docking, or contaminated ear taggers, can result in infection and disease. Other mechanical vectors include the screwworm fly (*Cochliomyia americana*).

The organism can be isolated from the nasopharynx of the sow, and direct infection from the sow to the piglet is suggested by some epidemiologic data.

### Economic Importance

Affected foals and other species may die or be worthless as working animals because of permanent injury to joints. There is also loss resulting from condemnation at slaughter.

### Zoonotic Implications

*S. zooepidemicus* is associated with human infections,<sup>8</sup> particularly nephritis, and many human infections can be traced back to the consumption of contaminated animal food products. Some strains of *S. equisimilis* can also infect humans.

### PATHOGENESIS

The infection spreads from the portal of entry to produce a bacteremia that is not detectable clinically. The period of bacteremia is variable but it may last several days in piglets. A terminal acute fatal septicemia is the common outcome in animals under 1 week of age; in older animals, suppurative localization in various organs is more common. Arthritis is the most common manifestation, with synovitis and invasion of medullary bone of the epiphysis with microabscessation and ischemic necrosis of bone. Other manifestations of infection include ophthalmitis in foals and calves, meningitis and endocarditis in piglets, meningitis in calves, and endocarditis and sudden death in lambs. Streptococcal endocarditis can be produced by the intravenous inoculation of group I *Streptococcus*. Lesions are well established within 5 days, the left

heart is most commonly affected, and myocardial and renal infarction occur.

## CLINICAL FINDINGS

### Foals

The disease is one of septicemia, often with localization of infection in joints (septic arthritis) or an eye (hypopyon), and is described in detail under “Neonatal Infection” (page 1874). Infection of the umbilicus can cause omphalitis and omphalophlebitis.

### Piglets

Arthritis and meningitis may occur alone or together and are most common in the 2- to 6-week age group. More commonly, several piglets within a litter are affected. The arthritis is identical to that previously described in foals. With meningitis there is a systemic reaction comprising fever, anorexia, and depression. The gait is stiff, the piglets stand on their toes, and there is swaying of the hindquarters. The ears are often retracted against the head. Blindness and gross muscular tremor develop, followed by inability to maintain balance, lateral recumbency, violent paddling, and death. In many cases there is little clinical evidence of omphalophlebitis. With endocarditis the young pigs are usually found comatose or dead, without premonitory signs having been observed.

### Lambs

Lameness in one or more limbs of lambs up to 3 weeks of age is the common presenting sign of infection with *S. dysgalactiae*, but approximately 25% of lambs can be initially recumbent. With this infection there is not major joint swelling in the early stages, and myopathy or delayed swayback may be initial considerations. In contrast with outbreaks that occur following docking, the incubation period is short, usually 2 to 3 days, and there is intense lameness, with swelling of one or more joints appearing in a day or two. Pus accumulates, and the joint capsule often ruptures. Recovery usually occurs with little residual enlargement of the joints, although there may be occasional deaths as a result of toxemia.

### Calves

Calves show polyarthritis, meningitis, ophthalmitis, and omphalophlebitis. The ophthalmitis may appear very soon after birth. The arthritis is often chronic and causes little systemic illness. Calves with meningitis show hyperesthesia, rigidity, and fever.

## CLINICAL PATHOLOGY

Pus from any source may be cultured to determine the organism present and its sensitivity to the drugs available. Bacteriologic examination of the uterine discharges of the dam may be of value in determining the source of infection. The success rate with blood cultures is not very high, but an attempt is worthwhile. The identification of

the causative bacteria is important, but the sensitivity of the organism may mean the difference between success and failure in treatment. The specific identity of the streptococcus should be determined.

## NECROPSY FINDINGS

Suppuration at the navel and severe suppurative arthritis affecting one or more joints are usual. Abscesses may also be present in the liver, kidneys, spleen, and lungs. Friable tan masses of tissue are common on the heart valves of affected piglets, and this valvular endocarditis may also be observed in other species. Peracute cases may die without suppurative lesions having had time to develop. Necropsy findings in the meningitic form in pigs include turbidity of the CSF, congestion of meningeal vessels, and the accumulation of white, purulent material in the subarachnoid space. Occasionally this exudate blocks the flow of CSF in the ventricular system, causing internal hydrocephalus. Histologically there is infiltration of the affected tissue by large numbers of neutrophils, usually accompanied by fibrin deposition.

## Samples for Confirmation of Diagnosis

Confirmation of diagnosis is made with the following samples:

- Bacteriology—culture swabs from joints, meninges, suppurative foci; tissue pieces of valvular lesions, lung, spleen, synovial membrane (culture)
- Histology—formalin-fixed samples of a variety of organs, including brain, lung, spleen, liver (light microscopy)

## DIFFERENTIAL DIAGNOSIS

Omphalophlebitis and suppurative arthritis in foals may result from infection with *Escherichia coli*, *Actinobacillus equuli*, or *Salmonella abortusequi*, but these infections tend to take the form of a fatal septicemia within a few days of birth, whereas streptococcal infections are delayed in their onset and usually produce a form of polyarthritis. In pigs there may be sporadic cases of arthritis as a result of staphylococci, but the streptococcal infection is the common one. Arthritis as a result of *Mycoplasma hyorhinis* is less suppurative, but it may require cultural differentiation. Glasser's disease occurs usually in older pigs and is accompanied by pleurisy, pericarditis, and peritonitis. Erysipelas in very young pigs is usually manifested by septicemia. Nervous disease of piglets may resemble arthritis on cursory examination, but there is an absence of joint enlargement and lameness. However, the meningitic form of the streptococcal infection can easily be confused with viral encephalitis. Meningitis in young calves may also be associated with *Pasteurella multocida*. Polyarthritis in calves, lambs, and

piglets may also be associated with infection with *Trueperella pyogenes* and *Fusobacterium necrophorum*. *S. suis* type 2 can also be the cause of meningitis in older pigs at 10 to 14 weeks of age.

The response of streptococcal infections to treatment with penicillin may be of value in the differentiation of the arthritides, and the microscopic and histologic findings at necropsy enable exact differentiation to be made. In lambs, suppurative arthritis occurs soon after birth and after docking. The other common arthritis in the newborn lamb is that associated with *Erysipelothrix rhusiopathiae*, but this usually occurs later and is manifested by lameness without pronounced joint enlargement. Calves may also develop erysipelous arthritis.

## TREATMENT

Penicillin is successful as treatment in all forms of the disease if irreparable structural damage has not occurred. In newborn animals, the dosage rate should be high (20,000 IU/kg BW) and should be repeated at least once daily for 3 days. If suppuration is already present, a longer course of antibiotics will be necessary, preferably for 7 to 10 days. Piglets treated early in the course of the disease will survive but may runt. Because of the common litter incidence in piglets and the occurrence of subclinical bacteremia, it is wise to also treat all littermates of affected piglets. Benzathine or benethamine penicillins can be used in conjunction with shorter-acting penicillins.

## CONTROL

The principles of control of infectious diseases of the newborn are described elsewhere. Because the most frequent source of infection in foals is the genital tract of the dam, some attempt should be made to treat the mare and limit the contamination of the environment. Mixed bacterins have been widely used to establish immunity in mares and foals against this infection, but no proof has been presented that they are effective. On heavily infected premises the administration of long-acting penicillin at birth may be advisable. A major factor in the control of navel and joint ill in lambs is the use of clean fields or pens for lambing because umbilical infection originating from the environment seems to be more important than infection from the dam in this species. Docking should also be done in clean surroundings; if necessary, temporary yards should be erected. Instruments should be chemically sterilized between lambs. Regardless of species and where practicable, all parturition stalls and pens should be kept clean and disinfected, and the navels of all newborn animals should be disinfected at birth. Where screwworms are prevalent, the unhealed navels should be treated with a reliable repellent.

## Neonatal Neoplasia

Congenital neoplasia is rare, occurring at a substantially lower rate than in adults, and accounts for a minor percentage of findings in surveys of neonatal mortality. It is probable that genetic rather than environmental factors influence its development.

Clinical signs depend on the type of neoplasm and its site, and they can result in dystocia or abortion. A variety of tumors have been recorded in all large animal species and are predominantly of mesenchymal origin.

In calves, malignant lymphoma is most commonly reported. It is usually multicentric and also affects the skin. Sporadic bovine leukemia of young calves may also be present at birth. Other tumors reported predominant in calves include diffuse peritoneal mesothelioma, mixed mesodermal tumor, mast cell tumor, hemangiomas, and cutaneous melanoma.

Melanomas (both benign and malignant) also occur in foals and piglets. Duroc Jersey, Vietnamese pot-bellied pigs, and Sinclair miniature pigs have a high incidence of congenital malignant melanoma, which is fatal in approximately 15% of affected pigs but regresses spontaneously, and without recurrence, in the remainder.

A breed predisposition to cardiac rhabdomyoma is recorded in Red Wattle pigs.

Papillomatosis is rare, but **lingual papillomatosis** is reported as a cause of enzootic disease of piglets in China.

**Mastitis** is inflammation of the parenchyma of the mammary gland regardless of the cause. Mastitis is therefore characterized by a range of physical and chemical changes in the milk and pathologic changes in the glandular tissue. The most important changes in the milk include discoloration, the presence of clots, and the presence of large numbers of leukocytes. There is **swelling, heat, pain, and edema** in the mammary gland in many clinical cases. However, a large proportion of mastitic glands are not readily detectable by manual palpation or by visual examination of the milk using a strip cup; these quarters represent subclinical infections. Because of the large numbers of subclinical cases, the diagnosis of mastitis depends largely on indirect tests, which depend, in turn, on the somatic cell concentration or electrolyte (sodium or chloride) concentration of milk. It seems practicable and reasonable to define mastitis as a disease characterized by the presence of a significantly increased somatic cell concentration in milk from affected glands. The increased somatic cell

concentration is, in almost all cases, caused by an increased neutrophil concentration, which represents a reaction of glandular tissue to injury and is preceded by changes in the milk that are the direct result of damage to glandular tissue. However, the exact clinical and laboratory changes that occur in the udder as a result of infection can also be caused by other factors in the absence of infection. Until it becomes common usage to define mastitis in terms of the sodium or chloride concentration of the milk (as measured by electrical conductivity) or increased permeability of the blood-milk barrier (as measured by albumin concentration), there appears to be no point in changing the current definition of mastitis based on an abnormal-looking secretion or an increased somatic cell concentration. Characterization of mastitis depends on the identification of the causative agent whether it be infectious or physical.

Most of the information presented here deals almost entirely with bovine mastitis because of its economic importance, but small sections on ovine, caprine, porcine, and equine mastitis are included at the end of the chapter.

**Bovine Mastitis****GENERAL FEATURES**

A total of about 140 microbial species, subspecies, and serovars have been isolated from the bovine mammary gland. Microbiological techniques have enabled precise determination of the identity of many of the mastitis pathogens. Based on their epidemiology and pathophysiology, these pathogens have been further classified as causes of **contagious, teat skin opportunistic** or **environmental** mastitis.

**SYNOPSIS****Etiology**

- **Contagious pathogens:** *Staphylococcus aureus*, *Streptococcus agalactiae*, *Corynebacterium bovis*, and *Mycoplasma*
- **Teat skin opportunistic pathogens:** Coagulase-negative staphylococci
- **Environmental pathogens:** Environmental *Streptococcus* spp. including *Streptococcus uberis* and *S. dysgalactiae*, which are the

most prevalent; less prevalent is *S. equinus* (formerly referred to as *S. bovis*).

Environmental coliforms include the gram-negative bacteria *Escherichia coli*, *Klebsiella* spp., and *Enterobacter* spp., and *Trueperella* (formerly *Arcanobacterium*, or *Actinomyces*, or *Corynebacterium*) *pyogenes*.

- **Uncommon pathogens:** Many, including *Nocardia* spp., *Pasteurella* spp., *Mycobacterium bovis*, *Bacillus cereus*, *Pseudomonas* spp., *Serratia marcescens*, *Citrobacter* spp., anaerobic bacterial species, fungi, and yeasts

#### Epidemiology

- Incidence of clinical mastitis ranges from 10%-12% per 100 cows at risk per year. Prevalence of intramammary infection is about 50% of cows and 10%-25% of quarters. Case-fatality rate depends on cause of mastitis.
- Contagious pathogens are transmitted at time of milking; teat skin opportunistic pathogens take any opportunity to induce mastitis; environmental pathogens are from the environment and induce mastitis between milkings.
- Environmental pathogens are the most common cause of clinical mastitis in herds that have controlled contagious pathogens.
- Prevalence of infection with contagious pathogens ranges from 7%-40% of cows and 6%-35% of quarters.
- Prevalence of infection with environmental pathogens: coliforms 1%-2% of quarters; streptococci less than 5%

#### Risk factors

- **Animal risk factors:** Prevalence of infection increases with age. Most new infections occur in the dry period and in early lactation. Highest rate of clinical disease occurs in herds with low somatic cell counts (SCCs). Morphology and physical condition of the teat are risk factors. Selenium and vitamin E status influence incidence of clinical mastitis. High-producing cows are more susceptible.
- **Environmental risk factors:** Poor quality management of housing and bedding increases infection rate and incidence of clinical mastitis caused by environmental pathogens.
- **Pathogen risk factors:** Ability to survive in the environment, virulence factors (colonizing ability and toxin production), susceptibility to antimicrobial agents
- **Economics:** Subclinical mastitis is a major cause of economic loss caused by loss of milk production, costs of treatment, and early culling.

#### Clinical signs

- **Gross abnormalities in secretion** (discoloration, clots, flakes, and pus)
- **Physical abnormalities of udder:** Acute, diffuse swelling and warmth, pain, and gangrene in severe cases; chronic, local fibrosis and atrophy

- **Systemic response:** May be normal or mild, moderate, acute, peracute with varying degrees of anorexia, toxemia, dehydration, fever, tachycardia, ruminal stasis, and recumbency and death

#### Clinical pathology

- **Detection at the herd level:** Bulk tank milk SCCs. Culture of bulk tank milk
- **Detection at the individual cow level:** Abnormal looking milk, culture of composite or quarter milk samples. Indirect tests include SCCs of composite or quarter milk samples, California mastitis test of quarter milk samples, and in-line milk conductivity tests of quarter milk samples.
- **Use of selective media to differentiate gram-positive and gram-negative pathogens** in cases of clinical mastitis
- **Differential diagnosis list:** Other mammary abnormalities include periparturient udder edema, rupture of the suspensory ligament, and hematomas; blood in the milk of recently calved cows.

#### Treatment

- **Clinical mastitis in lactating cow:** Mild cases of clinical mastitis (abnormal secretion only) may not require treatment; however, all clinical mastitis episodes accompanied by an abnormal gland or systemic signs of illness should be treated with antimicrobial agents given by intramammary infusion (all cases) and parenterally (selected cases). Acute and peracute mastitis cases also require supportive therapy (fluid and electrolytes) and nonsteroidal antiinflammatory agents. Culture milk of representative clinical cases but antimicrobial susceptibility testing has not been validated.
- **Dry cow therapy:** Intramammary infusion of long-acting antimicrobial agents at drying off provides the best treatment for subclinical mastitis caused by contagious pathogens. Must adhere to milk withholding times after treatment with antimicrobial agents to prevent milk drug residues, which is a major public health issue. Currently available cow-side antimicrobial residue tests are not reliable.

#### Control

- Principles of control:
  1. Eliminate existing infections
  2. Prevent new infections
  3. Monitor udder health status
- Components of a mastitis control program:
  1. Use proper milking management methods.
  2. Proper installation, function, and maintenance of milking equipment
  3. Dry cow management
  4. Appropriate therapy of mastitis during lactation
  5. Culling chronically infected cows
  6. Maintenance of an appropriate environment
  7. Good record keeping
  8. Monitoring udder health status
  9. Periodic review of the udder health management program
  10. Setting goals for udder health status

## Contagious Mastitis Pathogens

There are many contagious mastitis pathogens. The most common are *Staphylococcus aureus* and *Streptococcus agalactiae*. The usual source of contagious pathogens is the infected glands of other cows in the herd; however, the hands of milkers can act as a source of *S. aureus*. The predominant method of transmission is from cow to cow by contaminated common udder washcloths, residual milk in teat cups, and inadequate milking equipment. Programs for the control of contagious mastitis involve improvements in hygiene and disinfection aimed at disrupting the cow-to-cow mode of transmission. In addition, methods to eliminate infected cows involve antimicrobial therapy and the culling of chronically infected cows.

Generally, a conscientious mastitis control program will eradicate *S. agalactiae* from most dairy herds. It is much more difficult to deal with a herd that has a high prevalence of *S. aureus*, but it can be eradicated from low-prevalence herds.

*Mycoplasma bovis* is a less common cause of contagious mastitis; it causes outbreaks of clinical mastitis that do not respond to therapy and are difficult to control. Most outbreaks of *M. bovis* are associated with recent introductions of new animals into the herd. Characteristically, clinical mastitis occurs in more than one quarter; there is a marked drop in milk production, and there is little evidence of systemic disease. The laboratory diagnosis of mycoplasmal mastitis requires specialized media and culture conditions. Antimicrobial therapy is relatively ineffective, and culling is the predominant strategy.

## Teat Skin Opportunistic Mastitis Pathogens

The incidence of mild clinical mastitis associated with bacterial pathogens that normally reside on the teat skin is increasing, particularly in herds that have controlled major contagious mastitis pathogens. Teat skin opportunistic pathogens have the ability to create an intramammary infection via ascending infection through the streak canal. Accordingly, their epidemiology of infections differs from those of contagious and environmental pathogens, and it is useful to consider them in a separate category. Coagulase-negative staphylococci (CNS) are the most common teat skin opportunistic mastitis pathogens.

## Environmental Mastitis Pathogens

Environmental mastitis is associated with three main groups of pathogens, the coliforms (particularly *Escherichia coli* and *Klebsiella* spp.), environmental *Streptococcus* spp., and *Trueperella pyogenes*. The source of these pathogens is the environment of the cow. The major method of transmission is from the environment to the cow by inadequate management of the environment. Examples

include wet bedding, dirty lots, milking wet udders, inadequate premilking udder and teat preparation, housing systems that allow teat injuries, and poor fly control. Control strategies for environmental mastitis include improved sanitation in the barn and yard areas, good premilking udder preparation so that teats are clean and dry at milking time, and fly control. Special attention is necessary during the late dry period and in early lactation.

Coliform organisms are a common cause of clinical mastitis, occasionally in a severe peracute form. Clinical cases of coliform infection are generally found in low levels in most herds and do not routinely result in chronic infections. There is increasing evidence that, as the contagious pathogens are progressively controlled in a herd, the incidence of clinical cases associated with coliform organisms increases. The pathogenesis, epidemiology, predisposing risk factors, diagnostic problems, therapy, and control methods have been the subject of extensive, worldwide research efforts.

Environmental streptococci have become a major cause of mastitis in dairy cattle. Streptococcal infections are associated with many different species; however, the most prevalent species are *Streptococcus uberis* and *Streptococcus dysgalactiae*. Infections with these organisms can cause clinical mastitis that is commonly mild to moderate in nature. More frequently, these organisms cause a chronic subclinical infection with an increased milk somatic cell concentration. Many herds that have implemented the five-point program for mastitis control have found that environmental streptococci represent their most common mastitis problem.

*T. pyogenes* is an important seasonal cause of mastitis in dry cows and late pregnant heifers in some parts of the world. Intramammary infections with *T. pyogenes* are severe, and the gland is almost always lost to milk production.

Several other pathogens are included in the environmental class of infections. These pathogens invade the mammary gland when defense mechanisms are compromised or when they are inadvertently delivered into the gland at the time of intramammary therapy. This group of opportunistic organisms includes *Pseudomonas* spp., yeast agents, *Prototheca* spp., *Serratia marcescens*, and *Nocardia* spp. Each of these agents has unique microbiological culture characteristics, mechanisms of pathogenesis, and clinical outcomes. These infections usually occur sporadically. However, outbreaks can occur in herds or in an entire region and are usually the result of problems with specific management of hygiene or therapy. For example, mastitis associated with *Pseudomonas aeruginosa* has occurred in outbreaks associated with contaminated wash hoses in milking parlors. Iodide germicides used in wash lines are often at too low a concentration to

eliminate *Pseudomonas* spp. Outbreaks of clinical mastitis associated with *Nocardia* spp. have been associated with the use of blanket dry cow therapy and the use of a specific neomycin-containing dry cow preparation.

The mastitis pathogens, and their relative importance, continue to evolve as new management methods and control practices are developed. Thus there is an ongoing need for epidemiologic studies to characterize the pathogens and describe their association with the animals and their environment. Improved control methods can develop only from investigations into the distribution and pathogenic nature of the microorganisms isolated.

### ETIOLOGY

Bovine mastitis is associated with many different infectious agents, commonly divided into those causing **contagious mastitis**, which are spread from infected quarters to other quarters and cows, those that are normal teat skin inhabitants and cause **opportunistic mastitis**, and those causing **environmental mastitis**, which are usually present in the cow's environment and reach the teat from that source. Pathogens causing mastitis in cattle are further divided into **major pathogens** (those that cause clinical mastitis) and **minor pathogens** (those that normally cause subclinical mastitis and less frequently cause clinical mastitis).

### Major Pathogens

#### Contagious Pathogens

- *S. agalactiae*
- *S. aureus*
- *M. bovis*

#### Environmental Pathogens

Environmental *Streptococcus* species include *S. uberis* and *S. dysgalactiae*, which are the most prevalent; less prevalent is *S. equinus* (formerly referred to as *S. bovis*). The environmental coliforms include the gram-negative bacteria *E. coli*, *Klebsiella* spp., and *Enterobacter* spp. *T. pyogenes* mastitis can be an important problem in some herds.

### Minor Pathogens

Several other species of bacteria are often found colonizing the teat streak canal and mammary gland. They rarely cause clinical mastitis and are known as **minor pathogens**. They include the **coagulase-negative Staphylococcus** spp. such as *S. hyicus* and *S. chromogenes*, which are commonly isolated from milk samples and the teat canal. *S. xylosus* and *S. sciuri* are found free living in the environment; *S. warneri*, *S. simulans*, and *S. epidermidis* are part of the normal flora of the teat skin (and therefore are teat skin opportunistic pathogens). The prevalence of coagulase-negative *Staphylococcus* spp. is higher in first-lactation heifers than in cows and higher immediately after calving than in

the remainder of lactation. In recent studies, they have been found as teat canal and intramammary infections in nulliparous heifers.

*Corynebacterium bovis* is also a minor pathogen; it is mildly pathogenic and the main reservoir is the infected gland or teat duct. However, in some herds, *C. bovis* appears to be a common cause of mild clinical mastitis. *C. bovis* spreads rapidly from cow to cow in the absence of adequate teat dipping. The prevalence of *C. bovis* is low in herds using an effective germicidal teat dip, good milking hygiene, and dry cow therapy. The presence of *C. bovis* in a gland will reduce the likelihood of subsequent infection with *S. aureus*.

### Uncommon Mastitis Pathogens

Many other bacteria can cause severe mastitis, which is usually sporadic and usually affects only one cow or a few cows in the herd. These include *Nocardia asteroides*, *N. brasiliensis*, and *N. farcinica*, *Histophilus somni*, *Pasteurella multocida*, *Mannheimia* (formerly *Pasteurella*) *haemolytica*, *Campylobacter jejuni*, *Bacillus cereus*, and other gram-negative bacteria including *Citrobacter* spp., *Enterococcus faecalis*, *E. faecium*, *Proteus* spp., *Pseudomonas aeruginosa*, and *Serratia* spp. Anaerobic bacteria have been isolated from cases of mastitis, usually in association with other facultative bacteria, e.g., *Peptostreptococcus indolicus*, *Prevotella melaninogenica* (formerly *Bacteroides melaninogenicus*), *Eubacterium combesii*, *Clostridium sporogenes*, and *Fusobacterium necrophorum*.

Fungal infections include *Trichosporon* spp., *Aspergillus fumigatus*, *A. nidulans*, and *Pichia* spp.; yeast infections include *Candida* spp., *Cryptococcus neoformans*, *Saccharomyces* spp., and *Torulopsis* spp. Algal infections include *Prototheca trispora* and *P. zopfii*.

Leptospiras, including *Leptospira interrogans* serovar Pomona, and especially *Leptospira interrogans* Hardjo, cause damage to blood vessels in the mammary gland and gross abnormality of the milk. They are more correctly classified as systemic diseases with mammary gland.

Some viruses may also cause mastitis in cattle, but they are of little importance.

### EPIDEMIOLOGY

This section deals with the general aspects of epidemiology of bovine mastitis. For information about the epidemiology of mastitis in the other animal species see the appropriate sections at the end of this chapter.

### Occurrence and Prevalence of Infection

**Occurrence** refers to the location of the disease and the kinds of animals affected. **Prevalence** is the percentage of the population affected with a specific disease in a given population at a certain point in time. The **incidence** is a rate, such as the total number

of new cases of clinical mastitis, and is a percentage of the animals at risk that develop a specific disease during a certain period of time. Prevalence is a function of the incidence and the duration of infection.

### Prevalence

In most countries, surveys in dairy herds indicate that the **prevalence of infection** of mastitis pathogens is approximately 50% of cows and 10% to 25% of quarters. The prevalence of infection in dairy heifers of breeding age and in pregnant dairy heifers varies widely from 30% to 50% of heifers and 18% of quarters to as high as 97% of heifers and 75% of quarters.

### Incidence

The **average annual incidence of clinical mastitis**, calculated as the number of clinical quarter cases per 100 cows at risk per year, including the dry period, in individual herds ranges from 10% to 12% in most herds, but higher incidences, ranging from 16% to 65%, occur in some herds. The greatest risk of first acquiring mastitis occurs early in lactation, usually in the first 50 days. The risk of clinical mastitis also increases with increasing parity. In beef herds, 32% to 37% of cows and 18% of quarters may have intramammary infection, which has a significant negative effect on calf weaning weights.

**Case-fatality rates** vary widely depending largely on the identity of the causative organism. For example, *S. agalactiae* mastitis is not a fatal disease, but peracute staphylococcal mastitis in a recently calved cow often may be fatal. Details of the occurrence of the different types of mastitis are presented in their individual sections in this chapter.

### Relative Prevalence of Infection With Intramammary Pathogens

The prevalence of infection with intramammary pathogens in cattle with clinical mastitis differs from country to country, primarily based on whether cows are pasture based or confinement fed, and whether cattle were housed in free stalls or tie stalls. For example, in the United States, coliform bacteria are most frequently isolated from cows with clinical mastitis. The most frequently isolated bacteria from cattle with clinical mastitis in Canada are *S. aureus*, *E. coli*, *S. uberis*, and CNS.<sup>1</sup> In Europe, clinical mastitis caused by *Klebsiella* spp. occurs less frequently than *E. coli* mastitis, whereas the two pathogens are of equal importance in the United States because of the more frequent use of sawdust and wood shavings for bedding. In Norway, *S. aureus* is the predominant pathogen, followed by *S. dysgalactiae*. In Sweden, *S. aureus* is the predominant pathogen, followed by *E. coli*, *S. dysgalactiae*, *S. uberis*, CNS, *T. pyogenes*, and *Klebsiella* spp.<sup>2</sup> In Finland, *S. aureus* is also the predominant pathogen from clinical mastitis cases, followed by CNS, *S. uberis*, *S. dysgalactiae*, and

*E. coli*.<sup>3</sup> *S. uberis* was the most common cause of clinical mastitis in Belgium, followed by *E. coli*.<sup>4</sup> In comparison, *S. uberis* is the most common cause of clinical mastitis in New Zealand,<sup>1</sup> and *S. aureus* is the predominant pathogen in Ireland, followed closely by *S. uberis*, coliform bacteria, environmental streptococci, and finally CNS.<sup>5</sup>

The bacteriologic identification of mastitis pathogens is important because optimal control and eradication procedures depend on the prevalent pathogens in the herd. In addition, the validity of epidemiologic investigations aimed at determining transmission patterns or the impact of environmental and management factors to a large extent depends on exact bacteriologic diagnosis.

### Contagious Pathogens

The prevalence of infection with *S. aureus* in cows ranges widely, usually from 7% to 40%, but it is higher in some herds. A survey of Danish dairy herds found that 21% to 70% of all cows and 6% to 35% of all quarters were infected. *S. aureus* was isolated from 10% of quarter samples and was the most common species isolated. The prevalence of streptococci, including *S. agalactiae*, ranges from 1% to 8% of cows. A relative incidence of *S. agalactiae*, other streptococci and *S. aureus* of 1 : 1 : 2 is a common finding. *S. aureus* may still assume some importance as a cause of subclinical mastitis, but its prevalence has been reduced by modern mastitis control programs, leading to a higher proportion of culture-negative mastitic quarters and a corresponding, and perhaps consequent, increase in infections by *E. coli* and *Klebsiella* spp. The prevalence of infection caused by *Mycoplasma* spp. varies widely.

The prevalence of infection caused by an individual pathogen, and therefore the ratio between its incidence and that of other pathogens, depends on several risk factors such as size of herd and quality of management, especially milking parlor hygiene and cleanliness of accommodation, and parity of animal (heifer or cow). For example, large, zero-grazed herds kept in drylot conditions are likely to encounter more hygiene problems than conventionally housed herds mainly because of constant soiling of the udder by inadequate or improper bedding in larger units. In those circumstances there is likely to be a much higher prevalence than usual of mastitis associated with *E. coli* and *S. uberis*.

### Teat Skin Opportunistic Pathogens

Coagulase-negative staphylococcal species were found in 4.1% of samples; the most frequently isolated were *S. epidermidis* (1.3%), *S. chromogenes* (1.0%), and *S. simulans* (0.7%).

### Environmental Pathogens

The prevalence of intramammary coliform infections in a dairy herd seldom exceeds 1%

to 2%; the prevalence of intramammary environmental streptococci is less than 5% in well-managed herds but may exceed 10% in some problem herds. A characteristic of intramammary coliform infections is the short duration, with 40% to 50% persisting less than 7 days. The majority of environmental streptococci infections last less than 30 days. In a survey of Danish dairy herds, *S. dysgalactiae* (1.6%) and *S. uberis* (1.4%) were the second and third most common species isolated.

### Heifers

Surveys of intramammary infection of heifers in regions such as Louisiana indicate variability in prevalence and duration of intramammary infection according to species of bacteria present around the time of parturition. About 20% of heifers were infected with *S. aureus* and 70% with CNS, the minor pathogens that are part of the normal teat skin flora of heifers. *S. chromogenes* was isolated from 15% of all quarters of heifers before parturition but decreased shortly after parturition to 1%. Up to 97% of breeding age and pregnant dairy heifers and 75% of their quarters may be infected with *S. aureus*, *S. hyicus*, and *S. chromogenes*. Infections with *S. simulans* and *S. epidermidis* occurred in 1% to 3% of quarters both before and after parturition. *S. dysgalactiae* was isolated from 4% to 6% of quarters before and immediately after parturition. Intramammary infections with *S. aureus* rarely occurred before parturition but increased during the first week after parturition. There was no association between the prevalence of *S. aureus* in heifers before parturition and the prevalence in lactating cows.

### Distribution of Pathogens in Clinical Mastitis

The distribution of pathogens isolated from cases of clinical mastitis has changed with the adoption of control programs from a high frequency of isolation of *S. aureus* and *S. agalactiae* to a higher isolation rate of other pathogens, particularly environmental pathogens. For example, in 171 randomly selected dairy herds, the average annual incidence of clinical mastitis was 13 quarter cases per 100 cows per year. The most frequent isolates from clinical cases were *E. coli* (16%), *S. aureus* (14%), *S. uberis* (11%), and *S. dysgalactiae* (8%). In another survey, the most common isolates from clinical cases were CNS and *E. coli*, each at 15% of samples taken. In a 2-year observational study of 65 dairy herds in Canada, there was considerable variation in the incidence of clinical mastitis among farms. Overall, 20% of cows experienced one or more cases of clinical mastitis during lactation. The pathogens isolated were coliforms (17%), other *Streptococcus* spp. (14%), *S. aureus* (7%), gram-positive bacilli (6%), *C. bovis* (2%), *S. agalactiae* (1%), and other *Staphylococcus* spp. (29%). There

was no growth in 18% of samples, and 8% were contaminated. Clearly the main difference is that the rate of *S. aureus* in clinical cases is higher in continental Europe and lower in England and North America.

### Source of Infection

#### Contagious Pathogens

*S. agalactiae* and *S. aureus* reside primarily in the udder of infected cows; the source of infection is other infected cows and exposure to uninfected quarters is limited to the milking process.

#### Teat Skin Opportunistic Pathogens

A number of species of coagulase-negative staphylococcus reside primarily on the teat skin of cattle.

#### Environmental Pathogens

*S. uberis*, *S. dysgalactiae*, and coliforms are common inhabitants of the cow's environment such as bedding. The exposure of uninfected quarters to environmental pathogens can occur at any time during the life of the cow, including milking time, between milkings, during the dry period, and before first calving in heifers.

### Methods of Transmission

Infection of each mammary gland occurs via the teat canal, with the infection originating from either an infected udder or the environment; in dairy cattle the infection originating from infected udders is transmitted to the teat skin of other cows by milking machine liners, milkers' hands, washcloths, and any other material that can act as an inert carrier.

### Risk Factors

Risk factors that influence the prevalence of infection and the incidence of clinical mastitis are outlined here. Individual factors that are of particular importance in the individual types of mastitis are described under those headings.

#### Animal Risk Factors

##### Age and Parity

The prevalence of infected quarters increases with age, peaking at 7 years. Surveys of the prevalence of intramammary infection in dairy heifers a few days before their first parturition reveals that 45% are infected, and the quarter infection rate may be 18%. Some studies found intramammary infections in 97% of heifers and 74% of quarters.

##### Stage of Lactation

Most new infections occur during the **early part of the dry period** and in the **first 2 months of lactation**, especially with the environmental pathogens. In heifers, the prevalence of infection is often high in the last trimester of pregnancy and several days before parturition, followed by a marked decline after parturition. In dairy heifers, most of these prepartum infections are

associated with the minor pathogens, but some surveys have found evidence of infection by the major pathogens.

Some of these differences may be related to changes in the milk as a medium for bacterial growth. For example, bacteria such as *C. bovis* grow best in milk secreted in the middle of lactation, whereas dry period secretion inhibits its growth. During the dry period the quarter's capacity to provide phagocytic and bactericidal activities diminishes.

##### Season of Year

The relationship between the incidence of mastitis and season of the year is variable, depending on geographic and climatic conditions. In subtropical and tropical areas the incidence may be higher during winter or spring calvings from the increase in infection pressure associated with increased humidity. In temperate climates and confined dairy herds, the incidence of mastitis is typically higher in summer; this has been attributed to ambient temperatures facilitating the growth of mastitis pathogens in bedding.<sup>6</sup>

##### Somatic Cell Count

The highest average incidence of clinical mastitis caused by environmental bacteria may occur in herds with the lowest bulk tank milk somatic cell count (SCC; <150,000 cells/mL) and a low prevalence of subclinical infection.<sup>6</sup>

##### Breed

Generally, the incidence of mastitis is greater in Holstein Friesians than in Jerseys, but this may reflect differences in management rather than a true genetic difference. Valid comparisons between breeds have not been reported.

#### Milking Characteristics and Morphology of Udder and Teat

High milking rate and large teat canal diameter have been associated with increased SCC or risk of intramammary infection. Milk leaking in cows in herds with a low bulk tank milk SCC has also been associated with an increased rate of clinical mastitis. Decreasing teat-end-to-floor distance is also a risk factor for clinical mastitis and may be associated with an increased incidence of teat lesions.<sup>7</sup> Heritability estimates of teat-end-to-floor distance or udder height range from 0.2 to 0.7, which may be a consideration in the selection indices of bulls. Periparturient udder edema is also a risk factor for clinical mastitis.<sup>7</sup>

##### Physical Condition of Teat

The teat end is the first barrier against invading pathogens, and the efficiency of teat defense mechanisms depends on the integrity of teat tissue; its impairment leads to an increase in the risk of intramammary infection. Teat thickness is an aid to evaluating

teat tissue status. Milking machine characteristics can induce a decrease or increase in teat thickness after milking compared with premilking values. Increases in teat thickness of more than 5% are significantly associated with infection and new infection, but the association was not significant when teat thickness decreased by more than 5%. Coagulase-negative staphylococcal infections are significantly associated with both increases and decreases in teat thickness numerically greater than 5%, but there is no association between teat thickness and *S. aureus* infections. In a longitudinal study of 135 dairy cows teat condition, as assessed immediately after milking, did not appear to be associated with the risk of new intramammary infections, inflammatory response, or mastitis.<sup>8</sup>

Hyperkeratosis of the teat orifice is a commonly observed condition in the dairy cow because of machine milking; the degree of hyperkeratosis may be increased by a poor milking system. There is wide variation in the degree of hyperkeratosis between herds; the score increases with lactational age and peaks, for any lactation, and at 3 to 4 months after parturition, and declines as the cows dry off. There is no significant relationship between mean SCC and the degree of hyperkeratosis at the herd level. However, there is an association between higher hyperkeratosis scores and higher microbial teat canal load, particularly for two common environmental mastitis pathogens, *E. coli* and *S. uberis*, but surprisingly not for *S. aureus* teat canal load.<sup>9</sup> Severe hyperkeratosis of the teat end is associated with an increased risk of clinical mastitis in the UK, but moderate hyperkeratosis was not predictive of clinical mastitis incidence.<sup>10</sup> Together, these data indicate that only severe disruption of the normal anatomy of the teat orifice is associated with an increased risk of developing clinical mastitis.<sup>10</sup>

#### Udder Hygiene

Dirty udders are associated with increased SCC and an increased prevalence of intramammary infection caused by contagious and environmental pathogens.<sup>7</sup> It makes sense that an increased bacterial challenge of the teat and udder is associated with an increased risk of mastitis (Fig. 20-1). Udder hygiene could be a proxy for general mastitis management skills, because good mastitis control programs result in a low prevalence of infection with contagious and environmental pathogens.

#### Nutritional Status

Vitamins E and A as well as selenium may be involved in resistance to certain types of mastitis. Early reports found that supplementation with antioxidants such as selenium and vitamin E had a beneficial effect on udder health in dairy cattle by decreasing the incidence and duration of

**Fig. 20-1** The environmental bacterial challenge can be formidable in confinement dairy operations, as demonstrated from a Midwest dairy in the United States.

clinical mastitis. An increase in selenium concentration in whole blood was associated with a decrease in all infections, including *S. aureus*, *T. pyogenes*, and *C. bovis*. There was no association between different infections or SCC and concentrations of vitamin E, vitamin A, or  $\beta$ -carotene, but an association existed between vitamin A concentration and SCC. There may be an association between feed intake and risk of clinical mastitis: milk fat to protein ratios  $<1.0$  (typically indicating the presence of subacute ruminal acidosis) or  $>1.5$  (typically indicating the presence of excessive fat mobilization) predicts an increased likelihood of clinical mastitis within the following week.<sup>8</sup>

#### Genetic Resistance to Mastitis

A variety of morphologic, physiologic, and immunologic factors contribute to a cow's resistance or susceptibility to mastitis, and each of these factors is influenced to some extent by heredity.<sup>7</sup> Differences in udder depth, teat length, teat shape, and teat orifice morphology are thought to be associated with differences in mastitis occurrence. The production of keratin in the streak canal and the physical and biochemical characteristics of keratin are important contributors to mastitis resistance. Many of the defense mechanisms of the udder, including lysozyme, lactoferrin, immunoglobulins, and leukocytes, are direct products of genes and have a genetic basis. For dairy cattle, heritability estimates for clinical mastitis average about 0.05. These low heritability estimates indicate that there is very little genetic influence on clinical mastitis but a very strong environmental influence.

**Somatic Cell Count.** Differences in heritability between herds with high and low SCCs

are not significant. However, differences among bulls' daughter groups for both clinical mastitis and SCC are reasonably large, suggesting that selection of sires can be important in mastitis control. An analysis of the disease and breeding records of a large number of Swedish bulls siring daughters whose milk had a low SCC count found genetic correlations from 0.71 to 0.79 between SCC and clinical mastitis. It was concluded that it is possible to improve resistance to clinical mastitis by selecting for a low SCC.

The strong phenotypic and genetic association between SCC and mastitis indicates that breeding programs based on SCC may be effective as an indirect means of improving mastitis resistance. However, greater emphasis on SCC may decrease genetic gain in yield traits, which are economically more important.

#### Milk Yield

The genetic correlation between milk yield and mastitis is about 0.2 to 0.3, which suggests that animals genetically above average for milk yield are more susceptible to mastitis and that low-yielding cows tend to be more resistant. However, the low correlation value suggests that this relationship is not a strong tendency. The positive correlation implies that genetic improvement for milk yield is accompanied by a slow decline in genetic resistance to mastitis. Examination of the association between milk yield and disease in a large number of dairy cows found that higher milk yield was not a factor for any disease except mastitis. However, the association between milk yield and mastitis does not imply causation. At least two biological explanations are plausible: increased injury and leaking of milk between milkings.

Improved mastitis control efforts have offset the genetic trend for increased susceptibility to mastitis. The low heritability for mastitis indicates the great importance of environmental factors in causing differences in the prevalence of infection and the incidence of clinical mastitis.

In summary, selection for milk yield alone results in increased incidence of mastitis. The positive genetic correlation between milk yield and mastitis suggests that genes that increase milk yield tend to increase susceptibility to mastitis. Selection indices that maximize genetic improvement for net economic benefit will not decrease the incidence of mastitis, but indices that include SCC, udder depth, or clinical mastitis will diminish the rate of increase in mastitis by 20% to 25%. Using **predicted transmitting ability (PTA)**, an estimate of genetic merit, it has been found on average that daughters of bulls with high PTAs for SCC have a higher incidence of mastitis; sires with low PTA for somatic cell scores (SCCs) should therefore be selected. All of the economically important traits are weighted into a selection index for the selection of bulls, which will improve net income over cost of production.

Dairy cattle with enhanced and optimally balanced antibody and cell-mediated immune responses are known as **high immune responders**. These adaptive immune responses are separate to innate immunity and are heritable, with heritability estimates of 0.25 to 0.35. These estimates are similar in magnitude to those for milk production traits, indicating that an appropriately weighted selection index would improve overall cow health and production.<sup>11</sup>

#### Other Concurrent Diseases

These may be important risk factors for mastitis. Retained placentas, teat injuries, and teat sores may be associated with a higher incidence of mastitis. Sole ulceration of any severity occurring in more than one digit has been associated with an approximately three-fold higher risk of *S. aureus* infections in the first lactation. It is suggested that sore feet could increase the risk of teat lesions, presumably as a result of difficulty in standing.

#### Immunologic Function of Mammary Gland

The immune function of the mammary gland is impaired during the periparturient period; it is susceptible to mastitis during transition periods, such as drying off and colostrumogenesis. As a result, the **incidence of new intramammary infections is highest during the early nonlactating period and the periparturient period**.

Innate immunity plays an important role in maintaining a healthy mammary gland.<sup>12</sup> **Pattern recognition receptors (PRRs)** recognize well-conserved patterns on the surface of microbes called **pathogen-associated molecular patterns (PAMPs)**.

The initial interaction between PAMPs and PRRs plays an important role in the subsequent inflammatory response.<sup>13,14</sup> Lactoferrin is another component of innate immunity. It reaches high concentrations in the glandular secretions during the dry period, particularly during involution of the mammary gland. Because of its high secretion concentration and ability to bind iron, lactoferrin provides important innate antimicrobial activity against new intramammary infections in the dry period, particularly coliform bacteria.<sup>14,15</sup>

The most important components of the defense against common bacterial pathogens are blood-derived **neutrophils** and **opsonizing antibodies**. An inadequate rate of neutrophil recruitment to combat a new intramammary infection has a profound effect on the outcome of infection, because cows with a rapid and massive recruitment of neutrophils to an infected gland clear an intramammary infection within 12 to 18 hours postinfection.

It is also important that an early inflammatory response in the infected mammary gland enables leakage of IgG<sub>2</sub> (opsonizing antibodies) because this facilitates neutrophil phagocytosis of bacteria. The **staggered one-two punch of peak IgG<sub>2</sub> concentrations** within 4 hours of infection and **peak neutrophil response** within 6 to 12 hours of infection greatly facilitates clearance of new intramammary infections.

Blood-derived neutrophils must undergo **margination, adherence, and migration** to arrive in the mammary gland, in which they perform **phagocytosis, respiratory burst, and degranulation**. Margination is via expression of three adhesion molecules from the selectin family, specifically L-selectin (also called CD62L) on neutrophils, E-selectin (also called CD62E), and P-selectin (also called CD62P) on vascular endothelial cells. Neutrophil L-selectin makes the initial contact between “streaming” neutrophils in the bloodstream and the vascular wall; this contact slows neutrophil movement and allows them to “roll” along the endothelium while surveying for the presence of proinflammatory mediators at the sites of tissue infection. When the rolling neutrophils detect the presence of one or more proinflammatory mediators, they immediately shed surface L-selectin (CD62L) adhesion molecules and upregulate and activate Mac-1 (CD11b/CD18) adhesion molecules, stopping neutrophil rolling and permitting tight adherence of the neutrophil to the endothelium. Once adhered, neutrophils commence diapedesis by migrating between endothelial cells to the site of infection. Neutrophil migration therefore has three components: hyperadherence (cessation of rolling), diapedesis, and chemotaxis. Any delay or inhibition in this process can lead to peracute mastitis and severe clinical disease. This is best illustrated by bovine

leukocyte adhesion deficiency in Holstein Friesian cattle; affected calves cannot produce Mac-1 molecules and have a prominent neutrophilia because streaming neutrophils cannot migrate to the site of infection. Migration of neutrophils is slow during the first few weeks of lactation, and this delay in neutrophil migration is thought to be responsible for the increased incidence and severity of intramammary infections during early lactation.

#### Previous Mastitis

Cows with a history of mastitis in the preceding lactation may be almost twice as susceptible to clinical mastitis in the current lactation as those without mastitis in the preceding lactation.

#### Preexisting Intramammary Infections

Existing intramammary infections with minor pathogens has a **protective effect** against infections with major pathogens that is prominent in experimental infection studies that involve a large inoculum that bypasses the teat canal.<sup>16</sup> The observed protective effect of minor pathogen infection may not occur under commercial dairy conditions. The strongest protective effect was observed with coagulase-negative staphylococci, whereas intramammary infection with *C. bovis* did not provide protection against intramammary infection by a major pathogen.<sup>16</sup> Elimination of minor pathogens with postmilking teat disinfection may therefore result in an increase in the incidence of subclinical and clinical mastitis. Discontinuation of teat dipping may be associated with an increase in the prevalence of minor pathogens, increase in the incidence of *S. aureus* infections, and decrease in the incidence of *E. coli* infections.

#### Use of Recombinant Bovine Somatotropin

Because the risk of clinical mastitis increases as milk production increases, there has been considerable scientific and public controversy over the potential effects that the use of recombinant bovine somatotropin (bST) might have on the incidence of clinical mastitis and the subsequent use of antimicrobials from therapy. In some field trials, the use of bST did not result in an increase in the incidence of clinical mastitis compared with controls. In other trials, a significant increase in the incidence of clinical mastitis occurred in treated cows compared with controls. However, the incidence of clinical mastitis was greater in treated cows compared with controls before bST was used. In trials done on well-managed farms that had controlled contagious mastitis and had low rates of clinical mastitis caused by environmental pathogens, the use of bST was not associated with an increase in clinical mastitis, discarded milk because of therapy, or culling for mastitis. Interpretation of a direct effect of

bST on mastitis incidence is confounded by the higher incidence of mastitis in cows of higher milk production.

#### Environmental and Management Risk Factors

*Quality and Management of Housing*  
Factors such as climate, housing system, type of bedding, and rainfall interact to influence the degree of exposure of teat ends to mastitis pathogens. Because dairy cattle spend 40% to 65% of their time lying down, **the quality and management of housing for dairy cattle has a major influence on the types of mastitis pathogen that infect the mammary gland, as well as the degree of infection pressure.**

The major sources of environmental pathogens are the cow's environment, including bedding, soil, feedstuffs, and water supplies. Environmental pathogens multiply in bedding materials, with which the cow's teats are in close and prolonged contact. Bacterial growth in bedding depends on temperature, amount of moisture and nutrients available, and the pH. Fresh bedding can be a source of contamination even before it is used: *Klebsiella pneumoniae* can be present in green, hardwood sawdust in higher numbers than in other types of bedding, and major outbreaks of environmental mastitis caused by *K. pneumoniae* have occurred following the use of contaminated wood products in bedding, described in detail in that section. Dry, unused bedding contains few pathogens, but after being used it becomes contaminated and provides a source in which pathogens multiply to high numbers in 24 hours. Organic bedding materials such as straw, sawdust, wood shavings, and paper support the growth of pathogens. Inorganic materials such as sand retain less moisture and do not provide a supply of nutrients for the pathogens; bacterial counts in these materials are usually lower than in organic materials. Housing lactating cattle on sawdust leads to six times more *Klebsiella* bacteria and twice as much coliform bacteria on the teat ends compared with housing cattle on sand. In contrast, there were 10 times more environmental streptococci bacteria on teat ends when cows were housed on sand, compared with housing on sawdust. Surveys indicate that herds using wood chips or sawdust as bedding material have higher rates of clinical mastitis compared with those using straw bedding.

High humidity and high ambient temperatures favor growth of pathogens. Cows in confinement housing with organic bedding materials have the highest incidence of environmental mastitis in the warm, humid months of the year. Pasturing herds during the summer months usually reduces the incidence of coliform mastitis, although rates of environmental streptococci may remain high. In drylot systems the incidence of coliform mastitis may be associated with

periods of high rainfall. Herds with more months on pasture may have a higher incidence of clinical mastitis, which may be associated with factors such as sanitation and the stress of transition between pasture and confinement housing.

The **management and design of housing systems** influence the prevalence of intramammary infection and the incidence of clinical mastitis. Any housing factor or management system that allows cows to become dirty or damage teats or that causes overcrowding will result in an increase in clinical mastitis. This includes the size and comfort of free stalls, the size of the alleyways, ease of movement of cattle, and the cleaning system. Failure to keep alleyways, cow stalls and bedding clean and dry will increase the level of contamination of the teats. Overcrowding, poor ventilation, and access to dirty ponds of water and muddy areas in which cows congregate are major risk factors.

The **size of the milking cowherd** may be positively associated with an increased incidence of clinical mastitis, because it can be more difficult to control contagious mastitis in a herd with a greater prevalence of infection and a larger number of cow-to-cow contacts. As herd size increases, manure disposal and sanitation problems may increase exposure to environmental pathogens. However, regional and management differences may confound the association of size with infection status. Some recent data suggest lower SCC in large herds. The use of designated maternity areas providing an isolated and clean environment for parturition may be associated with a lower incidence of clinical mastitis.

If hygiene and bedding maintenance are neglected in the housing accommodation the prevalence of environmental forms of mastitis may increase markedly. Periodic inspection of dry cows is an essential part of mastitis control.

#### Milking Practices

**The failure to use established and reliable methods of mastitis control is an important risk factor.** This is a major subject, which includes efficiency of milking personnel, milking machines, high milking speed, and especially hygiene in the milking parlor. Wet teats and udders are a risk factor for increased SCC, especially in the presence of teat impacts from liner slippage. The use of a separate drying cloth for each cow is associated with a lower SCC. Effective use of a postmilking germicidal teat dip is critical for the control of contagious mastitis. Increasing person-hours spent milking per cow may be associated with a higher rate of clinical mastitis. Contaminated milking equipment—including milk hoses, udder wash towels, and teat dip products—has been associated with outbreaks of environmental mastitis from *S. marcescens* and *P. aeruginosa*. Drying off procedures at the end of lactation and an

active policy on drying off treatment are equally important.

**The absence of milk quality regulations that place emphasis on SCC is also a risk factor.** Conversely, the presence of strict regulations with penalties for high SCC is an important incentive to institute mastitis control programs that improve the quality of milk. The absence of a health management program consisting of regular farm visits by the veterinarian may also be a risk factor for mastitis, which may be associated with a relative lack of awareness by the producer of the importance of the principles of mastitis control.

#### Pathogen Risk Factors

##### Viability of Pathogens

The ability of the pathogen to survive in the cow's immediate environment (resistance to environmental influences including cleaning and disinfection procedures) is a characteristic of each pathogen. The causes of contagious mastitis are more susceptible to disinfection than the causes of environmental mastitis.

##### Virulence Factors

There is a wide variety of virulence factors among the mastitis pathogens. These are described under specific mastitides. The influence of many bacterial virulence factors depends on the stage of lactation and severity of the intramammary infection and the effects elicited by the virulence factors on bovine mammary tissue. A few examples of the common virulence factors are noted here.

##### Colonizing Ability

The ability of the pathogens to colonize the teat duct, then to adhere to mammary epithelium, and to initiate mastitis is a major characteristic of the major bacterial causes of mastitis. *S. aureus* strains that cause mastitis can bind to ductular udder epithelial cells and to explant cultures of bovine mammary glands. There are differences in the adhesion characteristics among strains of the organism, which may explain the different epidemiologic characteristics of the organisms in some herds. Comparison of strains isolated from different *S. aureus* mastitis cases between herds reveals that only a limited number of genotypes of *S. aureus* are most prevalent.

##### Toxins

*E. coli* isolates that cause mastitis produce lipopolysaccharide endotoxin, which is responsible for many of the inflammatory and systemic changes observed during acute coliform mastitis. *S. aureus* isolated from intramammary infections produces many potential virulence factors, including enterotoxins; coagulase and alpha-, beta-, and delta-toxins; hemolysin; hyaluronidase; and leukocidins, which are considered to be involved in the varying degrees

of inflammation characteristic of staphylococcal mastitis from subclinical to peracute gangrenous mastitis. Virulence factors of *S. uberis* include hyaluronidase and the hyaluronic capsule.

#### Production and Economic Losses

Although mastitis occurs sporadically in all species, it assumes major economic importance in dairy cattle and may be one of the most costly diseases in dairy herds. Mastitis results in economic loss for producers by increasing the costs of production and by decreasing productivity. The premature culling of potentially profitable cows because of chronic mastitis is also a significant loss. Because of the large economic losses, there is a potential for high returns on investment in an effective control program. The component economic losses can be divided into the following:

- Loss of milk production
- Discarded milk from cows with clinical mastitis and treated cows
- Replacement cost of culled cows
- Extra labor required for treatment and monitoring
- Veterinary service for treatment and control
- Cost of first trimester abortions caused by clinical mastitis
- Cost of decreased conception rate caused by clinical mastitis 1 week before or 2 weeks after artificial insemination<sup>17</sup>
- Cost of control measures

There are additional costs such as antimicrobial residues in milk from treated cows, milk quality control, dairy food manufacturing, nutritional quality of milk, degrading of milk supplies caused by high bacteria or SCC, and interference with the genetic potential of some cows from early involuntary culling because of chronic mastitis.<sup>18</sup> The total annual cost of mastitis in the dairy cattle population is estimated to be 10% of the total value of farm milk sales, and about two-thirds of this loss is caused by reduced milk production in subclinically affected cows. The production and economic losses are commonly divided into those associated with subclinical and clinical mastitis.

#### Subclinical Mastitis

Total milk losses from quarters affected with subclinical mastitis have been estimated to range from 10% to 26%. Lower SCCs are associated with higher milk production, and rolling herd average milk production has been estimated to decrease by 190 kg per unit increase of linear SCS. Most estimates indicate that on average an affected quarter results in a 30% reduction in productivity, and an affected cow is estimated to lose 15% of its production for lactation. This loss is sometimes expressed as a loss of about 340 kg of saleable milk, which is caused by the loss of production and the value of milk that has to be withheld from sale. The loss in

production by an infected quarter may be largely compensated by increased production in the other quarters so that the net loss from the cow may be less than expected. In addition to these losses, there is an added loss of about 1% of total solids by changes in composition (fat, casein, and lactose are reduced and glycogen, whey proteins, pH, and chlorides are increased), which interferes with manufacturing processes, and other losses include increased culling rates and costs of treatment. Comparisons between low- and high-prevalence herds always show a financial advantage of about 20% to the low-prevalence herds, with the gain varying with the local price of milk or butter fat. In beef herds the losses are in the form of rare deaths of cows and failure of the calves to gain weight.

Approximately 75% of the economic loss from subclinical mastitis is attributable to loss of milk production. Other costs include discarding milk from treated cows, drug costs, veterinary costs, labor, and loss of genetic potential of culled cows.

### Clinical Mastitis

Clinical mastitis results in marked decreases in milk production, which are much larger in early than late lactation.<sup>19</sup> Milk production losses are also greater in cows with multiple lactations than first-lactation cows<sup>19</sup> and vary with pathogen type. Generally, gram-negative clinical mastitis cases have a greater milk loss than gram-positive and other cases.<sup>20</sup> In primiparous cattle, the greatest production losses were associated with *E. coli* and “untreatable” mastitis pathogens including *T. pyogenes*, *Mycoplasma* spp., *Prototheca*, and yeast.<sup>21</sup> In multiparous cattle, the greatest production losses were associated with *Klebsiella* spp. and untreatable mastitis pathogens. Clinical mastitis episodes caused by CNS were not associated with a detectable production loss.<sup>21</sup>

Clinical mastitis also decreases the duration of lactation and increases the likelihood of culling. Clinical cases of brief duration that occur after the peak of lactation affect milk production very little but can induce abortion during the first 45 days of gestation. Clinically affected quarters may not completely recover milk production in subsequent lactations, but these carry-over losses are not as large as the losses from acute mastitis.

The **costs of clinical mastitis** in dairy herds have been estimated in a number of countries. In a large 5-herd study in New York state in 2008 each clinical mastitis case cost \$71 per cow-year, with a mean cost per clinical episode of \$179. The latter estimate was based on \$115 for milk yield loss, \$14 for increased mortality, and \$50 for treatment-associated costs.<sup>22</sup> These estimates did not include the cost of control programs.

The component causes of economic loss associated with mastitis outlined previously

vary according to the causative pathogen and are described under specific mastitides. In general terms *S. aureus* and *E. coli* may cause death from peracute mastitis; *T. pyogenes* causes complete loss of quarters; staphylococci and streptococci cause acute clinical mastitis, but their principal role is in causing subclinical mastitis, resulting in a reduction of milk produced and a downgrading of its quality. Of these, *S. agalactiae* causes the greatest production loss, whereas *S. aureus* has the higher infection rate, greater resistance to treatment, and longer duration of infection. At one time *S. aureus* represented the impassable barrier to mastitis control programs.

Other factors that affect the magnitude of the loss associated with mastitis include age (the loss is greatest in mature cows) and when the attack occurs in the first 150 days of lactation.

### Zoonotic Potential

With mastitis there is the danger that the bacterial contamination of milk from affected cows may render it unsuitable for human consumption by causing food poisoning, or interfere with manufacturing processes or, in rare cases, provide a mechanism of spread of disease to humans. Tuberculosis, listeriosis, salmonellosis, and brucellosis may be spread in this way. Raw (unpasteurized) milk can be a source of food-borne pathogens, and consumption of raw milk can result in sporadic disease outbreaks. For instance, sampling bulk tank raw milk in Ontario revealed the presence of *Listeria monocytogenes*, *Salmonella* spp., *Campylobacter* spp., or verocytotoxigenic *E. coli* in 2.7, 0.2, 0.5, and 0.9% of milk samples, respectively. These findings emphasize the importance of continued diligence in the application of hygiene programs within dairies and the separation of raw from pasteurized milk and milk products.

### PATHOGENESIS

Infection of the mammary gland always occurs via the teat canal and on first impression the development of inflammation after infection seems a natural sequence. However, the development of mastitis is more complex than this and can be most satisfactorily explained in terms of three stages: **invasion**, **infection**, and **inflammation**. Of the three phases, prevention of the invasion phase offers the greatest potential for reducing the incidence of mastitis by good management, notably in the use of good hygienic procedures.

**Invasion** is the stage at which pathogens move from the teat end to the milk inside the teat canal.

**Infection** is the stage in which the pathogens multiply rapidly and invade the mammary tissue. After invasion the pathogen population may be established in the teat canal and, with this as a base, a series of multiplications and extensions into

mammary tissue may occur, with infection of mammary tissue occurring frequently or occasionally depending on its susceptibility. Multiplication of certain organisms may result in the release of endotoxins, as in coliform mastitis, which causes profound systemic effects with minimal inflammatory effects.

**Inflammation** follows infection and represents the stage at which clinical mastitis occurs with varying degrees of clinical abnormalities of the udder and variable systemic effects from mild to peracute; gross and subclinical abnormalities of the milk appear. Abnormalities of the udder include marked swelling, increased warmth and, in acute and peracute stages, gangrene in some cases and abscess formation and atrophy of glands in chronic stages. The systemic effects are caused by the mediators of inflammation. Gross abnormalities of the milk include a decrease in milk yield, the presence of the products of inflammation, and marked changes in the composition of the milk.

The most significant subclinical abnormality of the milk is the increase in the SCC, the most common measurement of milk quality and udder health. Milk somatic cells in a healthy gland consist of several cell types, including neutrophils (<11%), macrophages (66%–88%), lymphocytes (10%–27%), and a smaller percentage of epithelial cells (0%–7%). Neutrophils are the predominant cell type found in mammary tissues and secretions during inflammation, and in mastitis they constitute more than 90% of total mammary gland leukocytes. Once at the site of infection, neutrophils phagocytose and kill pathogens. Neutrophils exert their bactericidal effect through a respiratory burst that produces hydroxyl and oxygen radicals, which are important components of the oxygen-dependent killing mechanism.

In the healthy lactating mammary gland, the SCC is less than 100,000 cells/mL of milk. During intramammary infection, the glandular SCC can increase to more than 1,000,000 cells/mL of milk within a few hours because of the combined effect of an increased number of neutrophils (numerator) and a decreased glandular secretion volume (denominator). **The severity and duration of mastitis are critically related to the promptness of the neutrophil migratory response and their bactericidal activity at the site of infection.** As they colonize and multiply in the mammary gland, some bacteria release metabolic by-products or cell-wall components (endotoxin if a gram-negative bacteria) that serve as chemoattractants for leukocytes. If neutrophils move rapidly from the bloodstream and are able to eliminate the inflammatory stimuli (bacteria), then recruitment of neutrophils ceases and the SCC returns to normal levels. If bacteria are able to survive this immediate host response, then the inflammation continues,

resulting in neutrophil migration between adjacent mammary secretory cells toward the alveolar lumen. Prolonged diapedesis of neutrophils damages mammary tissue, resulting in decreased milk production. The duration and severity of the inflammatory response therefore has a major impact on the quantity and quality of milk produced.

The major factor affecting the SCC at the herd and individual cow level is the prevalence of intramammary infection at a glandular level. Because marked increases in SCC are a result of cells being attracted to the mammary tissue because of the mediators produced during a local infection, events that do not affect udder health are unlikely to have a direct or dramatic effect on SCC. Little evidence exists that any factor other than normal diurnal variation has a major influence on SCC in the absence of intramammary infections.

The effects of mastitis on milk yield are highly variable and depend on the severity of the inflammation, the causative agents and the lesions produced, the efficiency of treatment, the production level, and the stage of lactation. Mastitis in early lactation causes a larger decrease in milk yield with long-term effects than mastitis in late lactation. Mastitis caused by *S. aureus* generally evolves into persistent but moderate infections, unlike those associated with coliforms. Mastitis associated with *T. pyogenes* results in suppurative lesions, poor response to treatment, and culling. *M. bovis* causes chronic induration and almost complete loss of milk production without recovery.

## CLINICAL FINDINGS

Details of the clinical findings are provided under each specific type of mastitis. The clinical findings should be used only as a guide because different pathogens can cause chronic, subclinical, subacute, acute, and peracute forms of the disease, and clinical differentiation of the different causes of mastitis is difficult. The greatest clinical accuracy achievable, even in a specialist hospital environment and after adaptation to suit local conditions, is about 70%, which is not sufficiently accurate to be clinically useful. In other words, bacteriologic culture of milk from an affected gland is required before specific pathogen-directed treatment can be implemented.

Clinical mastitis is detected using only the results of the physical examination, and a useful definition of clinical mastitis is a negative answer to the question: Would you drink this? In other words, "undrinkable" is a simple and generalizable concept for defining clinical mastitis, because milk from cows with clinical mastitis is not suitable for drinking. New cases of clinical mastitis are defined as being separated by at least 14 days.

The clinical findings in mastitis include abnormalities of secretion, abnormalities of

the size, consistency and temperature of the mammary glands and, frequently, a systemic reaction. In other words, there are **three categories of clinical mastitis: abnormal secretion, abnormal gland, and an abnormal cow** (systemic disease). Abnormal secretion is visibly abnormal (i.e., is not drinkable). An abnormal gland is larger and firmer than other quarters. An abnormal cow is pyrexia, depressed, or has decreased appetite or milk production. This three-part categorization scheme has excellent clinical utility, is readily understood by everyone, and provides a sound pathophysiological basis for treatment. In particular, it is likely that optimal treatment protocols can be developed for the three levels of clinical mastitis. Other categorization systems have been developed, but they lack the simplicity and generalizability of the secretion, gland, and cow system.

Clinical mastitis episodes are also categorized according to their severity and duration.

**Severity** is characterized as follows:

- **Peracute:** severe inflammation with swelling and heat and pain of the quarter with a marked systemic reaction, which may be fatal
  - **Acute:** severe inflammation without a marked systemic reaction
  - **Subacute:** mild inflammation with persistent abnormality of the milk
- Duration** is characterized as follows:
- **Short-term** (as in *E. coli* and *Klebsiella* spp.)
  - **Recurrent** (as in *S. aureus* and *S. dysgalactiae*)
  - **Persistent** (as in *S. agalactiae* and *M. bovis*)

## Abnormal Secretion

Proper examination of the milk requires the use of a **strip cup**, preferably one with a **shiny, black plate** that permits the detection of discoloration as well as clots, flakes, and purulent material. Milk is drawn on to the black plate in pools, and comparisons are made between the milk of different quarters. Because the herdsman frequently has little time to examine milk for evidence of mastitis, it is customary to milk the first few streams onto the floor; in some parlors black plates are set in the floor. The practice does not appear to be harmful if the floor is kept washed down.

Discoloration may be from blood staining or wateriness, with the latter usually indicating chronic mastitis when the quarter is lactating. Little significance is attached to barely discernible wateriness in the first few streams but, if this persists for two to three streams or more, it is an abnormality. One of the major unresolved issues in bovine mastitis is how to treat a cow with abnormal secretion on the first one to two streams that subsequently has normal-looking milk. Clots or flakes are usually accompanied by discoloration and they are always significant,

indicating a severe degree of inflammation, even when small and present only in the first few streams. Blood clots are of little significance in a mastitis case, and neither are the small plugs of wax that are often present in the milk during the first few days after calving, especially in heifers. Flakes at the end of milking may be indicative of mammary tuberculosis in cattle.

During the **dry period** in normal cows, the secretion changes from normal milk to a clear watery fluid, then to a secretion the color and consistency of honey, and finally to colostrum in the last few days before parturition. Some variation may occur between individual quarters in the one cow; if this is marked, it should arouse suspicion of infection.

The **strip cup** provides a valuable tool for detecting clinical mastitis and constitutes part of the routine physical examination of the lactating cow. The most sensitive use of the strip cup is to observe the ability of milk from one quarter to mix with milk from another quarter; incomplete mixing (evidence of streaming) indicates that secretions from the two quarters differ and suggests the presence of an intramammary infection in one of the quarters. However, it should be remembered that the strip cup can only detect clinical mastitis, and detection of subclinical mastitis requires use of indirect tests such as SCC of composite milk samples from individual cows, or application of the California mastitis test (CMT) to quarter samples or measuring the electrical conductivity of quarter samples.

## Abnormal Gland

Abnormalities of size and consistency of the quarters may be seen and felt. Palpation is of greatest value when the udder has been recently milked, whereas visual examination of both the full and empty udder may be useful. The udder should be viewed from behind, and the two hindquarters should be examined for symmetry. By lifting up the hindquarters, the forequarters can be viewed. A decision on which quarter of a pair is abnormal may depend on palpation, which should be performed simultaneously on the opposite quarter of the pair. Although in most forms of mastitis the observed abnormalities are mainly in the region of the milk cistern, the whole of the quarter must be palpated, particularly if tuberculosis is suspected. The teats should be inspected and palpated for skin lesions, especially around the teat end. The supramammary lymph nodes should also be palpated for evidence of enlargement.

Palpation and inspection of the udder are directed at the detection of fibrosis, inflammatory swelling, and atrophy of mammary tissue. Fibrosis occurs in various forms. There may be a diffuse increase in connective tissue, giving the quarter a firmer feel than its opposite number and usually a more nodular

surface on light palpation. Local areas of fibrosis may also occur in a quarter; these may vary in size from pealike lesions to masses as large as a fist. Acute inflammatory swelling is always diffuse and is accompanied by heat and pain and marked abnormality of the secretion. In severe cases there may be areas of gangrene, or abscesses may develop in the glandular tissue. The terminal stage of chronic mastitis is atrophy of the gland. On casual examination an atrophied quarter may be classed as normal because of its small size, whereas the normal quarter is judged to be hypertrophic. Careful palpation may reveal that, in the atrophic quarter, little functioning mammary tissue remains.

### Abnormal Cow (Systemic Response)

A systemic response including toxemia, pyrexia, tachycardia, tachypnea, ruminal hypomotility, depression, recumbency, and anorexia may or may not be present, depending on the type and severity of the infection.<sup>23</sup> The hock-to-hock distance is increased in cattle with clinical mastitis (Fig. 20-2), reflecting a change in stance caused by the presence of localized pain in the udder.<sup>23</sup> The mechanical threshold to pain of cows with clinical mastitis is lower than that of control cows.<sup>23</sup> Daily feed intake is decreased by approximately 1.2 kg during the 5 days before clinical mastitis is detected, and cows eat more slowly and are less competitive at the feed bunk when they have clinical mastitis.<sup>24–26</sup> Cows with clinical mastitis also spend more time standing and less time lying with affected quarter(s) on the down side.<sup>25,26</sup>

A systemic response is usually associated with severe mastitis associated with *E. coli*,

*Klebsiella* spp., or *T. pyogenes* and occasionally with *Streptococcus* spp. or *Staphylococcus* spp. Clinical mastitis episodes caused by *T. pyogenes* produces the greatest decrease in milk production. In contrast, clinical mastitis caused by environmental streptococci and CNS is associated with the smallest decrease in milk production. Clinical mastitis episodes caused by *S. aureus* are associated with the highest risk of culling.

## Diagnosis of Bovine Mastitis

### Detection of Clinical Mastitis

The initial diagnosis of clinical mastitis is made during routine physical examination. Laboratory culturing of milk samples for bacteria and *Mycoplasma* spp., and for determining the antimicrobial susceptibility of *S. aureus* (specifically whether it produces  $\beta$ -lactamase), is very useful for instituting optimal treatment protocols for cows with clinical mastitis and for instituting appropriate control measures. However, because subclinical mastitis has the greatest influence on the cost of mastitis to the producer, it is also advantageous to diagnose subclinical mastitis on a cow and quarter level.

### Detection of Subclinical Mastitis

Culturing large numbers of milk samples, although the gold standard for diagnosing intramammary infection, is too expensive and impractical for routine use. Much

attention has therefore been given to the development of indirect inexpensive tests to predict the presence of an intramammary infection. Currently available indirect tests detect only the presence of inflammation (subclinical mastitis) and not intramammary infection, but are of value as screening tests; milk from quarters or cows with a positive screening test are then submitted to bacteriologic culture. **Subclinical mastitis can only be detected by laboratory examination** and cannot, by definition, be detected during routine physical examination. In other words, the secretion from a quarter with subclinical mastitis appears drinkable.

### Detection at the Herd Level

The prevalence of intramammary infection or subclinical mastitis is monitored by determining the **bulk tank milk SCC**, and the most likely mastitis pathogens are identified by **culturing bulk tank milk**. These two methods are recommended for diagnosing the presence and prevalence of mastitis pathogens on a herd basis.

### Bulk Tank Milk Somatic Cell Counts

The SCC of bulk tank milk is an indirect measure of the prevalence of mastitis within a dairy herd. The SCC is increased primarily, but not exclusively, because of subclinical mastitis associated with gram-positive bacterial intramammary infections. There is a good correlation between the number of streptococci (*S. agalactiae*, *S. dysgalactiae*, and *S. uberis*) colony forming units (CFUs) found in bulk tank milk and its SCC. The number of CFUs of *S. aureus* is moderately correlated to the bulk tank milk SCC. As contagious mastitis has become more effectively controlled, environmental mastitis pathogens have become a relatively more important cause of high SCC in bulk tank milk, especially in herds with moderate (<400,000 cells/mL) to low (<150,000 cells/mL) bulk tank milk SCC.

The **SCC of bulk tank milk** has become a widely used test because it provides a sensitive and specific indicator of udder health and milk quality. The sample for analysis is obtained by agitating the milk for 5 to 10 minutes and collecting a sample from the top of the bulk tank milk using a clean dipper. The sample should not be collected near the outlet valve because this varies from that in the rest of the tank. The SCC of bulk tank milk is widely used to regulate whether milk may be legally sold and to determine the price paid for raw milk. Premium and penalty payments are calculated on the basis of a 3-month geometric mean of weekly bulk tank SCC measurements. Milk processing plants in most developed countries use automatic electronic somatic cell counters routinely to provide a monthly report of the bulk tank milk SCC. The test requires only that the sample for examination be taken randomly and not frozen, that it be prepared

**Fig. 20-2** Increased hock-to-hock distance in a Holstein Friesian cow with clinical mastitis in the right rear quarter.

**Table 20-1** Estimated prevalence of infection and losses in milk production associated with bulk tank milk somatic cell count

Bulk tank milk somatic cell count (cells/mL)	Infected quarters in herd (%)	Production loss (%)
200,000	6	0
500,000	16	6
1,000,000	32	18
1,500,000	48	29

with the correct reagent, that the laboratory counter be set at the right calibration, and that the sample be examined quickly or preserved with formalin to prevent cell losses during storage. The bulk tank milk SCC is extremely useful in creating awareness of the existence of a mastitis problem, so that when the SCC of bulk tank milk exceeds permissible limits further investigation of the herd is indicated. In a seasonal herd in which all cows are at the same stage of lactation, the bulk milk cell count will normally be high in early lactation and just before drying off. To overcome these and other factors that are likely to transiently influence bulk tank milk SCC, it is recommended that correction factors be introduced into the estimation or that a rolling SCC, in which monthly data are averaged for the preceding 3 months, be used. Consideration of this figure will avoid too hasty conclusions on one high count caused by an extraneous factor.

It is not possible to use the bulk tank milk SCC to determine the number of cows in a herd affected by mastitis, but it is possible to estimate fairly accurately the number of infected quarters. Generally, as the bulk tank milk SCC increases, the prevalence of infection increases and losses in production increase. Production losses calculated as a percentage of production expected with a count of 200,000 cells/mL are shown in Table 20-1. A bulk tank milk SCC of more than 300,000 cells/mL is considered to indicate a level of mastitis in the herd that warrants examination of individual cows. Herds with a high bulk tank milk SCC have significantly lower production levels and are less likely to use a postmilking teat dip or to have a regular program of milking machine maintenance or automatic cluster removal.

### Culture of Bulk Tank Milk

Bacteria present in bulk tank milk may originate from infected udders, from teat and udder surfaces, or from a variety of other environmental sources; however, despite the large number of potential sources for bacteria, culture of bulk tank milk is a useful technique for screening for major mastitis pathogens. The culture of *S. aureus* and *S. agalactiae* from bulk tank milk is a reliable indicator of infection by those pathogens in

the herd. The number of those pathogens found on culture is determined by the number of bacteria shed, the number of infected cows, the milk production level of infected cows relative to herd mates, and the severity of infection. A single culture of bulk tank milk has low sensitivity but high specificity for determining the presence of *S. agalactiae* or *S. aureus* in the herd. Thus many infected herds will be called negative, but very few uninfected herds will be called positive. Pathogens such as *Nocardia* spp. and *Mycoplasma* spp. have also been identified by culture of bulk tank milk. Generally, the sensitivity of a single bulk tank milk culture to detect the presence of intramammary infections caused by *S. agalactiae* ranges from 21% to 77%, for *S. aureus* it ranges from 9% to 58%, and for *M. bovis* it is 33%.

Environmental bacteria such as *S. uberis*, *S. dysgalactiae*, and coliforms may enter milk from intramammary infections, but also from nonspecific contamination. The presence of these organisms in bulk tank milk may relate to the general level of environmental contamination and milking hygiene in the herd. Udder infections with these environmental pathogens are predominantly of short duration and characterized by clinical disease, which makes their inadvertent introduction to the bulk tank less likely.

**String sampling** or milk line sampling from the positive pressure side of the milking system is the collection of milk samples from a group of cattle instead of the entire herd, as in bulk tank milk sampling. String sampling may have some merit in identifying subgroups of cattle with the highest prevalence of infection. It is thought to be more sensitive in monitoring herds for contagious pathogens than bulk tank milk sampling. If a production group tests positive on a string culture, then individual composite milk cultures can be performed to identify individual animals. Information of the culture results from string sampling should assist development of control programs; however, milk samples left in the pipeline from one string can confound the culture results of subsequent strings.

Numerous bacteriologic techniques have been used to isolate and identify pathogens in bulk tank milk, but none has been established as the gold standard method for the culture of milk from bulk tanks. The most suitable laboratory medium for growth and classification of the pathogens from bulk tank milk needs to be determined. Sampling strategies have included weekly and monthly samples, but it remains to be determined which strategy is optimal relative to herd size and management, disease characteristics, and practicality.

### Detection at the Individual Cow Level

**Abnormalities of the udder and gross abnormalities of milk** in cattle with clinical

mastitis have been described earlier. In individual cows with clinical mastitis, culture of the secretion from an infected quarter can be done. In animals without clinical mastitis, culture of the secretion represents a direct test for intramammary infection. The objective is to identify cows with contagious mastitis so that they can be treated or culled, or to identify the nature and source of environmental mastitis pathogens. Fulfillment of these requirements requires bacteriologic culture of milk samples so that the pathogens can be named; this is because **identification of mastitis pathogens is central to the development of effective treatment and control programs**. Detection of infected cows requires an individual cow examination and application of an indirect (screening) test for subclinical mastitis, such as the SCC of a composite milk sample, followed by culture of a representative subset of cows to determine the most prevalent pathogen. **Indirect tests estimate the prevalence of infection, and microbiological examination identifies the mastitis pathogens;** from this information an appropriate control plan can be formulated.

### Culture of Individual Cow Milk

Individual cow milk can be cultured as part of a herd examination for mastitis, or on individual **quarter samples**, or on **composite samples** including milk from all four quarters. A variety of definitions have been used for diagnosing the presence of an intramammary infection in research studies, such as the presence of the same pathogen in duplicate samples collected immediately after each other, or the presence of the same pathogen in two of three consecutive cultures obtained on different sampling dates. These definitions are too expensive and impractical for clinical practice. **Individual quarter samples are preferred** by some at dry off because the costs of treatment dictate that the least possible number of quarters be treated. With this technique only affected quarters are treated at dry off; if the quarter infection rate is low the saving in treatment costs is relatively large if the cost of culturing is low. A full economic comparative analysis of the balance between the cost of diagnosis versus the cost of treatment on a quarter or cow basis does not appear to have been performed. A confounding issue is that within a cow the four quarters are not independent in relationship to intramammary infection or subclinical mastitis; if one quarter is infected then there is an increased probability that one or more of the remaining quarters are infected or have subclinical mastitis.<sup>1</sup> On this basis, when treating subclinical intramammary infection at dry off, it makes more sense to treat the cow (i.e., all four quarters) and not specific quarters within a cow.

A consensus has been reached as to how best to interpret a single milk culture from a quarter (Table 20-2).<sup>2-4</sup> A reasonable

**Table 20-2** Sensitivities and specificities for diagnosing an intramammary infection based on the culture of a single milk sample from a quarter using a 10-μL volume

Threshold for detection (CFU/10 μL)	SENSITIVITY (%) / SPECIFICITY (%)			
	CNS <sup>a</sup>	<i>Staphylococcus aureus</i>	<i>Streptococcus</i> spp. <sup>b</sup>	<i>Escherichia coli</i>
≥1	61.2/84.3	90.4/99.8	29.1/94.8	76.5/99.9
≥10	26.0/98.1	72.0/100.0	6.9/99.9	47.1/100.0

<sup>a</sup>CNS, coagulase-negative staphylococci.  
<sup>b</sup>Primarily *S. uberis*.

definition of an intramammary infection is ≥1 CFU/10 μL. Culturing duplicate milk samples from the quarter (at the same milking or close together in time) can improve the sensitivity or specificity definition, but not both.

Milk sampling for culture must be performed with due attention to cleanliness because samples contaminated during collection are worthless. The technique of cleaning the teat is of considerable importance. If the teats are dirty, they must be washed and then properly dried or water will run down the teat to the teat end and infect the milk sample. The end of the teat is cleaned with a swab or gauze dipped in 70% alcohol, extruding the external sphincter by pressure to ensure that dirt and wax are removed from the orifice. Brisk rubbing is advisable, especially of teats with inverted ends. The first two or three streams are rejected because their cell and bacterial counts are likely to be a reflection of the disease situation within the teat rather than within the udder as a whole. The next few streams, the premilking sample, are the approved ones because of their greater accuracy. For complete accuracy a premilking and a postmilking sample are taken. Indirect and chemical tests for mastitis can be performed more accurately on foremilk as on later milk, partly because the strippings have a higher fat concentration that alters the water compartment of milk on a volume basis.

If individual quarter samples are collected, screw-cap vials are most satisfactory. During collection the vial is held at an angle to the ground to avoid as much as possible the entrance of dust, skin scales, and hair. If there is delay between the collection of samples and laboratory examinations, the specimens should be refrigerated or frozen. Freezing of milk samples appears to have variable effects on bacterial counts, depending on the bacteria. *T. pyogenes* and *E. coli* counts are decreased by freezing, coagulase-negative *Staphylococcus* spp. counts are increased, and *Streptococcus* and *S. aureus* counts are either unaffected or increased.

The laboratory techniques used vary widely and depend to a large extent on the facilities available. Incubation on blood agar

is most satisfactory, because selective media for *S. agalactiae* have the disadvantage that other pathogens may go undetected. Smears of incubated milk are generally unsatisfactory because not all bacteria grow equally well in milk, and the bacterial count has to be high for microscopic detection. Augmented systems of culturing milk samples, which can provide superior results in terms of the number of infected quarters detected depending on the pathogen, include a variety of approaches, such as preculture incubation,<sup>5</sup> centrifugation,<sup>6</sup> freezing of the milk sample at -20 or -196°C (-4 or -321°F),<sup>7,8</sup> and inoculation of the medium with a larger inoculum volume (100 μL) than the standard inoculum volume of milk.<sup>9</sup> The concern with augmented culture methods is that they may amplify contaminants obtained during sampling and therefore decrease the specificity of milk culture. Laboratory culturing techniques can be very time-consuming and expensive unless modern, prepackaged identification systems are used that provide the speed needed to make the examination a worthwhile one.

A milk sample is considered contaminated when three or more species of bacteria are isolated. A quarter is considered to be cured when bacteria, isolated at initial sample, are not present in any samples 14, 21, or 28 days later. An uninfected quarter at the initial sampling time that is infected when resampled at 14, 21, or 28 days indicates a new intramammary infection. A quarter that is infected at initial sampling but infected with another bacteria 14, 21, or 28 days later also indicates a new intramammary infection.

Selective culture media plates, such as biplates (MacConkey agar and blood agar with 1% esculin), triplates (MacConkey agar, blood agar, and TKT agar [thallium, crystal violet, and staphylococcal toxin] in 5% blood agar with 1% esculin), AccuMast, Minnesota Easy Culture System II, Petrifilm, and Veto-Rapid plates can be used to differentiate between gram-positive and gram-negative pathogens and no growth, and they may aid in the rational and targeted use of antimicrobial agents for clinical cases of mastitis.<sup>10-14</sup> A major advance in mastitis pathogen identi-

cation is the use of an automated mass spectrometry (MS) system that uses matrix-assisted laser desorption ionization time-of-flight (MALDI-TOF) technology. MS of representative bacterial colonies provides species information on bacterial isolates, particularly CNS.

There is interest in developing other cow-side tests to determine whether the causative pathogen is gram-negative or gram-positive. One such approach uses dilution of the milk sample, filtration through a membrane with a pore size that retains bacteria, and staining of the bacteria with specific stains. The filtration procedure takes 5 minutes, but the need for microscopic examination decreases the utility of this as a cow-side test. A commercially available cow-side test for endotoxin (Limast-test), which indicates the presence of gram-negative bacteria, was used in Scandinavia but appears to be no longer available.

A common diagnostic problem is a bacteriologically negative culture in cows with clinical mastitis. Even when milk samples are collected appropriately and bacteriologic culture is done using routine laboratory methods, 15% to 40% of samples from clinical mastitis episodes are bacteriologically negative (yield no growth). Failure of these samples to yield a mastitis pathogen may be the result of spontaneous elimination of infection, a low concentration of pathogens in the milk, intermittent shedding of the pathogen, intracellular location of the pathogens, or the presence of inhibitory substances in the milk. Augmented culture techniques may reduce, but do not eliminate, negative culture results and may facilitate growth of contaminant organisms. Dairy producers and veterinarians therefore face a dilemma when no bacteria or bacteria commonly regarded to be of minor pathogenicity, such as *C. bovis* or coagulase-negative *Staphylococcus* spp., are cultured from the milk of cows with clinical mastitis, particularly if clinical signs persist. Most bacteriologically negative cases of clinical mastitis appear to be caused by low-grade infections with gram-negative bacteria. When no bacterial pathogen can be isolated from cases of clinical mastitis using standard culture techniques, enzyme-linked immunosorbent assays (ELISAs) may be used to detect antigens against *S. aureus*, *E. coli*, *S. dysgalactiae*, and *S. agalactiae*. Antigens to these pathogens may be detectable using an ELISA in up to 50% of quarter samples from cows with clinical mastitis in which no pathogens were isolated but in which the SCC was more than 500,000 cells/mL. Despite these promising findings, ELISAs are not widely used in the identification of mastitis pathogens.

A real-time commercially available multiplex polymerase chain reaction (PCR) test (PathoProof) was globally launched in 2008 for the diagnosis of mastitis pathogens. The test has potentially valuable advantages of

greater sensitivity and faster time to produce a definitive result. The major disadvantages are cost (typically more expensive than routine milk culture), the inability to determine whether bacterial remnants detected by PCR in a milk sample reflect the presence of viable bacteria, and the lack of susceptibility testing results.<sup>15–19</sup> The bacterial remnant versus viability issues is particularly problematic when low amounts of pathogenic DNA have been detected, and a consensus on the economic value of PCR testing has not been reached.<sup>20,21</sup> In 2015, more than 80% of quarter milk samples in Finland were diagnosed using PCR.<sup>16</sup> Currently, PCR tests appear to provide their greatest value in the routine testing of bulk tank milk for pathogen surveillance, for research studies related to clinical mastitis episodes with no bacterial growth on culture, and for investigating mastitis epidemics caused by an unusual pathogen.

### Indirect Tests for Subclinical Mastitis

Indirect tests include SCCs using automated electronic counters, the CMT, increases in electrical conductivity of milk, and increases in the activity of cell associated enzymes (such as NAGase) in milk. ELISA tests to detect neutrophil components have been developed but are not commercially available. Of these indirect tests, only the CMT and electrical conductivity can be used cowside, with CMT providing a more accurate screening test than electrical conductivity. It is important to understand that these indirect tests detect the presence of inflammation (subclinical mastitis) and not the presence of intramammary infection, although the vast majority of subclinical mastitis episodes are caused by intramammary infection.

### The Somatic Cell Count of Composite or Quarter Samples

There is a strong relationship between the SCC of quarter samples of milk and the milk yield, with SCC increasing slightly as milk production decreases but increasing markedly with intramammary infection of the quarter. The distribution of SCC in a herd reflects the distribution of subclinical mastitis and therefore the likely distribution of intramammary infections. The most important factor affecting SCC in an individual cow is the number of quarters infected with a major or minor pathogen. In most herds, the prevalence of infection will increase through a lactation and will also increase with the age of the cow. Cell counts in the first few days of the lactation are often exceptionally high and unreliable as indicators of intramammary infection, and in uninfected cows the counts will drop to a low level within 2 weeks of calving and remain low throughout the lactation unless an intramammary infection occurs. The SCC of a cow that remains free of infection

**Fig. 20-3** Mean deviation (in log<sub>10</sub>) of selected milk constituents from the overall means in relation to somatic cell count ( $n = 9326$  quarter milk samples). (Reproduced with permission from Hamann J. XXII World Buiatrics Congress, Hannover, August 18-23, 2002, 334-345.)

throughout her life will remain very low. However, older cows may have higher counts because the prevalence of infection is higher with age, and older cows are more likely to have had previous infections with residual lesions and leaking of somatic cells into the milk. There are also consistent and significant differences in actual SCC between cows, with individual cows tending to maintain the same class of count throughout their lives. Cows that have consistently low SCC do not seem to be more susceptible to mastitis than others. Attempts to base a breeding program to reduce the prevalence of mastitis on the selection of cows with an innately low composite SCC have been discarded because of fluctuations in numbers within cows.

Healthy quarters have an SCC below 100,000 cells/mL, and **this cut point should be used to indicate the absence or presence of intramammary infection on a gland basis**. This cut point looks very solid for a gland, because many milk components differ from normal values whenever the SCC exceeds 100,000 cells/mL (Fig. 20-3). Moreover, mean SCC counts for bacteriologically negative quarters, quarters infected with minor pathogens, and quarters infected with major pathogens were 68,000, 130,000, and more than 350,000 cells/mL, respectively.

Because of the time and labor saved it is now customary to do automated electronic cell counts on **composite milk samples** that have already been collected for butterfat testing. Regular reports of individual cow SCCs are therefore widely available in herds that routinely test production parameters of their cattle. An exciting new development in mastitis control is the **portable somatic cell counter**, which was designed for on-farm use, providing targeted and immediate SCC information for quarter or composite milk

samples. Using the composite sample technique does distort the SCC; for example, the dilution of high-SCC milk from a bad quarter by low-SCC milk from three normal quarters could mean that a cow with one infected quarter might not be detected. Composite SCCs of less than 200,000 cells/mL are considered to be below the limit indicative of inflammation, even though uninfected quarters have an SCC of less than 100,000 cells/mL. Factors that affect the composite milk SCC include the number of quarters infected, the kind of infection (*S. agalactiae* is a more potent stimulator of cellular reaction than *S. aureus*), the strictness with which milk from cows with clinical mastitis is kept out of the bulk tank, the age of the cows (older cows have higher counts), the stage of lactation (counts are highest in the first days after calving and toward the end of lactation), and the herd's average production with the cell count reducing as milk yield increases.

An SCC scoring system that divides the SCC of composite milk into 10 categories from 0 to 9, known as the somatic cell score (SCS) (originally called the linear score), is becoming more widely used. The SCS is a base 2 logarithm of the SCC (in cells/mL), in which  $SCS = \log_2(SCC/100,000) + 3$ . Likewise, to calculate SCC (in cells/mL) from the SCS, the following formula is used:  $SCC = 100,000 \times 2^{(SCS - 3)}$ . An SCC of 100,000 cells/mL therefore converts to an SCS of 3. Each 1-unit increase (or decrease) in SCS is associated with a doubling (or halving) of the SCC. For example, score 2 is equivalent to an SCC of 50,000 cells/mL, and scores of 4 and 5 correspond to 200,000 and 400,000 cells/mL. Conversion of SCC to SCS values is performed as shown in Tables 20-3 and 20-4. The principal reason for using the SCS is to achieve properties that are required to use

conventional statistical methods: mean equal to median, normal distribution, and uniform variance among samples within lactation, among cows within herd or among daughters within sire.

The proportion of neutrophils in the SCC is very low (<11%) in healthy quarters but is

markedly increased in quarters with intramammary infection (to >90%). Accordingly, the percentage of neutrophils in the SCC may provide a useful indication of intramammary infection, but it is not currently performed.

SCSs can also be determined for colostrum, in which they are useful in indicating the presence of intramammary infection (Table 20-5).

#### California Mastitis Test of Quarter Samples

The CMT is the most reliable and inexpensive cowside test for detecting subclinical mastitis. It is also known as the rapid mastitis test, Schalm test, or the Mastitis-N-K test, which was developed in 1957 and constituted a modification of the Whiteside test. The CMT reagent contains a detergent that reacts with DNA of cell nuclei and a pH indicator (bromocresol purple) that changes color when the milk pH is increased above

its normal value of approximately 6.6 (mastitis increases pH to 6.8 or above). The CMT is mixed with quarter milk samples that have been previously collected into a white container, and the sample is gently swirled; the result is read within 15 seconds as a negative, trace, 1, 2, or 3 reaction depending on the amount of gel formation in the sample. Maximum gel formation actually occurs from 1 to 2.5 minutes, depending on the quarter SCC, and continued swirling of the mixture after the time of peak viscosity produces an irreversible decrease in viscosity. Cows in the first week after calving or in the last stages of lactation may give a strong positive reaction.

The close relationships between the CMT reaction and the SCC of milk, and the reduced productivity of affected cows, are shown in Tables 20-4 and 20-5, respectively. If the CMT is used to minimize the false-negative rate (produce the highest sensitivity), then the test should be read as negative (CMT = negative) or positive (CMT = trace, 1, 2, or 3). If the CMT is used to minimize the false-positive rate (produce the highest specificity) for culling decisions, then the test should be read as negative (CMT = negative or trace) or positive (CMT = 1, 2, or 3).

CMT scores can also be determined for colostrum, in which the score is useful in indicating the presence of intramammary infection (see Table 20-5). The equivalent SCC for CMT scores of negative or trace are different for colostrum and milk, but the SCC for CMT scores of 1, 2, and 3 are similar for colostrum and milk.

#### NAGase Test of Composite or Quarter Samples

The NAGase test is based on the measurement of the activity of a cell-associated enzyme (*N*-acetyl- $\beta$ -D-glucosaminidase) in

**Table 20-3** Calculating somatic cell score (previously called linear score) from the somatic cell count

Example: SCC = 200,000 cells/mL

- Divide the SCC by 100,000 cells/mL (200,000/100,000 = 2)
- Determine the natural log (ln) of the results of step 1 (ln 2 = 0.693)
- Divide this value by 0.693 (i.e., 0.693/0.693 = 1)
- Add 3 to the result of step c: 1 + 3 = 4 (SCS)

SCC, somatic cell count; SCS, somatic cell score.

**Table 20-4** Conversion of somatic cell scores (previously called linear scores) to somatic cells counts (cells/mL) and predicted loss of milk

SCS	Somatic cell count midpoint (cells/mL)	POUNDS OF MILK LOST PER LACTATION	
		First lactation	Second lactation
0	12,500	0	0
1	25,000	0	0
2	50,000	0	0
3	100,000	200	400
4	200,000	400	800
5	400,000	600	1,200
6	800,000	800	1,600
7	1,600,000	1,000	2,000
8	3,200,000	1,200	2,400
9	6,400,000	1,400	2,800

SCS, somatic cell score.

**Table 20-5** California mastitis test reactions and equivalent somatic cell counts and somatic cell scores for bovine milk and somatic cell counts for bovine colostrum

Test result	Reaction observed	Equivalent milk SCC	Equivalent SCS	Colostrum geometric mean SCC
Negative	The mixture remains fluid without thickening or gel formation.	0–200,000 cells/mL	0–4	500,000 cells/mL
Trace	A slight slime formation is observed. This reaction is most noticeable when the paddle is rocked from side to side.	150,000–500,000 cells/mL	5	670,000 cells/mL
1+	Distinct slime formation occurs immediately after mixing solutions. This slime may dissipate over time. When the paddle is swirled, fluid does not form a peripheral mass, and the surface of solution does not become convex or “domed up.”	400,000–1,500,000 cells/mL	6	890,000 cells/mL
2+	Distinct slime formation occurs immediately after mixing solutions. When the paddle is swirled the fluid forms a peripheral mass, and the bottom of the cup is exposed.	800,000–5,000,000 cells/mL	7–8	3,400,000 cells/mL
3+	Distinct slime formation occurs immediately after mixing solutions. This slime may dissipate over time. When the paddle is swirled the surface of the solution becomes convex or domed up.	>5,000,000 cells/mL	9	6,260,000 cells/mL

SCC, somatic cell count; SCS, somatic cell score.

**Fig. 20-4** Schematic representation of the development of mastitis in an infected udder. Contagious and environmental pathogens invade the udder via the streak canal and teat cistern. The pathogens then multiply in the udder in which they are attacked by neutrophils. Epithelial cells lining the alveoli are damaged during bacterial multiplication and subsequent immunologic response, with release of enzymes such as NAGase and lactate dehydrogenase (depicted). The tissue response to infection varies based on pathogen, infective dose, immunologic state, and response of the cow, as well as other factors. (Reproduced with permission from Viguier C, Arora S, Gilmartin N, Welbeck K, O Kennedy R (2009) Mastitis detection: current trends and future perspectives. *Trends Biotechnol* 27:486-493.)

the milk, with a high enzyme activity indicating a high cell count (Fig. 20-4). NAGase is an intracellular lysosomal enzyme derived primarily from damaged mammary epithelial cells with a small contribution from neutrophils.<sup>22</sup> The test is suited to the rapid handling of large numbers of samples because of the ease of its automation, and the test can be done on fresh milk and read on the same day. However, because most of the NAGase activity is intracellular, samples should be frozen and thawed before analysis to induce maximal NAGase activity. The NAGase test is reputed to be the most accurate of the indirect tests and as good as SCC in predicting the infected status of a quarter.<sup>23,24</sup> It uses a less sophisticated reading instrument than the average automatic cell counter. If all tests are available it is best to consider the NAGase test and SCC as complementary tests and perform both of them. Milk NAGase levels are high at the beginning and the end of lactation, as with cell counts. The test has also been validated for use with goat milk.

Related tests that have not been studied as extensively as NAGase but show promise in the detection of subclinical mastitis are milk lactate dehydrogenase (LDH) and

alkaline phosphatase (ALP) activity.<sup>24-29</sup> Both enzymes are cytoplasmic constituents of cells, and an increase in milk activity of LDH or ALP indicates the presence of cellular injury.

#### Electrical Conductivity Tests of Quarter Samples

A test that has received a great deal of attention because it can be used in robotic milking systems is based on the increase in concentration of sodium and chloride ions, and the consequent increase in electrical conductivity, in mastitic milk. The electrolyte changes in milk are the first to occur in mastitis, and the test is attractive for this reason. A number of factors affect these characteristics; however, and to derive much benefit from the test it is necessary to examine all quarters and use differences between the quarters to indicate affected quarters. For greater accuracy all quarters need to be monitored each day. An experimental unit that takes all these factors into consideration has been fitted to a milking machine and, by a computer-prepared analysis, monitors variations in electrical conductivity in each quarter every day. Electrical conductivity is attractive as a test because it measures actual injury to the

udder rather than the cow's response to the damage like SCC and NAGase activity do. However, a meta-analysis indicated that using an absolute threshold for conductance did not provide a suitable screening test, because both sensitivity and specificity were unacceptably low. In addition, in a study of 173 dairy cows in South Africa, the CMT was more accurate than electrical conductivity for identifying quarters having an intramammary infection or an SCC > 200,000 cells/mL.<sup>30</sup> The use of differential conductivity (within cow quarter comparison) results in improvement in test sensitivity and specificity and is currently the only recommended application of this indirect test.

The most commonly promoted method for measuring electrical conductivity is a handheld device with a built-in cup into which milk is squirted (foremilk is preferred). Experimentally induced clinical mastitis caused by *S. aureus* and *S. uberis* was detectable by changes in electrical conductivity of foremilk: 90% of cases were detectable when clots first appeared and 55% of cases were detectable up to two milkings before the appearance of clots. This suggests that clinical mastitis associated with these

two major pathogens may be able to be detected earlier by electrical conductivity than by waiting for milkers to detect visible changes in the milk.

Changes in electrical conductivity reflect changes in secretion Na, K, and Cl concentration, and it is likely that measurement of Na and K ion concentrations in milk will provide a low-cost clinically useful diagnostic test for subclinical mastitis.<sup>30,31</sup>

L-lactate, glucose, lactose, and haptoglobin concentration in quarter samples. L-lactate concentration is markedly increased in the milk of cows with clinical mastitis, and is mildly to moderately increased in cows with subclinical mastitis.<sup>29,31</sup> The magnitude of the increase appears to be correlated with the leukocyte count in milk and the number of CFUs.<sup>32</sup> Glucose concentration is decreased in the milk of cows with clinical mastitis and subclinical mastitis through a yet to be determined mechanism.<sup>31</sup> Milk lactose percentage is decreased in cows with subclinical mastitis because milk is isotonic and inflammation increases the secretion concentration of Na, K, and Cl. Because milk is isotonic and lactose is the predominant osmotic agent in milk, the increase in electrolyte concentrations directly leads to a decrease in lactose concentration, measured on a percentage basis.<sup>22</sup>

The concentration of serum amyloid A and haptoglobin, which are acute phase reactants, increases in the secretion from glands with subclinical mastitis.<sup>28</sup> Skim milk haptoglobin concentration can discriminate between mastitis episodes caused by major or minor pathogens,<sup>27</sup> although this is most likely an indirect association, because major pathogens, by definition, cause greater injury to the mammary gland.

### Comparison of Indirect Methods

The effects of subclinical intramammary infection on several parameters in foremilk from individual quarter milk samples have been compared. The SCC, electrical conductivity, pH, NAGase activity, and the concentrations of sodium, potassium, lactose, and  $\alpha$ -1-antitrypsin were measured from individual quarters. The SCC, NAGase activity, electrical conductivity, and concentrations of sodium,  $\alpha$ -1-antitrypsin, and lactose were all useful indirect indicators of infection. The SCC was able to discriminate between infected and uninfected quarters in cows better than electrical conductivity, pH, and NAGase activity.

### Hematology and Serum Biochemistry

In severe clinical mastitis there may be marked changes in the leukocyte count, packed cell volume, and serum creatinine and urea nitrogen concentration because of the effects of severe infection and toxemia. In particular, clinical mastitis episodes associated with gram-negative bacteria frequently cause a profound leukopenia, neutropenia,

lymphopenia, and monocytopenia as a result of the endotoxemia, as well as an increased packed cell volume. In contrast, the leukogram in cattle with clinical mastitis associated with gram-positive bacteria is normal or mildly increased.

### Ultrasonography of the Mammary Gland

Two-dimensional (2D) ultrasonographic images of the gland cistern, parenchymal tissue, and teat are easily obtained using a 5-, 7.5-, or 8.5-MHz linear array transducer, and ultrasonography is becoming more widely used to guide treatment of teat and gland cistern abnormalities. However, there are few reports of the use of ultrasonography to diagnose or prognose clinical mastitis episodes, although this is likely to be a fruitful area for investigation.

The best 2D images of the udder parenchyma are obtained by clipping the hair on the udder and applying a coupling gel. This minimizes the air between the transducer face and skin. Imaging the normal adjacent quarter is very helpful in identifying abnormalities. Imaging should be performed in two planes, sagittal to the teat (and therefore perpendicular to the ground), and transverse to the teat (and therefore horizontal to the ground). The injection of sterile 0.9% NaCl through a teat cannula into the gland provides a practical contrast agent that can help further define the extent of any abnormalities. The superficial supermammary lymph nodes can be seen on ultrasound using a 7.5-MHz linear transducer, and the lymph node is well demarcated from the surrounding tissues. Mean lymph node length was 7.4 cm (range 3.5–15.0 cm) and mean depth was 2.5 cm (range 1.2–5.7 cm). Lymph node size increased with age and is predictive of the presence of subclinical intramammary infection in cattle.<sup>33</sup> Similarly, superficial inguinal lymph node size is predictive of SCC in sheep.<sup>34</sup>

Mastitis produces an increased heterogeneous echogenicity to the milk in the gland cistern, compared with an uninfected quarter.<sup>35</sup> It is important to make this visual comparison without altering the contrast and brightness setting on the ultrasonographic unit.

### Infrared Thermography of the Mammary Gland

Infrared thermography shows promise for the real-time noninvasive diagnosis of mastitis in dairy cattle. This will be particularly valuable in cattle that are robotically milked, in which the diagnosis of clinical mastitis remains problematic.

Methodology for infrared thermography has been developed for the mammary gland.<sup>36</sup> Thermograms should be obtained with the animal in an environment to which it has been adapted for 30 minutes and out of direct sunlight and wind. The udder

should be free from moisture, dirt, and foreign material; this is usually accomplished by brushing the hair on the udder or washing and drying the udder. Thermography is effective for the early diagnosis of clinical mastitis.<sup>37–39</sup> There have been mixed reports regarding the accuracy of thermography to detect subclinical mastitis in dairy cattle<sup>40,41</sup> using mean quarter temperature and maximum quarter temperature.<sup>36,39</sup>

### Biopsy of Mammary Tissue

A biopsy of mammary tissue can be used for histologic and biochemical evaluation in research studies. The use of a rotating stainless steel cannula with a retractable blade at the cutting edge has been described for obtaining biopsy material from cows. Despite some postoperative bleeding, milk yield and composition in the biopsied gland were affected only transiently.

### NECROPSY FINDINGS

Necropsy findings are not of major interest in the diagnosis of mastitis and are omitted here but included in the description of specific infections.

### DIFFERENTIAL DIAGNOSIS

The diagnosis of clinical mastitis is not difficult if a careful clinical examination of the udder is performed as part of the complete examination of a cow with systemic clinical findings. Examination of the udder is sometimes omitted in a recumbent animal only for severe mastitis to be discovered later. The diagnosis of mastitis depends largely on the detection of clinical abnormalities of the udder and gross abnormalities of the milk or the use of an indirect test like the California mastitis test to detect subclinical mastitis.

Other mammary abnormalities that must be differentiated from clinical mastitis include **udder edema**, **rupture of the suspensory ligament**, and **hematoma**. These are not accompanied by abnormalities of the milk unless there is hemorrhage into the udder. The presence of stray voltage in the milking plant should not be overlooked in herds in which the sudden lowering of production arouses an unfounded suspicion of mastitis. Differentiation of the different causes of mastitis is difficult on the basis of clinical findings alone but must be attempted, especially in peracute cases in which specific treatment must be given before results of laboratory examinations are available. A pretreatment sample of milk from the affected glands for culture and antimicrobial sensitivity may provide useful information about the health record of the cow and the need to consider alternative therapies, and could provide information on new infections in the herd.

## TREATMENT OF BOVINE MASTITIS

The treatment of the different causes of clinical and subclinical mastitis may require specific protocols, which are described under specific mastitis pathogens later in the chapter. The general principles of mastitis treatment are outlined here.

## Historical Aspects of Antimicrobial Therapy for Clinical and Subclinical Mastitis

Between about 1950 and 1990, on a worldwide basis, all forms of both clinical and subclinical bovine mastitis were treated with a wide variety of antimicrobial agents either by intramammary infusions or parenterally and commonly by both routes in acute and peracute cases. Most veterinarians treated clinical mastitis and evaluated the response on the basis of clinical outcome. Generally, it was thought that antimicrobial agents were effective for the treatment of clinical and subclinical mastitis in lactating cows. However, there are very few scientific publications based on randomized clinical trials in which the efficacy of intramammary antimicrobial agents for treatment of clinical mastitis was compared with untreated controls. If antimicrobial agents were used and the animal recovered, it was assumed that treatment was efficacious. If the cow did not respond favorably, several reasons were usually enumerated for the treatment failure. However, most of these reasons, although biologically attractive, are hypothetical and have not been substantiated scientifically. Gradually, over the years, veterinarians began to doubt the efficacy of antimicrobial agents for the treatment of all cases of clinical mastitis. In addition, and of major importance, milk from treated cows had to be discarded for up to several days after the last day of treatment because of antimicrobial residues; this was a major expense. Currently, optimized treatment strategies focus on efficacy, economics, animal welfare aspects, and the milk withhold time of antimicrobial treatment.

Efficacy is assessed on the basis of **clinical cure** or **bacteriologic cure**. Most producers are interested in the return to normal milk (clinical cure) and are much less interested in the return to a sterile quarter (bacteriologic cure). Because clinical mastitis is defined as abnormal milk, the return to normal (drinkable) milk represents a clinical cure. Bacteriologic cure represents the inability to isolate the initial pathogen 14 to 28 days after the start of treatment. Other important indicators of efficacy are milk production, dry matter intake, the amount of saleable milk, and mortality or culling rates after treatment.

Some examples of the efficacy or inefficacy of antimicrobial agents illustrate the controversy. It is well accepted that the cure rate following intramammary treatment of clinical or subclinical mastitis caused by *S. agalactiae* in the lactating cow is high (80%–90%). In contrast, the cure rate of clinical and subclinical mastitis caused by *S. aureus* in the lactating cow is considerably lower (40%–50%), but certainly not 0%. In herds with a low prevalence of contagious mastitis, most cases of mild clinical mastitis (abnormal secretion only) in lactating cows are caused by environmental streptococci and coliforms

and may recover without antimicrobial therapy, although antimicrobial administration increases the clinical and bacteriologic cure rate. Antimicrobial agents may be ineffective for the treatment of clinical mastitis associated with *M. bovis*, *T. pyogenes*, *Nocardia* spp., and *P. aeruginosa*.

In the 1970s dairy processing plants, veterinarians, consumer advocates, public health authorities, and milk-quality regulating agencies began to express concern about antimicrobial residues in milk from cows treated for mastitis. The public health and milk industry concerns about residues combined with the controversy about the efficacy of antimicrobial agents for clinical mastitis has also provided a stimulus to evaluate the efficacy and consequences of using antimicrobial agents. Since the early 1990s, much emphasis has been placed on alternative methods of treating clinical mastitis, leading to a reduction in the use of antimicrobial agents during the lactating period. Such strategies have been defended based on a lack of information concerning the efficacy and economics of antimicrobial therapy associated with pathogens other than *S. agalactiae*, and by the need to reduce the risk of residue violation. However, a recent study concluded that not administering antibiotics to cows with clinical mastitis was imprudent and unethical.

There is a need for additional randomized controlled field trials to evaluate the use of antimicrobial agents for the treatment of clinical mastitis. Well-conducted clinical mastitis treatment trials represent an invaluable, although difficult and expensive, effort to evaluate efficacy of antimicrobial agents under field conditions. It should be noted that the use of antimicrobial agents for the treatment of **subclinical mastitis** at the end of lactation, known as **dry cow therapy**, is accepted worldwide and is based on scientific evidence using randomized clinical trials. Dry cow therapy is one of the principles applied in the effective control of bovine mastitis, in which much progress has been made since the early 1970s.

## Treatment Strategy

The treatment strategy will depend on whether the mastitis is **clinical** or **subclinical** and the health status of the herd, including its mastitis history. Clinical mastitis is further categorized as **abnormal secretion**, **abnormal gland**, or **abnormal cow**, as described previously. If treatment is indicated, the major decision is whether to administer antimicrobial agents parenterally or by intramammary infusion.

An important aspect of treatment is the accurate positive identification of the animal(s) to be treated, the recording of the relevant clinical and laboratory information, the treatments being used, and monitoring the response. Useful information would include:

- Cow identification
- Quarters affected
- Date of mastitis event
- Lactation number
- Date of calving
- Identification of pathogen(s)
- Treatment used, including dose, route, and duration
- Milk withholding time and time when returned to the milking string
- Most recent level of milk production

Options for treating cows with clinical mastitis include treating all cows with antimicrobial agents, treating none of the cows with antimicrobial agents, or treating only specific cows with antimicrobial agents. Treating all cows results in increased costs for those cows with clinical mastitis associated with pathogens not susceptible to the antimicrobial agent used, especially if the signs are likely to resolve before the milk withholding period has expired. Treatment of all cows is also associated with increased risk of violative residues in the bulk milk. Treating none of the cows with antimicrobial agents has animal welfare implications, because an effective treatment is not administered to some cattle with clinical mastitis, and non-treatment allows gram-positive pathogens to persist, increasing the probability of a recurrence of clinical mastitis or causing a herd epidemic of mastitis. Accordingly, **nontreatment of all cases of mastitis is not a viable option.** Treating only specific cows with antimicrobial agents requires an accurate method of determining which animals should be treated. However, clinical judgment and predictive models are too inaccurate to distinguish between clinical mastitis associated with gram-negative and gram-positive pathogens. To select cows for antimicrobial therapy on the basis of bacteriologic culture is costly and delays treatment; clinical judgment would still be necessary because bacteria are not isolated from 15% to 40% of milk samples from cows with clinical mastitis.

Veterinarians should always ask and answer four questions related to antimicrobial therapy in bovine mastitis:

1. Is antimicrobial therapy indicated?
2. Which route of administration (intramammary, parenteral, or both) should be used?
3. Which antimicrobial agent should be administered?
4. What should be the frequency and duration of treatment?

#### Is Antimicrobial Therapy Indicated?

The first decision is **whether to treat** a particular case with antimicrobial agents and whether supportive therapy is required. Therapy decisions should be made in context with the overall objectives of the lactating cow treatment protocol. The availability of approved, effective treatment products is an essential component of the program. A

number of factors are important in determining which cases of mastitis should be treated during lactation. These factors include the type of pathogen involved, the type and severity of the inflammatory response, the duration of infection, the stage of lactation, and the age and pregnancy status of the cow.

#### Type of Pathogen Involved

There are marked differences in the bacteriologic cure rates of the various major mastitis pathogens after therapy during lactation. The outcome of treatment during lactation is poor for cases of *S. aureus* mastitis. On the other hand, *S. agalactiae* responds extremely well to lactating cow therapy, and all infected cows should be treated. Cases of mastitis associated with environmental organisms have reasonable, but variable, cure rates.

#### Type and Severity of the Inflammatory Response

The predominant type of inflammatory process involved influences the objectives of the therapy program. Herds with clinical mastitis problems will aim at reducing clinical signs, returning the milk to saleable quality and avoiding residue violations. Herds with a predominance of subclinical mastitis are concerned with avoiding the spread of infection and reducing the prevalence of the major pathogens involved. Both types of herd have the primary objective of restoring the production potential.

The severity of the inflammatory response is also important in the selection of cases for mastitis therapy during lactation. Heat, pain and swelling of the quarter (abnormal gland) are clinical signs that indicate the need for antimicrobial therapy. Many producers, however, will treat any cow that shows clots in the milk (abnormal milk). There are no reports to verify that treatment of cows exhibiting abnormal milk only is efficacious and economically justifiable, although it is probable that treatment of clinical mastitis episodes of abnormal milk but normal gland caused by *S. agalactiae* is efficacious and economic. Treatment success is lower in cows with high NAGase concentrations in milk compared with cows with low NAGase concentrations.

#### Duration of Infection

For the contagious organisms, especially *S. aureus*, the duration of infection is an important determinant of its susceptibility to therapy during lactation. In chronic *S. aureus* mastitis, the organism survives intracellularly in leukocytes, becomes walled off in small abscesses of mammary ducts, and has the ability to exist in the L-form state. At this point *S. aureus* is virtually incurable during lactation. With new methods of automated detection of subclinical intramammary infection such as in-line electrical conductivity measurement, new infections may be detected much earlier. The cure rate

of *S. aureus* during lactation needs to be reevaluated when treatment is administered early in the course of infection.

#### Stage of Lactation

The stage of lactation is an important determinant of the benefit:cost ratio of mastitis therapy during lactation. It may be uneconomical to treat even cases with a high probability of cure during late lactation.

#### Age and Pregnancy Status of Cow

The probability of a cure is greater in young cows, and age should be considered in selecting cases for mastitis therapy during lactation.<sup>1</sup> The economic aspects of treatment for late-lactation, nonpregnant cows are obviously different from those for midlactation pregnant cows.

A mastitis therapy program for lactating cows should be based on a complete understanding of the mastitis status of the herd, and individual cow treatment decisions should be consistent with the overall herd mastitis therapy program.<sup>2</sup> A record system for treatment should be established so that it is possible to monitor the efficacy of the mastitis treatment program.

The udder health status in a particular herd will determine whether the lactating cow mastitis therapy strategy should be targeted at the individual cow level or at the herd level. The level of emphasis should clearly reflect the objectives of the therapy program. For example, a herd with low bulk tank milk SCC and sporadic cases of environmental mastitis should target the lactating cow therapy strategy at the cow level. The primary objectives would be to alleviate clinical signs, to achieve a bacteriologic cure, and to restore the cow's production. On the other hand, a herd with moderate to high bulk tank milk SCCs and a significant prevalence of contagious organisms should aim the program at the herd level. In this case the objective would be to limit the spread of infection, markedly reduce or eradicate a specific pathogen, and increase herd production. A clear statement of treatment philosophy (individual cow level or herd level) in a particular herd is needed to direct establishment of well-defined treatment protocols for mastitis in lactating cows.

Intramammary infection (mastitis) is identified by the presence of clinical signs or the results of a direct test (culture of milk) or indirect tests such as SCC, CMT, or electrical conductivity. The detection of clinical or subclinical mastitis does not necessarily indicate that therapy should be administered, although animal welfare issues dictate that treatment must be administered to cattle with an abnormal gland or systemic signs (abnormal cow) because these animals are undergoing pain and discomfort. A decision to use treatment during lactation should be based on the likelihood of achieving the objectives of the therapy program. Several

factors are important in the selection of cows for treatment. These factors can significantly influence the cure rate achieved with therapy or the economic benefit realized.

The herd history of udder health will indicate the probable cause of clinical mastitis. Cows with mild cases of clinical mastitis (abnormal secretion only) in herds with a low prevalence of contagious mastitis pathogens are likely to be affected with environmental pathogens and commonly return to clinically normal milk in four to six milkings. This has led to the development of treatment algorithms based on the results of culturing clinical cases using selective media. Using this approach, milk cultures are obtained from all cattle with clinical mastitis and plated using biplates or triplates. All cattle with abnormal glands or signs of systemic illness (abnormal cow) are immediately treated with antimicrobial agents and appropriate ancillary treatment, with subsequent antimicrobial treatment based on the preliminary culture results at 18 to 24 hours or the final culture results at 48 hours. In contrast, treatment is initially withheld from all cattle demonstrating abnormal secretion only; antimicrobial treatment is instituted based on the culture results. One such scheme recommends using intramammary antibiotics to treat affected quarters with *S. aureus*, CNS, and environmental streptococci, infusing intramammary antibiotics into all quarters of cows with one or more quarters infected with *S. agalactiae* and not administering antibiotics to cows with coliform bacteria or no growth. When using this delayed approach to antimicrobial treatment, it is important that cattle with abnormal milk only are closely monitored, and that antimicrobial treatment is immediately instituted when signs of an abnormal gland or abnormal cow are present. The major difficulty with implementing the delayed approach is the difficulty in transporting the milk sample to and receiving the results from the diagnostic laboratory in a time-effective manner. For practical reasons, this approach works only if on-farm culturing is performed.

An 8-herd study involving 422 cows with clinical mastitis in the Great Lakes region of North America was conducted to investigate the effectiveness and safety of selective treatment of clinical mastitis using on-farm culture results. The secretion from affected quarters was cultured for 18 to 24 hours using a biplate. Quarters with a gram-positive or mixed growth were treated with intramammary cephapirin sodium. Quarters with a gram-negative or no growth were not treated. Unfortunately, the study design enrolled cattle with clinical mastitis and abnormal secretion (72% of total), or abnormal secretion and abnormal gland (28% of total); as discussed previously the latter group should not have an effective treatment withheld for 24 hours, because an abnormal

**Table 20-6** Summary of three-compartment model for anatomic location of infection caused by mastitis pathogens in cattle

gland is associated with pain and discomfort. Use of selective antibiotic treatment based on 24-hour culture results reduced intramammary antibiotic use by half without impacting days to clinical cure, bacteriologic cure risk, and treatment failure risk within 21 days.<sup>3</sup> Selective treatment also had no impact on long-term outcomes, such as recurrence of clinical mastitis in the same quarter, increased SCS, decreased milk production, or cow survival for the remainder of the lactation.<sup>4</sup> This study supports the selective treatment of clinical mastitis episodes using intramammary cephapirin and an on-farm culture system for those mastitis episodes that have abnormal secretion.

A decision tree analysis of treatment strategies, including selective treatment of clinical mastitis using on-farm culture results, indicated that the optimal economic strategy was to treat clinical mastitis episodes caused by gram-positive organisms for 2 days (compared with a 5-day or 8-day treatment protocol) and to not treat mild clinical mastitis episodes caused by gram-negative organisms or associated with no bacterial growth.<sup>1</sup> This economic analysis needs to be updated based on recent studies with naturally occurring mastitis documenting improved efficacy with extended treatment durations.<sup>5,6</sup>

#### Which Route of Administration (Intramammary, Parenteral, or Both?)

The second decision is the route of administration. The goal of antimicrobial treatment is to attain and maintain an effective

concentration at the site of infection. Three pharmacologic compartments are recognized for infection by mastitis pathogens:

- Milk and epithelial lining of the ducts and alveoli
- Parenchyma of the mammary gland
- The cow (Table 20-6)

Generally, infections confined primarily to the milk and ducts (such as *C. bovis* and CNS) are easily treated with intramammary antibiotics. In contrast, infections caused by mastitis pathogens with the potential for systemic infection (such as *E. coli*, *K. pneumoniae*, and *M. bovis*) are best treated with parenteral antibiotics. Mastitis pathogens that are the most difficult to treat are those that are principally infections of parenchymal tissue (such as *S. aureus* and *T. pyogenes*); this is because it is more difficult to attain and maintain an effective antibiotic concentration at this anatomic site when administering antibiotics by the intramammary or parenteral routes.

#### Which Antimicrobial Agent Should Be Administered?

The third decision is the antimicrobial agent. The selection of the antimicrobial class for the particular mastitis pathogen has traditionally been based on culture and susceptibility testing and, although some in vivo data are now available, the choice is still largely dependent on case studies rather than on controlled experiments. Culture and antimicrobial susceptibility testing of the pathogen is not necessarily a justifiable basis for selecting the antimicrobial agent to be used

in individual cows, and the response to treatment of clinical mastitis in two recent studies was unrelated to the results of in vitro susceptibility tests.

Antimicrobial agents are usually selected based on availability of labeled drugs, clinical signs in the cow, milk culture results for previous mastitis episodes in the herd, experience of treatment outcome in the herd, treatment cost and withdrawal times for milk, and slaughter. Many veterinarians and researchers have also recommended the routine use of susceptibility testing to guide treatment decisions. Susceptibility testing for guiding treatment of clinical mastitis should not be a routine recommendation for a number of reasons. First, the cost of susceptibility testing and a minimum 2-day delay in obtaining the results makes susceptibility testing irrelevant to the initial treatment protocol. Second, the medical profession does not routinely apply susceptibility testing to the initial treatment of a non-life-threatening illness; it is therefore difficult to understand why treatment of bovine mastitis should be held to a higher standard. Third, and most importantly, the validity of agar diffusion susceptibility breakpoints derived from humans in the treatment of bovine mastitis has not been established and is extremely questionable because bovine mastitic milk pH, electrolyte, fat, protein, and neutrophil concentrations; growth factor composition; and pharmacokinetic profiles differ markedly from those of human plasma. Moreover, antibiotics are distributed unevenly in an inflamed gland, and high antibiotic concentrations can alter neutrophil function in vitro, having the potential to inhibit bacterial clearance in vivo.

Adequate databases of in vitro minimum inhibitory concentration (MIC) values for clinical mastitis pathogens are currently unavailable, although adequate databases are available for subclinical mastitis isolates. Although we have a good knowledge of the pharmacokinetics of many parenteral antibiotics used to treat clinical mastitis, most pharmacokinetic data have been obtained in healthy cattle, and it has become increasingly clear that the pharmacokinetic values in healthy cows are different to those in cows with clinical mastitis. In addition, pharmacokinetic values for many of the intramammary antibiotics used to treat clinical mastitis are unknown, and there is a limited understanding of the pharmacodynamics of antibiotics in treating mastitis. More importantly, the breakpoints currently recommended for all parenterally and almost all intramammarily administered antibiotics used to evaluate susceptibility or resistance<sup>7-10</sup> are based on achievable serum and interstitial fluid concentrations in humans after oral or intravenous antibiotic administration. The relevance of these breakpoints to achievable milk concentrations in lactating dairy cows after

intramammary, subcutaneous, intramuscular, or intravenous administration is dubious at best.

Results from field studies are available to evaluate the validity of susceptibility breakpoints in guiding treatment of cows with clinical or subclinical mastitis. The results from these field studies suggest that the following antibiotics may have valid (but not necessarily optimal) breakpoints for treating clinical or subclinical mastitis associated with specific bacteria: parenteral penicillin G for subclinical *S. aureus* infections, intramammary cephalixin for clinical *Streptococcus* spp. infections, and parenteral trimethoprim-sulfadiazine for clinical *E. coli* infections. Of these three antibiotics, the breakpoints for penicillin G and cephalixin have only been validated for bacteriologic cure, whereas the breakpoint for trimethoprim-sulfadiazine is validated for clinical cure. Because duration of infection before treatment, antibiotic dosage, dosage interval, and duration of treatment influence treatment outcome, many more field studies must be completed to validate the currently assigned antibiotic breakpoints for pathogens causing clinical mastitis.

To properly use the known pharmacokinetics of parenterally and intramammarily administered drugs, it is necessary to know something about their diffusion into mammary tissue, the degree of binding of a drug to mammary tissues and secretions, the ability to pass through the lipid phase of milk, and the degree of ionization. All of these factors influence the level of the antibiotic in the mammary gland.<sup>11</sup> Major challenges with modeling the milk concentration-time relationship exist for antibiotics administered parenterally or by the intramammary route. As a consequence, a new pharmacokinetic modeling approach for the treatment of mastitis has been developed.<sup>12</sup> Much of the published pharmacokinetic data are based on foremilk concentration, which is not representative of the antibiotic concentration in quarter milk<sup>13,14</sup> and has been conducted in healthy cows without clinical mastitis. The latter issue is of great importance because clinically important differences in pharmacokinetic values have been identified for ruminants with and without experimentally induced mastitis.<sup>15</sup> For lactating cows the preferred treatment is one that maintains an MIC for 72 hours without the need for multiple infusions and without prolongation of the withdrawal time. The most successful antimicrobial agents for dry period treatment are those that persist longest in the udder, preferably as long as 8 weeks. These characteristics depend on the release time from the transport agent in the formulation and the particle size and diffusion capabilities of the antibiotic.

The formulation of the preparation will affect the duration of the maintenance of the MIC. The third-generation cephalosporins

(such as ceftiofur) and fluoroquinolones are the drugs of choice for use in cases in which the infection may be associated with either a gram-positive or gram-negative organism; however, these antimicrobial agents may not be able to be used to treat mastitis in some countries. Mixtures of penicillin and an aminoglycoside are also in common use for this purpose. Penicillin G and penethamate are favored for gram-positive infections. Of special importance are the  $\beta$ -lactamase-producing strains of *S. aureus*, against which  $\beta$ -lactam penicillins are ineffective; cloxacillin is a commonly used and effective intramammary formulation for these strains of *S. aureus*. The drugs that have the best record of diffusion through the udder after intramammary infusion are penethamate, ampicillin, amoxicillin, erythromycin, and tylosin. Those of medium performance are penicillin G, cloxacillin, and tetracyclines. Poor diffusers, which have a longer half-life in the udder because they bind to protein, include streptomycin and neomycin. Streptomycin is not used much now because of the high level of resistance to it, especially by *S. uberis* and *E. faecalis*.

In summary, treatment of clinical mastitis should be based on bacteriologic diagnosis or assessment of the likely causative agent and take current guidelines on the prudent use of antimicrobials into account. The initial treatment of clinical mastitis episodes should be based on herd data and personal experience for the geographic region<sup>16</sup> or the results of on-farm culture for clinical mastitis episodes with only abnormal secretion.<sup>3,4</sup> The treatment of subclinical mastitis during lactation is rarely economical.

### What Should Be the Frequency and Duration of Treatment?

The fourth decision is the **frequency and duration of treatment**. The frequency of administration for parenterally administered antimicrobial agents is dependent primarily on their pharmacokinetics and pharmacodynamics. Fluoroquinolones and aminoglycosides are **concentration-dependent** antimicrobial agents in which increasing concentrations at the site of infection increase the bacterial kill rate. Macrolides,  $\beta$ -lactams, and lincosamides are **time-dependent** antimicrobial agents in which exceeding the MIC at the site of infection for a prolonged percentage of the interdosing interval correlates with improved efficacy. In contrast, the frequency of administration for intramammary formulations is dependent primarily on the milking schedule, because these agents are primarily cleared by milk removal. For example, the clearance of pirlimycin is strongly and positively correlated ( $r = 0.97$ ) to 24-hour milk production at the time of dosing. With all intramammary formulations being licensed based on the results of studies of twice-daily milking, the recent industry trend in some

parts of the world toward thrice-daily milking has created uncertainty as to whether intramammary treatment should be repeated after every milking or even whether once-a-day intramammary administration is as efficacious as twice- or thrice-daily administration.<sup>13,17,18</sup>

Recent studies have confirmed long-held beliefs that **appropriate antimicrobial therapy** (commonly called **extended or aggressive antimicrobial therapy**) for 5 to 8 days is more effective in treating intramammary infections than label intramammary therapy (2–3 days).<sup>5,6,19</sup> In other words, increasing the duration of antimicrobial administration increases treatment efficacy. Extended antimicrobial therapy is opposed by some producers because such treatment may be off-label and results in a longer milk withhold time and, consequently, the amount of milk that has to be discarded. In contrast, extended therapy of clinical mastitis episodes that have been treated for 2 to 3 days but the secretion remains abnormal is perceived by some producers as part of the social norm of “being a good farmer.”<sup>20</sup> Extended therapy is opposed by dairying administrators because of the inevitable increase in the number of infringements of health regulations relating to antibiotic residues in milk. The inappropriately short treatment duration for most intramammary products has been a major hindrance to developing effective antimicrobial treatment protocols.

### Intramammary Antimicrobial Therapy

For reasons of convenience and efficiency, antimicrobial udder infusions are in common use for the treatment of certain causes of mastitis in lactating cows and for dry cow therapy. For example, the cure rate of *S. agalactiae* using intramammary infusions in lactating cows exceeds 95%. Disposable tubes containing suitable antimicrobials in a water-soluble ointment base are ideal for dispensing and for the treatment of individual cows. Multiple-dose bottles containing aqueous infusions are adequate and much cheaper per dose when large numbers of quarters are to be treated, but repeated use of the same container increases the risk of contamination. The degree of diffusion into glandular tissue is the same when either water or ointment is used as a vehicle for infusion; the duration of retention within the gland depends on the vehicle.

Most antimicrobial agents currently available in the United States in commercial intramammary infusion products are active against the staphylococci and streptococci, with cephalixin (a first-generation cephalosporin) having good activity against coliform bacteria, and ceftiofur (a third-generation cephalosporin) having excellent activity against coliform bacteria. Until recent years the emphasis was on the elimination of gram-positive cocci from the udder, but

gram-negative infections, especially *E. coli*, have increased in prevalence to the point where a broad-spectrum preparation is almost essential for both lactation and dry period treatments. Generally, antimicrobials administered by the intramammary route for the treatment of clinical mastitis should be bactericidal because neutrophil phagocytosis of bacteria is impaired in milk.

The choice of antimicrobial agents for intramammary infusion should be based on the following:

- Mechanism of antimicrobial action and spectrum of bacteria controlled
- Diffusibility through mammary tissue
- Cost

Strict hygiene is necessary during treatment to avoid the introduction of bacteria, yeasts, and fungi into the treated quarters; the use of a short cannula that just penetrates the external sphincter is preferred because it is less likely to introduce bacteria and leaves more of the keratin plug in place in the streak canal. This is important because the keratin plug has antimicrobial properties. Care must be taken to ensure that bulk containers of mastitis infusions are not contaminated by frequent withdrawals and that individual, sterilized teat cannulas, usually part of commercial, single-dose ointment tubes, are used for each quarter. Bulk treatments are best avoided because of the high risk of spread of pathogens.

### Infusion Procedure

The teats must be cleaned and sanitized before infusing the quarter to avoid introduction of infection. The following steps are recommended:

- Clean and dry the teats.
- Dip teats in an effective germicidal product. Allow 30 seconds' contact time before wiping teats with an individual disposable towel (one towel per cow, use one corner of the towel for each teat).
- Thoroughly clean and disinfect each teat end with cotton soaked in 70% alcohol. Use a separate piece of cotton for each teat.
- Prepare teats on the far side of the udder first, followed by teats on the near side.
- Treat quarters in reverse order: near side first, far side last.
- Insert only the tip of the cannula into the teat end (**partial insertion**). Do not allow the sterile cannula to touch anything before infusion. Most approved dry cow infusion products (and lactating tubes) are marketed with a dual cover that can be used for partial or full insertion.
- Dip teats in a germicidal product after treatment.
- Identify treated cows and remove them from the milking herd to prevent antimicrobials from entering the milk supply.

Diffusion of infused intramammary drugs is often impeded by the blockage of lactiferous ducts and alveoli with inflammatory debris. Complete emptying of the quarter by the parenteral injection of oxytocin (10–20 IU intramuscularly) followed by hand stripping of affected quarters before infusion has been recommended in cases of clinical mastitis, but efficacy studies are lacking, the volume stripped is usually small, and the procedure is painful to the cow. If stripping is performed, the intramammary infusion is given after the last stripping of the day has been done, avoiding any further milking of the gland until the next milking.

### Parenteral Antimicrobial Therapy

This should be considered in all cases of mastitis in which there is an abnormal gland and is preferred in all cases of mastitis in which there is an abnormal cow (fever, decreased appetite, or inappetence). The systemic reaction can usually be brought under control by standard doses of antimicrobial agents, but a bacteriologic cure of the affected glands may not be achieved because of the relatively poor diffusion of the antimicrobial from the blood into the milk. However, the rate of diffusion is greater in affected than in normal quarters. Parenteral treatment is also recommended when the gland is markedly swollen and intramammary infusions are unlikely to diffuse to all parts of the glandular tissue.<sup>19</sup> To achieve adequate therapeutic levels of an antimicrobial in the mammary gland by parenteral treatment it is necessary, for the above reasons, to use higher than normal dose rates daily for 3 to 5 days.<sup>19</sup> Milk from treated cows must be withheld from the bulk tank for the stated period of time of that antimicrobial following the date of last treatment.

### Treatment of Lactating Quarters

There are three situations to consider: the emergency single case of clinical mastitis requiring immediate treatment; the herd with a problem of too many clinical cases or intractable cases, but where the identity of the pathogen is known; and the cow with subclinical mastitis.

### Emergency Treatment When the Type of Infection Is Unknown

Cases of acute and peracute mastitis (abnormal cow) in lactating cows, and in dry cows close to calving, are serious problems for the field veterinarian. The need for treatment is urgent; it is not possible to wait for the results of laboratory tests to guide the selection of the most appropriate antibiotic. Clinical findings, season of the year; and management practices may give a broad hint as to the specific bacterial cause, but in most such circumstances it is necessary to use a broad-spectrum approach to treatment. Parenteral therapy with oxytetracycline (administered intravenously to increase bioavailability and therefore plasma and milk concentrations),

penethamate hydriodide, a potentiated sulfonamide or similar broad-spectrum antimicrobial agent should be supplemented with intramammary infusion with a  $\beta$ -lactamase-resistant antimicrobial such as a first-generation cephalosporin (cephapirin), a third-generation cephalosporin (e.g., ceftiofur), penicillin G–neomycin combination, or other approved broad-spectrum intramammary infusion. Parenteral ceftiofur is not effective in clinical mastitis episodes that have abnormal secretion or abnormal gland and secretion.

A consensus is developing that clinical mastitis episodes that manifest as abnormal secretion or abnormal secretion and gland should be treated only by the intramammary route, and that clinical mastitis episodes that manifest as abnormal secretion, gland, and cow should be treated by both the intramammary and parenteral routes. The latter group would also benefit from the administration of antiinflammatory agents and intravenous fluid therapy, depending on the severity of the systemic signs. A consensus is also developing that extended intramammary therapy (effectively more appropriate duration therapy) beyond the traditional 2- to 3-day treatment regimen is preferred when permitted by label directions and country recommendations<sup>5,6</sup>; however, the optimal duration of intramammary therapy remains to be determined.

In a multicenter study in Europe comparing three  $\beta$ -lactam–based intramammary products for the treatment of 491 clinical mastitis episodes, the bacteriologic cure rate for intramammary administration of a combination of cephalexin (200 mg, first-generation cephalosporin) and kanamycin (133 mg) or cefquinome (75 mg, fourth-generation cephalosporin) were similar but higher than that for intramammary infusion of cefoperazone (100 mg, third-generation cephalosporin).<sup>16</sup> In a multifarm ( $n = 28$ ) study in New Zealand comparing three cephalosporin-based intramammary products for the treatment of 1462 clinical mastitis episodes, the bacteriologic cure rates were similar for intramammary administration of procaine penicillin (1 g), cefuroxime sodium (250 mg, second-generation cephalosporin), or a combination of procaine penicillin G (1,000,000 U) and dihydrostreptomycin (0.5 g).<sup>21</sup> However, quarters treated with cefuroxime were more likely to be retreated within 30 days than quarters receiving either of the other two treatments.<sup>21</sup>

Field studies show that, in herds in which clinical mastitis is often caused by environmental pathogens, intravenous administration of oxytetracycline, intramammary infusion of cephalosporin, and supportive therapy (including intravenous administration of flunixin meglumine or fluids) produce a higher rate of clinical and bacteriologic cure than supportive treatment alone. In addition, antimicrobial treatment is more

effective than supportive treatment alone. In cows with clinical mastitis caused by *E. coli* the use of procaine penicillin G intramuscularly was no more effective than not using antimicrobial agents; this result is expected based on penicillin's gram-positive spectrum of activity. Knowledge of the likely causative agent is therefore helpful when making decisions about therapy of clinical mastitis episodes during lactation.

Provision of other supportive therapy, such as fluids and electrolytes, is also crucial to the survival of the cow and minimization of the severity of the mastitis and extent of permanent injury to the udder. The efficacy of frequent stripping, with or without intramammary infusion, is uncertain. Nonsteroidal antiinflammatory drugs (NSAIDs) decrease pain associated with an abnormal gland; in addition, they enhance recovery and reduce fever in severe cases.

### Treatment When the Infecting Organism Is Known

A common situation encountered by a bovine practitioner is the dairy herd that has had an outbreak of clinical mastitis or has received a warning notice from the milk processor that the bulk milk SCC or bacterial count is above acceptable limits. The situation calls for a complete mastitis control program, including conducting an investigation to determine the causative bacteria present, the source of the infection, hygiene in the milking parlor, and the importance of risk factors such as milking machine management, plus recommended antimicrobial preparations selected on the basis of the causative agent. Treatment of a number of identified subclinical cases at the commencement of the program, and of individual cases subsequently, can be based on the known common infection in the herd. Among gram-positive cocci, the response to antimicrobial agents is excellent for streptococci. For staphylococci a cure rate of 65% is about the best that can be expected, and unless there are good reasons for doing otherwise it is recommended that treatment be postponed until the cow is dry. Standard treatments for lactating cows include penicillin alone (100,000 units) or in combination with streptomycin (1 g) or neomycin (500 mg), and a combination of ampicillin (75 mg) and sodium cloxacillin (200 mg). Acid-resistant penicillins, e.g., phenoxymethylpenicillin, are probably best not used as mammary infusions because of their ability to pass through the human stomach, thus presenting a more serious potential threat to humans drinking contaminated milk. Because of the widespread and often indiscriminate use of penicillin, a large part of the mastitis that occurs is associated with penicillin-resistant bacteria, especially *S. aureus*. Treatment programs need to take this into account when recommendations are made about the antibiotic to be used.

Intramammary infections associated with **environmental streptococci** that manifest signs of clinical mastitis are usually acute but only moderately severe. In most of these cases the streptococci are sensitive to antimicrobial agents, and they often recover spontaneously with good management and nursing care. If not, they usually respond well to therapy.<sup>22</sup> Bacteriologic cure rates of 60% to 65% can be expected following a single intramammary infusion of a cephalosporin product.

In one randomized controlled field trial of clinical mastitis associated with *Streptococcus* spp. or coliform bacteria, the clinical cure rate by the 10th milking was significantly higher when intramammary cephalosporin, intravenous oxytetracycline, or both were used along with supportive therapy (oxytocin and stripping of affected glands and, in severely affected cows, the use of flunixin meglumine and fluids) compared with supportive treatment alone. These results indicate that, in herds in which clinical mastitis is often associated with environmental pathogens, antimicrobial therapy and supportive therapy may result in a better outcome than supportive therapy alone.

### Treatment of Subclinical Mastitis

It is generally considered not advisable to treat subclinical mastitis during lactation.<sup>23,24</sup> However, it is important to consider the causative organism, the age of the cow, the number of intramammary infections for the cow, and the udder health status of the herd.<sup>25</sup> There are several situations in which lactational therapy of subclinical mastitis is indicated; for example, herds with *S. agalactiae* infections should consider several approaches to therapy during lactation. *S. agalactiae* infections respond well to therapy during lactation, with cure rates of 80% to 100% expected. All approved intramammary therapy preparations are efficacious, including penicillin, cephalosporins, cloxacillin, and erythromycin. In herds with a high prevalence of *S. agalactiae* mastitis, **blitz therapy** can be used for eradication of the pathogen, increased milk production, and reduced penalties for high SCCs. There is, however, a risk of residue violation, problems with disposal of milk from treated cows, and considerable costs involved. It is also important to ensure that standard mastitis control procedures, such as postmilking teat disinfection and blanket dry cow therapy, have been implemented. The benefit:cost ratios for various approaches to blitz therapy of *S. agalactiae*-infected herds have been studied. The prevalence of infected cows, and their stage of lactation, are important determinants of the type of program selected.

Therapy of cows with subclinical mastitis caused by *S. aureus* during lactation is much less rewarding. Under field conditions, cases of *S. aureus* are difficult to cure during lactation. Reported cure rates following

intramammary therapy are between 15% and 60%. Lactational therapy of subclinical *S. aureus* mastitis using intramuscular penicillin along with intramammary amoxicillin infusion, compared with the intramammary infusion alone, increased the cure rate to 40%, which represented a doubling of the cure rate with intramammary therapy alone. Improvements in the cure rate of subclinical gram-positive intramammary infections have also been obtained with parenteral penethamate hydroiodide.<sup>25</sup> If treatment by this method is used in combination with data on the age of cow, stage of lactation, duration of infection, and level of SCC, the economic benefit of treating some cases of *S. aureus* mastitis during lactation may be attractive.

Subclinical infections associated with environmental streptococci, and occasionally by coliform organisms, can be found in moderate numbers in some herds. Although spontaneous cure rates are higher with these environmental infections, individual cows may merit treatment during lactation. In these cases, the previously listed factors should be used and are important in the selection of cases to be treated.

Prepartum antibiotic treatment of heifers is of benefit in herds experiencing a high incidence of clinical mastitis in recently calved heifers. CNS are frequently isolated from late-gestation heifers, and intramammary treatment with sodium cloxacillin (200 mg) or cephapirin sodium (200 mg) 7 days before expected parturition is highly effective and economically beneficial.

### Antiinflammatory Agents

NSAIDs have been evaluated for the treatment of field and experimental cases of acute and peracute mastitis. They have beneficial effects on decreasing the severity of clinical signs based on changes in rectal temperature, heart rate, rumen motility, and pain associated with the mastitis and are routinely administered as part of the initial treatment of cattle with severe clinical mastitis and marked systemic signs (pyrexia, tachycardia, tachypnea, and ruminal hypomotility). On the basis of one comparative study, NSAIDs appear to ameliorate systemic abnormalities to a greater degree than corticosteroids. The strongest evidence to support the administration of NSAIDs is available for meloxicam, ketoprofen, and phenylbutazone.

Administration of meloxicam (250 mg subcutaneously once) to dairy cows in New Zealand with acute clinical mastitis being treated with three daily intramuscular injections of penethamate hydroiodide (5 g) decreased posttreatment SCC and decreased culling from the herd from 28% to 16%.<sup>26</sup> Ketoprofen at 2 g intramuscularly once daily combined with sulfadiazine and trimethoprim intramuscularly given daily to cows with acute clinical mastitis, and complete milking of affected quarters several times daily, significantly improved survival and

milk production compared with cows not receiving the NSAID. A reanalysis of the published results indicated that phenylbutazone at 4 g intramuscularly once daily combined with sulfadiazine and trimethoprim intramuscularly given daily to cows with acute clinical mastitis significantly improved the percentage of cows with milk production returning to more than 75% of previous levels compared with cows not receiving the NSAID. However, intramuscular administration of phenylbutazone is not currently recommended because of the potential for myonecrosis. Moreover, phenylbutazone is not permitted to be administered to dairy cattle greater than 20 months of age in the United States. Dipyrone (20 g, intramuscularly) administered once daily in the same study was not effective. It is not permitted to be administered to food-producing animals in some countries, including the United States.

There is minimal evidence that treatment of clinical cases with NSAIDs alters the inflammatory response in the udder, although pretreatment of cattle with experimentally induced mastitis does alter the local (glandular) inflammatory response to infection. Flunixin meglumine concentrations are low in milk, which is consistent with its properties as a weak acid that has difficulty crossing the blood-milk barrier. Flunixin meglumine (2 mg/kg, intravenously, twice 24 hours apart) did not alter the survival rate of dairy cows with severe *E. coli* or *S. uberis* mastitis compared with intravenous administration of 45 L of isotonic crystalloid fluids. Flunixin meglumine is often administered as part of the initial treatment of clinical mastitis in cows manifesting systemic signs of illness, and flunixin residues are being detected in milk from dairy cattle being sent for human consumption. This may reflect the markedly slower clearance of flunixin in cows with clinical mastitis.<sup>27</sup> The one-time administration of 1 g of flunixin meglumine intravenously or 4 g of phenylbutazone intravenously, along with intramammary infusion of gentamicin (150 mg) at 12-hour intervals for four treatments, had no significant beneficial effect in cows with acute toxic mastitis associated with *E. coli* and *Klebsiella* spp. However, the results of this study do not indicate a lack of effectiveness of flunixin meglumine or phenylbutazone, because it is difficult for one dose of any NSAID to have a detectable effect on clinical signs in naturally occurring mastitis cases.

### Supportive Therapy

Supportive treatment, including the intravenous administration of large quantities of isotonic crystalloid fluids, is indicated in cattle with severe systemic illness. Large volumes of isotonic crystalloid fluids can be rapidly administered under pressure at 0.5 L/min through a 12-gauge catheter in the jugular vein, using a 7.5-L garden weed killer

spray pump. The administration of hypertonic saline followed by immediate access to drinking water is a practical method of providing fluid therapy to cows with severe mastitis, especially peracute coliform mastitis. A dose of 4 to 5 mL/kg body weight (BW) of 7.5% saline is given intravenously over 4 to 5 minutes. This is usually followed by the animal consuming large quantities of water. Circulating blood volume is increased and there is mild strong ion (metabolic) acidosis, improved renal function, and changes in calcium and phosphorus homeostasis compared with cows given a similar volume of 0.9% NaCl. Fluid therapy is covered extensively in Chapter 5.

### Adjunctive Therapy

Cytokines may be useful as adjunctive therapy with existing antimicrobials to improve therapeutic efficacy, particularly in lactating cows. Cytokines are natural regulators of the host defense system in response to infectious diseases. The combination of a commercial formulation of cephapirin with recombinant interleukin (IL)-2 consistently improved the cure rate of treating *S. aureus* mastitis by 20% to 30% compared with use of the antimicrobial alone.

Ozone is a gas (O<sub>3</sub>) that rapidly inactivates bacteria and viruses. It was prepared with a commercially available ozone therapy device and administered to cattle with clinical mastitis. The administration of 100 mL of 70% ozone decreased SCC over 1 week, suggesting that ozone may be an effective adjunct therapy.<sup>28</sup>

### Magnitude of Response to Therapy

The treatment of some causes of mastitis can be highly effective in removing infection from the quarter and returning the milk to normal composition. However, the yield of milk, although it can be improved by the removal of congestion in the gland and inflammatory debris from the duct system, is unlikely to be returned to normal in severe clinical cases, at least until the next lactation. The degree of response obtained depends particularly on the causative agent, the speed with which treatment is commenced, and other factors described earlier. A "cure" may mean disappearance of clinical signs, elimination of the infectious cause, or both of those plus return to normal function and productivity. Which of these is the objective in any particular case or herd will influence the decisions to be made about treatment in an individual case of the disease.

**Failure to respond to therapy** of the lactating cow may be caused by the following:

- The presence of microabscesses and inaccessibility of the drug to the pathogen
- Ineffective drug diffusion
- Inactivation of the antimicrobial by milk and tissue proteins

- Inefficient killing of the bacteria and intracellular survival of bacteria
- Increased antimicrobial resistance
- The development of L-forms of bacteria

### Dry Cow Therapy

Dry cow therapy is the use of intramammary antimicrobial therapy immediately after the last milking of lactation and is an important component of an effective mastitis control program. Intramammary infusions at drying off **decrease the number of existing infections and prevent new infections during the early weeks of the dry period.** Dry cow therapy should be routinely administered and remains one of the cornerstones of an effective mastitis control program. **Blanket dry cow therapy** is treatment of all four quarters at drying off, compared with **selective dry cow therapy** based on treatment of only those quarters that are infected. When subclinical mastitis is very low in some herds, selective dry cow therapy can be considered, but nearly all herds use blanket dry cow therapy. The problem with selective dry cow therapy is the accuracy of available indirect tests to “select” cows for treatment or nontreatment. Currently available indirect tests are not sufficiently accurate (the exception being quarter milk cultures) to be used as a basis for selective dry cow therapy.

Intramammary infusions approved for dry cow therapy contain high levels of antimicrobial agents in a slow-release base that maintains therapeutic levels in the dry udder for long periods of time. Most dry cow therapy infusion products are intended to eliminate existing infections caused by *S. aureus* and *S. agalactiae* at drying off and to prevent new infections caused by the same pathogens and environmental streptococci in the early dry period.

In herds with a high prevalence of contagious mastitis, dry cow therapy has been efficacious and economically beneficial in reducing the prevalence of intramammary infections. The consistent application of effective mastitis control procedures has reduced the prevalence of contagious pathogens and the bulk tank milk SCC (<300,000 cells/mL), and owners of these herds questioned dry cow therapy because of the economics and the concerns of residues in the milk. Field trials in herds with a low prevalence of contagious mastitis indicate that dry cow therapy at the end of lactation increased 17-week milk production during the subsequent lactation and was economically beneficial compared with not treating them. However, in the subsequent lactation, the incidence of clinical mastitis was not reduced and the SCCs were not significantly different from those of cows not treated at the end of lactation.

The most effective time to treat subclinical intramammary infections is at drying off. Dry cow therapy has the following advantages over lactation therapy:

- The cure rate is higher than that achieved by treatment during lactation.
- A much higher dose of antimicrobial can be used safely.
- Retention time of the antimicrobial in the udder is longer.
- The incidence of new infections during the dry period is reduced.
- Tissue damage by mastitis may be regenerated before parturition.
- Clinical mastitis at calving may be reduced.
- The risk of contaminating milk with antimicrobial residue is reduced.

Selection of a suitable dry period treatment should take into account the fact that gram-negative infections are not common at that time because of the high concentration of lactoferrin in the dry secretions. Accordingly, attention should be directed at the inclusion of a potent antibiotic against *Streptococcus* spp.,  $\beta$ -lactamase-producing *S. aureus*, and *T. pyogenes*. Cloxacillin and cephalosporins are popular for the purpose; for example, a recommended treatment is cephapirin or sodium cloxacillin in a slow-release base with an expected cure rate of 80% against streptococci and 60% against *S. aureus*. A large North American trial involving 6 dairy herds and 1091 cows identified no difference in the risk of cure between dry off and calving, and no effect of treatment on the risk for the presence of a new intramammary infection for the first 6 days in milk after calving, for cattle treated at dry off with intramammary procaine penicillin G (1,000,000 U) and dihydrostreptomycin (1 g), ceftiofur hydrochloride (500 mg), or cephapirin (300 mg) dry cow formulations.<sup>29</sup> In contrast, a study in Central Florida involving 2 dairy herds and 402 cows identified that cattle treated at dry off with intramammary ceftiofur hydrochloride (500 mg) had lower odds of having clinical and subclinical mastitis in the early part of the subsequent lactation than cows treated with intramammary procaine penicillin G (1,000,000 U) and dihydrostreptomycin (1 g).<sup>30</sup>

Most dry cow preparations maintain an adequate minimum concentration in the quarter for about 4 weeks, but some persist for 6 weeks. There is little, if any, value in treating cows again before the due calving date. There is always a possibility of introducing infection while infusing an intramammary preparation and farmers are reluctant to break the teat canal seal, but it may be necessary to do so if summer mastitis is prevalent in the area.

### Prepartum Antimicrobial Therapy in Heifers

Intramammary infusion of a cephapirin dry cow therapy preparation into pregnant heifers 10 to 12 weeks prepartum eliminated over 90% of the intramammary infection caused by *S. aureus*, *Streptococcus* spp., CNS spp., and coliforms. The SCCs of cured

quarters were comparable to uninfected control quarters after parturition. At parturition, 24% of treated quarters were positive for the antimicrobial; however, no quarters were positive at 5 days postpartum.

### Treatment of Mastitis on Organic Dairy Farms

The sale of organic dairy products is increasing worldwide, and the common occurrence of mastitis in dairy cattle provides an animal welfare challenge about how to appropriately treat clinical mastitis episodes in organic dairy farms. In the United States, use of antimicrobials to treat dairy cattle results in permanent loss of organic status for that animal,<sup>31</sup> whereas organic dairy farms in the European Union and Canada are permitted limited use of antimicrobials for emergency treatments per year.<sup>32</sup> Consequently, organic farmers use a variety of treatments for clinical mastitis, including homeopathy, vitamin supplements, and botanicals.<sup>31</sup> They also use veterinarians less frequently than similarly sized conventionally managed dairy herds.<sup>33</sup>

Treatment with a botanical preparation containing extracts of *Thymus vulgaris*, *Gaultheria procumbens*, *Glycyrrhiza uralensis*, *Angelica sinensis*, and vitamin E did not affect the resolution of clinical mastitis at day 4 of treatment, but it decreased the time to clinical recovery in cattle with clinical mastitis in Colorado.<sup>32</sup> This botanical formulation contained chemicals with documented antiinflammatory, antiseptic, or nutritional effects. Intramammary infusion of a live culture of *Lactococcus lactis* may be efficacious in the treatment of subclinical and clinical mastitis in dairy cattle.<sup>34</sup>

### Antimicrobial Residues in Milk and Withholding Times

Label instructions must be followed to ensure that drug residues do not occur, especially from cows with a shorter than normal dry period. Antibiotic residue testing of the milk of a recently calved cow can be done if there is a suspicion of residues, but this is a misuse of a test designed for bulk tank milk testing and therefore suffers from problems with sensitivity and specificity.

Treatment and control of mastitis accounts for the largest percentage of antimicrobial use on dairy farms. Following treatment by the intramammary or parenteral route, the concentration of antimicrobial agents in the milk declines over time to levels that are considered safe and tolerable for humans. The duration of time for the concentrations to decline to acceptable limits is known as the **withholding time** or the **withdrawal period** during which the milk cannot be added to the bulk tank supply but must be withheld and discarded. The presence of residues in milk is a major public health concern that adversely affects the dairy industry, the practicing veterinarian, and the perception the public has of the safety of milk for human

consumption. The public perception of the safety of milk is crucial, and veterinarians have a responsibility to respond to these concerns through public education and quality control of milk production.

Other serious consequences of antimicrobial residues in milk are their effect on the manufacture of dairy products and the potential development of antimicrobial sensitivity syndromes in humans. In most countries the maximum intramammary dose of antimicrobial agents is limited by legislation, and the presence of detectable quantities of antimicrobial agents in milk constitutes adulteration. Attention has also been directed to the excretion of antimicrobial agents in milk from untreated quarters, after treatment of infected quarters, and after their administration by parenteral injection or by insertion into the uterus. The degree to which this excretion occurs varies widely between animals and in the same animal at different points in the lactation period, and it differs from one antibiotic to another. Milk from cows subjected to dry period treatment is usually required to be withheld for 4 days after calving. The use of any dry period treatments in lactating cows causes prolonged retention of the antimicrobial in milk and is a most serious violation of the legislation.

Veterinarians have the responsibility to warn farmers of the need to withhold milk, and both should be aware of the withholding times of each product, the details of which are usually required to be included on its label. Marking the cow in some way to remind the farmer, by application of a leg band or placing dye on the udder, is advisable.

### Antimicrobial Residue Tests

Several cowside tests are available to detect antimicrobial residues in the milk of cows that have been treated for mastitis. The goal of cowside testing is to assist in the production of high-quality, antimicrobial-residue-free milk from dairy herds. To be consistent with the intent of a quality assurance program, cowside testing would be used only on cows recently treated with antimicrobial agents and only after appropriate milk withholding times had been followed. The ideal test would have a high sensitivity and high specificity.

Most of the cowside screening tests for antimicrobial residues are imperfect because of a high rate of false-positive results when used on field samples. The direct costs to producers can be high because of the unnecessary disposal of milk and imposition of fines and penalties. False-positive results also cause the unnecessary culling of some cows, and concern about the interpretation of positive assay results, the appropriateness of withholding periods, and the safety of milk creates mistrust among consumers, producers, veterinarians, and regulatory personnel.

The specificity of four commercially available tests ranged from 0.78 to 0.95. None of the test kits has been validated to meet performance standards for sensitivity and specificity. This applies to individual cow samples, bulk tank milk samples, and tanker truck samples.

The presence of naturally occurring bactericidal products in the milk of cows with acute and convalescent mastitis is the most likely cause of the false-positive results of the tests (such as Delvotest) that are based on bacterial growth inhibition of  $\beta$ -lactam antimicrobial agents. Immunoglobulins, complement, lysozyme, lactoferrin, and phagocytic cells are products of inflammation in the milk of cows with mastitis that can inhibit bacterial growth. The milk from cows with experimental endotoxin-induced mastitis is at increased risk for false-positive assay results using commercial residue tests. The incidence of false-positive results is very low in milk from cows that have not had a history of mastitis or antimicrobial therapy. Naturally occurring bactericidal products in mastitic milk can be removed by heating at 82°C (180°F) for 5 minutes; this temperature does not denature antimicrobial agents present in milk. Heat treatment therefore appears to provide a very practical way to reduce false-positive results on milk from individual cows.

A sample of milk can be submitted for antimicrobial residue testing up to three times. First, a producer may test a sample from a specific cow at the end of her withdrawal period. Second, milk is sampled at the tanker truck level. Third, should the tanker truck sample have positive results, bulk tank milk samples from each dairy herd that contributed to that tanker truck are tested.

There is a need for validation of the diagnostic assays used to detect antimicrobial residues in milk. Acceptance of assays for regulatory purposes must be based on protocols that include field estimates of assay performance before the assays are used by the public. Three strategies have been suggested to balance public health concerns with economic concerns of dairy producers caused by false-positive results:

1. Retest samples that yield positive results with a confirmatory assay of specificity close to 100%. Only those samples that also yield positive results on the second assay are considered to be positive for violative residues.
2. Recalibrate the assay to increase specificity. This will usually result in loss of sensitivity.
3. Use an alternative assay of higher specificity.

It is suggested that regulatory monitoring of residues at a national level will be best served by use of a combination of at least two assays: initial screening with a highly sensitive and inexpensive assay followed by confirmation

testing with an assay of high specificity (>99%) that can quantify the concentration of the antimicrobial residue. All tanker samples that yield positive results with a screening assay should be rechecked with a quantitative assay. If the quantitative assay detects a concentration greater than the safe level, safe concentration, or tolerance level, only then would the milk be deemed to have violative residue and fines and penalties be imposed. The complex dynamics of current milk residue tests discourage practitioners from recommending testing procedures to dairy producers.

As an approximate guide, the recommended periods for which milk should be withheld from sale after different methods of antimicrobial administration are (in times after last treatment)

- Udder infusion in a lactating cow (72 hours)
- Parenteral injection, one only (36 hours)
- Parenteral injections, series of (72 hours)
- Antimicrobial agents parenterally in long-acting bases (10 days)
- Intrauterine tablet (72 hours)
- Dry cow intramammary infusion (to be administered at least 4 weeks before calving and the milk withheld for at least 96 hours afterward)

### Permanently Drying Off Chronically Affected Quarters

If a quarter does not respond to treatment and is classified as incurable, the affected animal should be isolated from the milking herd, or the affected quarter may be permanently dried off by inducing a chemical mastitis. Historically used methods, arranged in decreasing order of severity, are infusions of

- 30 to 60 mL of 3% silver nitrate solution
- 20 mL of 5% copper sulfate solution
- 100 to 300 mL of 1:500, or 300 to 500 mL of a 1:2000 acriflavine solution

If a severe local reaction occurs, the quarter should be milked out and stripped frequently until the reaction subsides. If no reaction occurs, the quarter is stripped out 10 to 14 days later. Two infusions of these solutions may be necessary.

The best method for permanently drying off a quarter is infusion of 120 mL of 5% povidone iodine solution (0.5% iodine) after complete milk out and administration of flunixin meglumine (1 mg/kg BW, intravenously). This causes permanent cessation of lactation in the quarter but does not alter total milk production by the cow. If the goal is chemical sterilization, then three daily infusions of 60 mL of chlorhexidine suspension should be administered after complete milk out. The majority of treated cows (5/7) returned to milk production in the quarter in the subsequent lactation. The

infusion of 60 mL of chlorhexidine, followed by milking out at the next subsequent milking and repeat of the infusion 24 hours after the initial treatment, is also effective in making infused quarters nonfunctional within 14 to 63 days. Histologic evaluation of the infused quarters revealed that secretory tissues had involuted to a nonsecretory state and appeared similar to blind or nonfunctional quarters. However, as noted earlier, milk production may return in the gland in the subsequent lactation. Studies have demonstrated that the intramammary infusion of 10 mL of a peptide concentrate of casein hydrolysate is efficacious in drying off a quarter for the remainder of the lactation, but the quarter recovers over the dry period and milk production returns to similar levels the following lactation.<sup>22,35</sup> The infusion of casein induces an accelerated involution of the mammary gland. The effectiveness of this approach in drying off infected quarters does not appear to have been evaluated.

#### TREATMENT AND CONTROL OF CLINICAL MASTITIS IN LACTATING DAIRY COWS<sup>a</sup>

##### Treatment

###### Abnormal secretion

Perform on-farm culture and treat gram-positive isolates 18–24 hours later with an intramammary formulation that has proven efficacy against common gram-positive mastitis pathogens per label directions (R-1).

Administer broad-spectrum intramammary formulation per label directions (R-2).

###### Abnormal secretion and abnormal gland

Administer broad-spectrum intramammary formulation per label directions (R-1)

Administer extended duration of intramammary therapy (R-2).

###### Abnormal secretion, abnormal gland, and abnormal cow

Administer broad-spectrum intramammary formulation per label directions (R-1).

Administer extended duration of intramammary therapy (R-2).

Parenteral cefquinome, ceftiofur, fluoroquinolones, penethamate hydriodide, or oxytetracycline per label directions (R-1)

Intravenous fluid therapy with low-volume hypertonic saline or high-volume isotonic crystalloids (R-2)

Antiinflammatory agents, including meloxicam (250 mg, subcutaneously, once) (R-2)

##### Control

See extensive section on control of mastitis later in this chapter.

<sup>a</sup>Causative agent unknown. If the causative agent is known, then refer to specific treatment and prophylaxis recommendations for the etiologic agent in this chapter.

## Mastitis Pathogens of Cattle

In the following sections, the special features of each mastitis associated with one or a group of pathogens will be described using the usual format of the book. Mastitis in cattle is categorized as being associated with contagious, teat skin opportunistic or environmental pathogens, and as being common (major pathogen) or less common (minor pathogen). The features that are unique to the diagnosis, treatment, and control of each mastitis pathogen will be outlined, but details

applicable to all causes of mastitis were presented earlier.

## Mastitis of Cattle Associated With Common Contagious Pathogens

### STAPHYLOCOCCUS AUREUS

#### SYNOPSIS

**Etiology** *Staphylococcus aureus* is a major pathogen of the mammary gland and a common cause of contagious bovine mastitis. *S. aureus* also causes mastitis in sheep and goats.

**Epidemiology** Major cause of mastitis in dairy herds without an effective mastitis control program. Prevalence of infection 50%–100%; prevalence of 1%–10% in herds with low bulk tank milk SCCs, 50% in high-SCC herds, quarter infection rate 10%–25% in high-SCC herds. Source of infection is infected udder; infection transmitted at milking. Chronic or subclinical *S. aureus* mastitis is of major economic importance.

#### Clinical findings

- Chronic *S. aureus* mastitis is most common and is characterized by high SCC and gradual induration of udder, drop in milk yield, and atrophy with occasional appearance of clots in milk or wateriness.
- Acute and peracute *S. aureus* mastitis most common in early lactation. Acute swelling of gland with fever; milk is abnormal with thick clots and pus; gangrene of gland and teat in peracute form. Systemic reaction with anorexia, toxemia, fever, ruminal stasis

**Clinical pathology** Culture individual cow milk sample (composite or quarter) or polymerase chain reaction (higher sensitivity); indirect tests are high SCC and California mastitis test results.

**Necropsy findings** Peracute, acute, and chronic (recurrent) clinical mastitis, subclinical mastitis common

**Diagnostic confirmation** Culture milk for pathogen

#### Differential diagnosis

- Peracute mastitis
- Peracute coliform mastitis
- Trueperella* (formerly *Arcanobacterium* or *Corynebacterium*) *pyogenes* mastitis
- Parturient paresis
- Acute and chronic mastitis. Not clinically distinguishable from other causes of mastitis. Must culture milk

#### Treatment

- Lactating cows:** Cure rates for lactating cows with subacute staphylococcal mastitis less than 50%. Intramammary infusions daily for at least 3 days, preferably 5–8 days

- **Peracute mastitis:** Antimicrobial agents parenterally and intramammary that are  $\beta$ -lactamase resistant, fluid and electrolyte therapy
- **Dry cow therapy:** Chronic or subclinical mastitis best treated at drying off with long-acting intramammary antimicrobial infusions that are  $\beta$ -lactamase resistant

#### Control

- Prevent new infections by early identification, culling infected cows, and good milking procedures, including hygienic washing and drying of udders and teats before milking and postmilking germicidal teat dips. Regular milking machine maintenance. Consider segregation of infected cows.
- Eliminate existing infections by dry cow therapy.
- Immunization with vaccines may be possible in future.

SCC, somatic cell count.

## ETIOLOGY

**Coagulase-positive *S. aureus*** is a major pathogen of the bovine mammary gland and a common cause of contagious mastitis in cattle. It also causes mastitis in sheep and goats.

## EPIDEMIOLOGY

### Occurrence and Prevalence of Infection

#### Coagulase-Positive Staphylococci

Historically, *S. aureus* was one of the most common causes of bovine mastitis in dairy cattle worldwide. In the last 25 years, the prevalence of infection and the occurrence of clinical mastitis caused by *S. aureus* has decreased in herds using effective mastitis control measures. However, surveys indicate that 50% to 100% of herds may be infected. In low-SCC herds, the prevalence of infection in cows ranges from 1% to 10%. In other herds, especially those with high SCCs, up to 50% of cows may be infected with *S. aureus*, with quarter infection rates ranging from 10% to 25%. The prevalence of infection of *S. aureus* in heifers at parturition can range from 5% to 15%. **The majority of intramammary infections caused by *S. aureus* are subclinical.** The incidence of clinical mastitis caused by *S. aureus* is dependent on its prevalence of infection in the herd. With an effective mastitis control program, the most common causes of clinical mastitis are the environmental pathogens. However, in some herds with a low rolling SCC, incidence of clinical mastitis caused by *S. aureus* ranges from 190 to 240 cases per 100 cows per year, with about 47% of the clinical cases being *S. aureus*.

### Source of Infection and Method of Transmission

*S. aureus* is ubiquitous in the environment of dairy cattle. The infected mammary gland of

lactating cows is the major reservoir and source of the organism. The prevalence of intramammary infection in primiparous heifers at parturition ranges from 2% to 50% and may represent an important reservoir of infection in herds with a low prevalence of infection. The organism may be present on the skin of the teats and external orifices of heifers, bedding materials, feedstuffs, housing materials, nonbovine animals on the farm, and equipment. In herds with a high prevalence of infection (>10% of cows), the organism was present in bedding, the hands and noses of dairy herd workers, insects, and water supplies. Transmission between cows occurs at the time of milking by contaminated milkers' hands and teat cup liners. Although *S. aureus* can multiply on the surface of the skin and provide a source of infection for the udder, the teat skin lesions are usually infected originally from the udder, and teat skin is a minor source of infection. In herds with a low prevalence of infection, most new cases of *S. aureus* mastitis may be from extramammary sources rather than indicating cow-to-cow transmission.<sup>1</sup>

The horn fly (*Hemotobia irritans*) is an important vector for transmitting *S. aureus* mastitis in heifers, particularly in heifers with scabs on the teat ends. Prevention of high populations of flies in heifers is therefore needed to decrease new infections in this group.<sup>2</sup>

## Risk Factors

### Animal Risk Factors

Several animal risk factors influence the prevalence of infection and the occurrence of clinical mastitis caused by *S. aureus*.

### Local Defense Mechanisms

**Abrasions of the teat orifice epithelium** are an important risk factor for *S. aureus* mastitis. In experiments, teat canal infection or colonization may develop in 93% of experimentally abraded teat canal orifices compared with 53% in control quarters. Chapping of the teats and thickness of the teat barrel are correlated and significantly influence recovery of *S. aureus* from the skin.

### Colonization With Minor Pathogens

The presence of minor pathogens such as CNS protects against new intramammary infections associated with the major pathogen *S. aureus*. This may be the result of an elevated SCC or an antimicrobial-like substance provided by the CNS that inhibits the growth of *S. aureus*. Conversely, quarters infected with CNS may be more susceptible to new infections with *S. agalactiae*. Quarters that are infected with *C. bovis* are protected against *S. aureus* infection but not against most streptococcal species.

### Parity of Cow

The prevalence of intramammary infection and subclinical infection caused by *S. aureus*

increases with the parity of the cow. This is probably from the increased opportunity of infection with time and the prolonged duration of infection, especially in a herd without a mastitis control program.

### Presence of Other Diseases

The presence of periparturient diseases such as dystocia, parturient paresis, retained placenta, and ketosis has been identified as a risk factor for mastitis. The occurrence of sole ulcers in multiple digits may be associated with *S. aureus* in the first lactation.

### Heredity

Experimentally, the presence of certain bovine lymphocyte antigens increased the susceptibility to *S. aureus* infection, but heritability estimates of susceptibility after experimental challenge were low and unstable.

### Immune System

The infection rate of *S. aureus* is dependent on the ability of the immune system to recognize and to eliminate the bacteria. Staphylococcal antibodies are present in the blood of infected cows, but they appear to afford little protection against mastitis associated with *S. aureus*. This may be because of the low titer of the antibodies in the milk. Antibody titers in the serum rise with age and after an attack of mastitis.

The development or persistence of *S. aureus* mastitis depends on the interaction between invading bacteria and the host's defense system, principally the somatic cells in an infected gland, which are more than 95% polymorphonuclear cells. The number of bacteria isolated from milk samples of *S. aureus*-infected mammary glands is characterized by a cyclic increase and decrease concomitant with an inverse cycling of the SCC. This relationship between SCC and numbers of bacteria indicates that the cells within the mammary gland have a central role in the pathogenesis of *S. aureus* infection. There appear to be qualitative changes in the ability of the animal's somatic cells to phagocytose the bacteria. During the period of high SCC, the cells are able to kill bacteria 9000 times more efficiently than during the low-SCC period. The relative inability of the polymorphonuclear cells to kill bacteria during the low-SCC period may explain the source of reinfection. Phagocytosis and killing of the bacteria may also be inefficient because of low concentrations of opsonins, a lack of energy source, and the presence of casein and fat globules in the milk. The function of the intramammary polymorphonuclear cell (somatic cells) may also be affected by immunosuppression induced by cortisol and dexamethasone in treated cows.

### Environmental and Management Risk Factors

Several herd-level management risk factors are important for the spread of *S. aureus*.

Poor teat and udder cleaning can allow spread of the organism among quarters of the same cow, and can allow contamination of milking units, which are commonly transferred among cows without washing or rinsing. The use of high-line parlors is a risk; this may be caused by the greater fluctuation in vacuum, especially when units are removed, leading to a greater occurrence of teat-end impacts in which bacteria in the milking unit may enter the teat canal to establish a new udder infection.

Extensive surveys reveal that management procedures that are most effective in reducing infection rates and cell counts associated with infections with *S. aureus* are

- Postmilking teat dipping
- Maintaining a good supply of dry bedding for housed cows
- Thorough disinfection of the teat orifice before infusing intramammary preparations
- Milking clinical cases last

Failure to use these management techniques will increase the risk of intramammary infection with *S. aureus*.

### Pathogen Risk Factors

#### Virulence Factors

It has been known since 1961 that a variety of strains of *S. aureus* associated with clinical mastitis exist and that some of these strains appear to be more infectious within a herd, differing in the severity of clinical signs and persistence of infection.<sup>3-9</sup> *S. aureus* has several virulence factors that account for its pathogenicity and persistence in mammary tissue in spite of adequate defense mechanisms and antimicrobial therapy. **Most isolates from cattle appear to be host adapted and different from human *S. aureus* isolates.** *S. aureus* has the ability to **colonize the epithelium** of the teat and the streak canal and can adhere and bind to epithelial cells of the mammary gland. The specific binding is to the extracellular matrix proteins fibronectin and collagen, which can induce the epithelial cell to internalize the organism, protecting it from both exogenous and endogenous bactericidal factors. Some strains of *S. aureus* are capable of **invading bovine mammary epithelial cells** in culture, and the invasion process requires eukaryotic nucleic acid and protein synthesis as well as bacterial synthesis.

Some strains of *S. aureus* produce **toxins**, some of which may cause **phagocytic dysfunction**. The  $\beta$ -toxin, or a combination of  $\alpha$ - and  $\beta$ -toxins, is produced by most pathogenic strains isolated from cattle, but its pathogenic significance is uncertain. The  $\beta$ -toxin damages bovine mammary secretory epithelial cells, increases the damaging effects of  $\alpha$ -toxin, increases the adherence of *S. aureus* to mammary epithelial cells, and increases the proliferation of the organism. All strains produce **coagulase** (hence the term coagulase-positive *S. aureus*), which

converts fibrinogen into fibrin; this appears to assist the invasion of tissues. **Leukocidin** produced by *S. aureus* may inactivate neutrophils. There is one report in a small number of cases that the presence of small colonies on bacterial culture (reflecting a slower rate of growth) is associated with chronic mastitis in cattle.<sup>10</sup>

Many staphylococcal strains (coagulase negative and coagulase positive) are able to produce an **extracellular exopolysaccharide layer** surrounding the cell wall called a **biofilm**. This capsular structure and its production of slime have been associated with virulence against host defense mechanisms because it facilitates bacterial adherence and colonization on mammary glandular epithelial cells and provides a protective “blanket” against immunologic attack and barrier to antibiotic diffusion. In addition, bacteria contained in a biofilm can have a low metabolic rate and therefore be less susceptible to antibiotic activity.<sup>11-14</sup> Biofilm-forming ability has been identified in 36% to 38% of cows with subclinical *S. aureus* mastitis.<sup>12,14</sup>

A major pathogenic factor is the ability of the organism to colonize and produce microabscesses in the mammary gland so that it is protected from normal defense mechanisms, including phagocytic activity from neutrophils. The difficulty in removing staphylococci from an infected quarter is largely caused by the bacteria's ability to survive in intracellular sites. There is also an ability to convert to a **nonsusceptible L-form** when exposed to antimicrobial agents and to return to standard forms when the antimicrobial is withdrawn.

#### Genotype of Strains

**Phage typing and ribotyping** can be used to classify strains from clinical and subclinical *S. aureus* mastitis. **DNA fingerprinting techniques**, using PCR, are also being used to differentiate various strains of the organism. A large number of different types of *S. aureus* can be isolated from cases of bovine mastitis, but a few types predominate within different countries. Surveys have found that only a small number of genotypes cause most cases of *S. aureus* mastitis, which may be useful information in determining the dynamics of infection in a herd and how infection spreads from cow to cow. Fine-structure molecular epidemiologic analysis of *S. aureus* recovered from cows in the United States and Ireland indicates that only a few specialized clones of *S. aureus* are responsible for the majority of cases of bovine mastitis and that these clones have a broad geographic distribution. **A predominant strain is usually responsible for most clinical and subclinical *S. aureus* infections in a herd**, and it is currently thought that *S. aureus* is a clonal organism that spreads from cow to cow.<sup>3,5,6</sup> Moreover, most strains isolated from milk are different from strains isolated from the teat skin. In

other words, most *S. aureus* strains isolated from mastitis demonstrate both host and site specificity. This has important implications in the control of mastitis associated with *S. aureus*, because a rational and effective strategy for control of intramammary infections should be directed against clones that commonly cause disease.

#### Methicillin-Resistant *Staphylococcus Aureus*

The increased concern about nosocomial **methicillin-resistant *S. aureus* (MRSA)** infections in human medicine and small animal practice<sup>15</sup> has led to surveys of MRSA prevalence in cattle with mastitis. In a study of 207 clinical mastitis cases in Iran, 20% were caused by *S. aureus* and 2.4% were caused by MRSA.<sup>16</sup> In 36 cows with subclinical mastitis in Brazil, 11% of infections were caused by MRSA,<sup>17</sup> and in Serbia 5% of 213 *S. aureus* isolates were identified as MRSA.<sup>18</sup> There are no data available indicating that the clinical course of MRSA mastitis episodes in cattle differs from episodes caused by methicillin-susceptible strains of *S. aureus*; however, MRSA isolation in Italian herds was more likely to be isolated in herds with low *S. aureus* prevalence, with 9% of *S. aureus* isolates being MRSA.<sup>19</sup>

#### Economic Importance

The overall prevalence of mastitis caused by *S. aureus* is much higher than for *S. agalactiae*, and the need for culling causes much greater economic consequences. The risk of new infections is a continuing concern. Response to treatment is comparatively poor, and satisfactory methods for the eradication of staphylococcal mastitis from infected herds have yet to be devised.

#### Zoonotic Implications

The presence of *S. aureus* in market milk may present a degree of risk to the consumer because of the organism's capacity to produce enterotoxins and a toxic shock syndrome toxin, which cause serious food poisoning. Mastitic milk does not constitute any large risk for *S. aureus* enterotoxin food poisoning.

#### PATHOGENESIS

The disease can be reproduced experimentally by the injection of *S. aureus* organisms into the udder of cattle and sheep, but there is considerable variation in the type of mastitis produced. This does not seem to be caused by differences in virulence of the strains used, although strain variations do occur, but may be related to the size of the inoculum used or, more probably, to the lactational status of the udder at the time of infection. It is possible to induce *S. aureus* infection in the bovine teat cistern; the teat tissues are able to mount a marked local inflammatory response, but in spite of large numbers of neutrophils that invade the teat

they are unable to control the infection, except when the numbers of bacteria are low.

Infection during early lactation may result in the peracute form of mastitis, with gangrene of the udder. During the later stages of lactation or during the dry period new infections are not usually accompanied by a systemic reaction but result in the chronic or acute forms. Chronic *S. aureus* mastitis in cows has been converted to the peracute, gangrenous form by the experimental production of systemic neutropenia.

In the **gangrenous form** the death of tissue is precipitated by thrombosis of veins causing local edema and congestion of the udder. *S. aureus* is the only bacteria that commonly causes this reaction in the udder of the cow, and the resulting toxemia is caused by bacterial toxins and tissue destruction. Secondary invasion by *E. coli* and *Clostridium* spp. contributes to the severity of the lesion and production of gas.

The pathogenesis of acute and chronic *S. aureus* mastitis in the cow is the same; the variation occurs only in degree of involvement of mammary tissue. In both forms each focus commences with an acute stage characterized by proliferation of the bacteria in the collecting ducts and, to a lesser extent, in the alveoli. In **acute** mastitis the small ducts are quickly blocked by fibrin clots, leading to more severe involvement of the obstructed area.

In the **chronic** form there are fewer foci of inflammation, and the reaction is milder; the inflammation is restricted to the epithelium of the ducts. This subsides within a few days and is replaced by connective tissue proliferations around the ducts, leading to their blockage and atrophy of the drained area. The leukocyte infiltration into the stroma, the epithelial lining, and the lumina indicate an obvious deficiency of secretory and synthesizing capacity caused by limitation of the alveolar lumina and the distension of the stroma area.

A characteristic of chronic *S. aureus* mastitis that is important in its diagnosis is the cyclical shedding of the bacteria from the affected quarter. Paralleling this variation is a cyclical rise and fall in the number of polymorphonuclear cells in the milk and their capacity to phagocytose bacteria. In some cases abscesses develop and botryomycosis of the udder, in which granulomata develop containing gram-positive cocci in an amorphous eosinophilic mass, is also seen.

## CLINICAL FINDINGS

### Chronic *Staphylococcus aureus* Mastitis

The most important losses are caused by the chronic form or subclinical form of mastitis. Although 50% of cattle in a herd may be affected, only a few animals will have abnormalities recognizable by the milker. Many cases are characterized by a slowly developing induration and atrophy with

the occasional appearance of clots in the milk or wateriness of the first streams. The SCC of the milk is increased, as well as the CMT results of infected quarters, but the disease may go unnoticed until much of the functional capacity of the gland is lost. The infection can persist and the disease may progress slowly over a period of many months.

### Acute and Peracute *Staphylococcus aureus* Mastitis

Acute and peracute staphylococcal mastitis are rare but do occur and can be fatal, even if aggressively treated. **Acute *S. aureus* mastitis** is most common in early lactation. There is severe swelling of the gland, and the milk is purulent or contains many thick clots. Extensive fibrosis and severe loss of function always result.

**Peracute *S. aureus* mastitis** occurs usually in the first few days after calving and is highly fatal. There is a severe systemic reaction with elevation of the temperature to 41°C to 42°C (106°F–107°F), rapid heart rate (100–120 beats/min), complete anorexia, profound depression, absence of ruminal movements, and muscular weakness, often to the point of recumbency. The onset of the systemic and local reactions is sudden. The cow may be normal at one milking and recumbent and comatose at the next. The affected quarter is grossly swollen, hard and sore to touch, and causes severe lameness on the affected side.

**Gangrene** is a constant development and may be evident very early. A bluish discoloration develops that may eventually spread to involve the floor of the udder and the whole or part of the teat, or may be restricted to patches on the sides and floor of the udder. Within 24 hours the gangrenous areas become black and ooze serum and may be accompanied by subcutaneous emphysema and the formation of blisters. The secretion is reduced to a small amount of bloodstained serous fluid without odor, clots, or flakes. Unaffected quarters in the same cow are often swollen, and there may be extensive subcutaneous edema in front of the udder caused by thrombosis of the mammary veins. Toxemia is profound, and death usually occurs unless early, appropriate treatment is provided. Even with early treatment the quarter is invariably lost and the gangrenous areas slough. Separation begins after 6 to 7 days, but without interference the gangrenous part may remain attached for weeks. After separation, pus drains from the site for many more weeks before healing finally occurs.

## CLINICAL PATHOLOGY

### Culture of Individual Cow Milk

Bacteriologic culture of milk is the best method for identifying cows with *S. aureus* intramammary infection. A problem in the laboratory identification of *S. aureus* is that **bacteria are shed cyclically from infected**

**quarters, thus a series of samples are necessary to increase overall test sensitivity when culture is used.** The sensitivity of a composite (4-quarter) sample may be as low as 53%, but it is higher when performed on a quarter basis.<sup>20</sup> Factors that have the greatest impact on the sensitivity of culture, in order of importance, are the

- Type of milk sample
- Volume of milk cultured
- Time interval between repeated milk sample collection strategies

Quarter samples taken on day 1 and repeated either on day 3 or day 4, and cultured separately using 0.1 mL of milk for culture inoculum, were predicted to have sensitivities of 90% to 95% and 94% to 99%, respectively. Repeated quarter samples collected daily and cultured separately gave a sensitivity of 97% and a specificity from 97% to 100%. Culturing of composite milk samples instead of individual quarter samples increases the number of false-negative results in diagnosing *S. aureus* mastitis, but the sensitivity of composite samples can be increased by using 0.05 mL of milk for inoculation instead of 0.01 mL, which is the volume recommended by the National Mastitis Council (NMC). Freezing of milk samples before processing either does not affect the bacterial count or enhances it by about 200%; the latter response is attributed to fracturing of cells containing viable *S. aureus* bacteria. Bacterial counts of more than 200 CFU/mL are commonly used as a criterion for a positive diagnosis of infection.

Milk is typically plated onto sheep blood agar plates to facilitate the growth of a large range of potentially pathogenic microorganisms, but this does not facilitate the growth of all known pathogens. Biochemical tests such as a positive coagulase test and a positive catalase test are routinely used to differentiate *S. aureus* from other gram-positive cocci. *S. aureus* grows very well on sheep blood agar and typically produces a zone of incomplete lysis of erythrocytes around the colony, which may contain an inner zone of complete lysis called double hemolysis.<sup>21</sup> The presence of double hemolysis is diagnostic for *S. aureus*, but colony types that do not demonstrate this morphology need a tube coagulase test to be positive to make a diagnosis of *S. aureus* mastitis with 100% specificity. However, it needs to be recognized that not all coagulase-positive staphylococci are *S. aureus*. Differentiation is best performed by subculturing colonies on sheep blood agar with complete hemolysis at 24 hours' incubation onto CHROMagar plates; *S. aureus* isolates grow on this media as mauve to rose colonies.<sup>21</sup>

**MALDI-TOF MS** shows great promise as a rapid method for accurately differentiating *S. aureus* from the other seven staphylococcal spp. that are coagulase positive by analyzing the metabolic signature of a bacterial colony in under 4 hours.<sup>22</sup>

The Pathoproof Mastitis PCR assay has the highest test sensitivity (91%) and specificity (99%) from cow-level composite samples,<sup>20</sup> and it may provide the preferred test method for composite milk samples when the trade-off between test cost, sensitivity, and specificity is evaluated.

Numerous immunodiagnostic tests have been developed to diagnose *S. aureus* mastitis, with an emphasis on rapid cowside diagnostic tests, but none of these tests has been able to achieve the appropriate balance between sensitivity, specificity, and cost.<sup>23</sup> Increased concentrations of haptoglobin and mammary-associated serum amyloid A occur in the milk of cows with *S. aureus* mastitis, accompanied by increases in serum concentrations of haptoglobin and serum amyloid A.<sup>24</sup>

### Culture of Bulk Tank Milk

The culture of 0.3 mL of bulk tank milk for *S. aureus* using special Baird–Parker culture media is a practical method for detecting the organism in bulk tank milk and monitoring its spread in dairy herds; the sensitivity and specificity for detection of the bacteria ranged from 90% to 100%.

### Somatic Cell Counts and California Mastitis Test

In an attempt to decrease the cost of sampling all quarters for culture, an alternative strategy is to use the SCC as a screening test to identify which cows to culture for *S. aureus*. For all intramammary infections, the sensitivity and specificity of SCC range from 15% to 40% and 92% to 99%, respectively. Composite milk sample SCCs have a low sensitivity, ranging from 31% to 54% for detecting cows with *S. aureus*. Individual quarter SCCs have a higher sensitivity, ranging from 71% to 95% depending on the study and cut point chosen, but quarter sampling is impractical because SCC is usually performed on a composite sample. Both composite and quarter milk SCC testing result in an unacceptably high proportion of infected cows being missed, and are therefore not currently recommended as a screening test if the goal is to identify all cows with an *S. aureus* intramammary infection in the herd.

CMT has also been used as a screening test to identify quarters or cows to culture. Using a CMT trace, 1, 2, or 3 to indicate the presence of an intramammary *S. aureus* infection produced a range of sensitivities from 0.47 to 0.96 and specificities of 0.41 to 0.80.<sup>20</sup>

In summary, culture of quarter milk samples (preferably) or a composite milk sample is superior to a quarter SCC or CMT for the diagnosis of *S. aureus* intramammary infection. Culture is strongly preferred if it is important to identify all positive cows in a herd because the sensitivity of indirect tests (such as SCC and CMT) is inadequate.

### Enzyme-Linked Immunosorbent Assays for Antibody in Milk

ELISA tests for detecting *S. aureus* antibody in milk have been developed but are not widely used. Rapid laboratory tests incorporating these ELISAs, including the Staph-Zym test, have demonstrated 84% to 90% accuracy in identifying staphylococci.

### Acriflavine Disk Assay

The acriflavine disk assay is a practical, accurate method for differentiating *S. aureus* isolates from non-*S. aureus* staphylococci.

### NECROPSY FINDINGS

In peracute staphylococcal mastitis, the affected quarter is grossly swollen and may contain bloodstained milk dorsally but only serosanguineous fluid ventrally. There is extreme vascular engorgement and swelling, often progressing to moist gangrene of the overlying skin. Bacteria are not isolated from the bloodstream or tissues other than the mammary tissue and regional lymph nodes. Histologically, there is coagulation necrosis of glandular tissue and thrombosis of veins.

In milder forms of staphylococcal mastitis the invading organisms often elicit a granulomatous response. Microscopically, such “botryomycotic” cases are characterized by granulomas with a central bacterial colony and by progressive fibrosis of the quarter.

### Samples for Confirmation of Diagnosis

- Bacteriology: chilled mammary tissue, regional lymph node
- Histology: fixed mammary tissue

### DIFFERENTIAL DIAGNOSIS

Because of the occurrence of the peracute form in the first few days after parturition, the intense depression, and inability to rise, the dairy producer may conclude that the cow has **parturient paresis**, which is characterized by weakness, recumbency, hypothermia, rumen stasis, dilated pupils, tachycardia with weak heart sounds, and a rapid response to intravenous calcium gluconate. The mammary gland is usually normal in parturient paresis.

**Peracute *S. aureus* mastitis** is characterized by marked tachycardia, fever, weakness, and evidence of severe clinical mastitis with swelling, heat, abnormal milk with serum and blood, and sometimes gas in the teat and often with gangrene of the teat up to the base of the udder. Other bacterial types of mastitis, particularly *Escherichia coli* and *Trueperella pyogenes*, may cause severe systemic reactions, but gangrene of the quarter is less common.

**Peracute coliform mastitis** is a much more common cause of severe mastitis than *S. aureus* mastitis. The chronic and acute

forms of staphylococcal mastitis are indistinguishable clinically from many other bacterial types of mastitis, and bacteriologic examination is necessary for identification.

### TREATMENT

The bacteriologic cure rates for the treatment of *S. aureus* mastitis with either intramammary infusion or parenteral antimicrobial administration are notoriously less than satisfactory, particularly in the lactating cow. Bacteriologic cure rates after antimicrobial treatment seldom exceed 50%, and infections commonly persist throughout the lifetime of the cow. There are three likely reasons: inadequate penetration of the antimicrobial agent to the site of infection, formation of L-forms of *S. aureus*, and  $\beta$ -lactamase production.

### Inadequate Penetration of Antimicrobial Agent

There is **inadequate penetration of the antimicrobial agent** into the site of intramammary infection in the lactating cow, and the organism survives in phagocytes that are inaccessible. There may also be inactivation of the antimicrobial by milk and serum constituents, and the formation of L-forms of the organism during treatment, varying between 0% and 80% of bacteria.

### Antimicrobial Resistance

**Antimicrobial-resistant strains** of *S. aureus* occur in specific geographic regions because of predominant *S. aureus* clones and are often  $\beta$ -lactamase producers; the enzyme confers resistance to  $\beta$ -lactam antimicrobial agents such as penicillin G, penethamate hydrochloride, ampicillin, and amoxicillin.<sup>25</sup> This emphasizes the need for knowledge of local epidemiologic factors when determining treatment in cases in which the results of culture and susceptibility testing are not available. Cloxacillin and nafcillin are effective, but only against gram-positive bacteria; they are less effective against nonlactamase staphylococci. Clavulanic acid added to amoxicillin overcomes this  $\beta$ -lactamase resistance as does **cloxacillin** added to ampicillin, and this is made use of in a popular intramammary formulation. First- and third-generation cephalosporins and erythromycin are effective against  $\beta$ -lactamase-producing staphylococci, and first- and third-generation cephalosporins are also effective against gram-negative bacteria. A cephalirin dry cow product administered to heifers with *S. aureus* infections resulted in bacteriologic cure and left the quarters clear well into their first lactation. Intramammary cloxacillin and ampicillin is generally considered to be the preferred initial treatment for *S. aureus* mastitis because  $\beta$ -lactamase production by *S. aureus* is sufficiently common.

Antimicrobial therapy for *S. aureus* subclinical mastitis during the lactating period

is not economically attractive because of low bacteriologic cure rates, discarding of milk during the withholding period, and the lack of an economically beneficial increase in production following treatment. Dry cow treatment at the end of lactation is much more effective, being successful in 40% to 70% of cases, although treatment should be attempted in heifers infected early in lactation. Cows that are infected with *S. aureus* should be appropriately identified, segregated if possible, and milked last or with separate milking units. Culling of infected cows is also an option for consideration, but a detailed economic analysis of this popular recommendation is lacking.

### Lactating Cow Therapy

The treatment of clinical cases of *S. aureus* mastitis using intramammary antimicrobial infusions is less than satisfactory but is often done. However, clinical recovery following therapy does not necessarily eliminate the infection, and some of the published literature on cure rates has not made the distinction between clinical and bacteriologic cure rates. Generally, the cure rate depends on the duration of infection, the number of quarters infected, whether it is a hindquarter or front quarter, whether the strain of *S. aureus* is a  $\beta$ -lactamase producer, the immune status of the cow, the antimicrobial agent administered, and the duration of treatment. Current recommendations to ensure the best treatment success rate are to combine intramammary and parenteral antimicrobial treatment or **use extended intramammary treatment alone for 4 to 8 days**. Penicillin G is regarded as the antimicrobial agent of choice for *S. aureus* strains that are penicillin sensitive. Intramammary pirlimycin also has good clinical efficacy when administered as extended therapy for 8 days.<sup>1</sup> An additional advantage of extended therapy with pirlimycin is decreased transmission of *S. aureus* infection within the herd and decreased incidence of strain-specific clinical mastitis within the herd.<sup>1</sup>

The following intramammary infusions, given daily at 24-hour intervals for 3 treatments (unless stated otherwise), have been used for the treatment of clinical cases of *S. aureus* mastitis, with expected clinical cure rates of about 27% to 60% in lactating cows. Subclinical cases are left until the cow is dried off:

- Sodium cloxacillin (200–600 mg for three infusions)
- Tetracyclines (400 mg)
- Penicillin-streptomycin combination (100,000 units, 250 mg)
- Penicillin-tylosin combination (100,000 units, 240 mg)
- Novobiocin (250 mg per infusion for three infusions)
- Cephalosporins (most strains of *S. aureus* are sensitive to cephapirin)

- Cefquinome (75 mg per infusion for three infusions; fourth-generation cephalosporin)
- Pirlimycin-extended therapy (eight 50-mg doses, 24 hours apart, for 8 days)

In a study of 184 cases of subclinical *S. aureus* mastitis in New York, commercially available intramammary infusions were not significantly more effective than untreated controls (43% bacteriologic cure), with the following bacteriologic cure rates: erythromycin (65%), penicillin (65%), cloxacillin (47%), amoxicillin (43%), and cephapirin (43%). In a multicentered randomized clinical trial in Europe, extended intramammary treatment with cefquinome improved clinical cure in lactating dairy cattle from 60% (three infusions 12 hours apart) to 84% (additional three infusions 24 hours apart), but did not alter bacteriologic cure.<sup>26</sup>

A slightly more effective treatment for subclinical *S. aureus* intramammary infection, with a cure rate of 50%, is simultaneous intramammary infusion of amoxicillin (62.5 mg) and intramuscular injection of procaine penicillin G (9,000,000 units). This study was the first to demonstrate that combined parenteral and intramammary therapy was more effective than intramammary infusion alone. Because of the persistence of the infection in each herd, the final choice of the antimicrobial to be used should be based on a culture and susceptibility test; the latter is to determine whether the predominant *S. aureus* strain in the herd is a  $\beta$ -lactamase producer; this is because  **$\beta$ -lactamase-producing strains are harder to cure and require a specific antibiotic protocol**. The bacteriologic cure rate for penicillin-sensitive infections treated with parenteral and intramammary penicillin G was 76%, compared with  $\beta$ -lactamase-producing strains treated with parenteral and intramammary amoxicillin-clavulanic acid (29%).

The application of cytokines as an adjunct to antimicrobial therapy may help to increase the number of phagocytes in the mammary gland and enhance cell function. The experimental intramammary infusion of recombinant interleukin into infected or uninfected mammary glands elicited an influx of polymorphonuclear leukocytes exhibiting subsequent enhanced activity and increased the cure rate 20% to 30% in quarters infected with *S. aureus*.

A novel method for decreasing the transmission of *S. aureus* within a herd is to **selectively cease lactation in infected quarters of lactating cattle**. The best method for permanently drying off a quarter is infusion of 120 mL of 5% povidone iodine solution (0.5% iodine) after complete milk out and administration of flunixin meglumine (1 mg/kg BW, intravenously). Therapeutic cessation of milk production in one quarter does not alter daily milk production but does decrease individual cow SCC and its contribution to

the bulk tank milk SCC. The final outcome of selectively drying off infected quarters is a decrease in the rate of new intramammary infections in the herds and a lowering in the bulk tank milk SCC.

### Peracute Mastitis

Early parenteral treatment of peracute cases with adequate doses of antimicrobials such as trimethoprim-sulfonamide or penicillin is deemed necessary to improve the survival rate. When penicillin is used the initial intramuscular injection should be supported by an intravenous dose of crystalline penicillin, with subsequent intramuscular doses to maintain the highest possible blood level of the antimicrobial over a 4- to 6-day period; ampicillin or penethamate hydriodide are preferred to achieve this. Intramammary infusions are of little value in such cases because of failure of the drugs to diffuse into the gland. The intravenous administration of large quantities of electrolyte solutions is also recommended. Hypertonic saline, as recommended for peracute coliform mastitis, has not yet been evaluated but may be indicated. Frequent massage of the udder with hot wet packs and milking out the affected gland is recommended. Oxytocin is used to promote letdown but is relatively ineffective in severely inflamed glands. Surgical amputation of the teat may be indicated to promote drainage of the gland, but only in cows with necrotic teats.

### Dry Cow Therapy

It has become a common practice to leave chronic *S. aureus* cases until they are dried off before attempting to eliminate the infection. The material is infused into each gland after the last milking of the lactation and left in situ. The major benefits of dry cow therapy are the **elimination of existing intramammary infections and prevention of new intramammary infections during the dry period**. In addition, milk is not discarded and bacteriologic cure rates are superior to those obtained during lactation.

The factors associated with a bacteriologic cure after dry cow therapy of subclinical *S. aureus* mastitis have been examined. The probability of cure of an infected quarter decreased when

- SCC increased (>250,000 cells/mL)<sup>26</sup>
- Age of cow increased
- Another quarter was infected in the same cow
- Infection was in a hindquarter
- The percentage of samples that were positive for *S. aureus* was higher before drying off

Cows with more than one infected quarter were 0.6 times less likely to be cured than cows with one infected quarter. The cure rate of quarters affected with *S. aureus* can be predicted using a formula that considers several cow factors and quarter factors. The prediction of the probability of cure in an 8-year-old cow with three quarters infected

with the organism and an SCC of 2,300,000 is 36%. In a 3-year-old cow with one quarter infected and an SCC of 700,000, the probability of cure is 92%. This information is often available at drying off and can be used to select cows that are unlikely to be cured to be removed from the herd by designating them as “do not breed” and culling when it is economically opportune.

Most intramammary antimicrobial infusions are satisfactory for dry cow therapy provided they are combined with slow-release bases. Bacteriologic cure rates vary between herds from 25% to 75% and average about 50%. The use of parenteral antimicrobials such as oxytetracycline along with an intramammary infusion of cephalixin did not improve the cure rate for *S. aureus*.

## CONTROL

Because of the relatively poor results obtained in the treatment of staphylococcal mastitis, any attempt at control must depend heavily on effective methods of preventing the transmission of infection from cow to cow. *S. aureus* is a contagious pathogen, the udder is the primary site of infection, and hygiene in the milking parlor is of major importance. To reduce the source of the organism, a program of early **identification, culling, and segregation** is important to control *S. aureus* mastitis in a dairy herd, although successful implementation of all three aspects is challenging. Satisfactory control of *S. aureus* mastitis has historically been difficult and unreliable; however, at the present time the quarter infection rate can be rapidly and profitably reduced from the average level of 30% to 10% or less.

The strategies and practices described under the control of bovine mastitis later in this chapter are highly successful for the control of *S. aureus* mastitis when applied and maintained rigorously. The control program includes the following:

- Ensure optimal teat condition, particularly around the teat orifice.
- Hygienic washing and drying of udders before milking, wearing disposable gloves during milking
- Regular milking-machine maintenance
- Teat dipping after milking. Teat dipping in 1% iodine or 0.5% chlorhexidine, either in 5% to 10% glycerin, is effective against *S. aureus* mastitis. In vitro studies have demonstrated that bacteria can grow at concentrations of iodine at  $\leq 0.1\%$  and chlorhexidine at  $\leq 0.0002\%$ .<sup>27</sup> Teat dipping helps to eliminate infected quarters and reduces the new infection rate by 50% to 65% compared with controls, and the addition of glycerin to the teat dip improves teat and teat-orifice condition. The disinfection of hands or use of rubber gloves provides additional advantages.
- Dry cow treatment on all cows
- Culling cows with chronic mastitis

- Milking infected cows last (very difficult to implement in free-stall housing or pasture feeding)

An alternative but radical control strategy when all else has failed is to permanently dry off the infected quarter using a povidone iodine infusion.

## Vaccination

Immunization against *S. aureus* mastitis has been widely researched for 100 years. Different vaccines based on cellular or soluble antigens with and without adjuvants have been given to dairy cows, but protection against infection and clinical disease has been unsatisfactory when used in the field. Currently available vaccines are autogenous bacterins (made to order using isolates from clinical cases on the farm), recombinant protein, DNA-recombinant protein, or contain one or more *S. aureus* strains that are thought to provide good cross-protection.<sup>28</sup> The goals of such vaccines are to decrease the severity of clinical signs and increase the cure rate, particularly when administered to heifers before they calve. Vaccination has also been used simultaneously with antimicrobial therapy during lactation or at dry off in an attempt to augment the cow's immune response, with mixed success. For example, combined administration of 3 doses of a polyvalent *S. aureus* bacterin over 21 days and intramammary administration of pirlimycin in all 4 quarters once daily for 5 days (days 16–20) eliminated *S. aureus* infection at a higher rate (40%) than untreated controls (9%).<sup>29</sup>

Based on published efficacy studies, currently available vaccines cannot be recommended as part of the routine measures for controlling *S. aureus* mastitis. Challenges with developing an effective vaccine include the intracellular location of infection, ability to produce a biofilm, and insufficient vaccine-induced opsonizing antibody in milk to facilitate phagocytosis and clearance of *S. aureus* from infected mammary gland tissue.<sup>30,31</sup>

Development of an effective *S. aureus* vaccine remains one of the most important issues confronting the control of infectious diseases in cattle.

## TREATMENT AND CONTROL

### Treatment

Treat mild to moderate clinical cases during lactation with penicillin G formulation if susceptibility is known, otherwise administer  $\beta$ -lactamase-resistant intramammary formulation; consider using extended therapy (R-1).

Treat moderate to severe clinical cases during lactation with parenteral  $\beta$ -lactamase antimicrobial (such as penethamate hydriodide) and intramammary formulation; consider using extended therapy (R-1).

Treat subclinical infections in freshly calved heifers with penicillin G formulation if susceptibility is known, otherwise administer  $\beta$ -lactamase-resistant intramammary formulation; consider using extended therapy (R-1).

Treat subclinical infections during lactation (R-3).

### Control

Implement 10-point mastitis control plan (R-1).

Cull chronically infected *S. aureus* mastitis cows (R-1).

Blanket dry cow therapy with  $\beta$ -lactamase-resistant intramammary formulation (R-1)

Milk *S. aureus*-infected cows last (R-2).

Eradicate infection from herd (R-2).

Vaccinate using *S. aureus* bacterins (R-3).

## STREPTOCOCCUS AGALACTIAE

### SYNOPSIS

**Etiology** *Streptococcus agalactiae* is a major pathogen of the mammary gland and a common cause of contagious bovine mastitis in some countries.

**Epidemiology** Major cause of mastitis in dairy herds without an effective mastitis control program. Prevalence of infection 10%–50% of cows and 25% of quarters. In herds with an effective control program there is a prevalence of less than 10% of cows. Has been eliminated from many herds with treatment and control. Highly contagious obligate pathogen. Infection is transmitted at milking.

**Clinical findings** Individual repeated episodes of subacute to acute mastitis are most common. Gland is swollen and warm, and milk is watery and contains clots. Gradual induration of udder if not treated

**Clinical pathology** Culture of individual cow milk samples or bulk tank milk samples. Latex agglutination test

**Necropsy findings** Not important

**Diagnostic confirmation** Latex agglutination test for specific identification of organism

**Differential diagnosis** Cannot differentiate clinically from other causes of acute and chronic mastitis. Must culture milk

**Treatment** Mastitis associated with *S. agalactiae* in lactating cows is sensitive to intramammary therapy with a wide variety of antimicrobial agents resulting in a high rate of clinical and bacteriologic cures. Blitz therapy (simultaneous treatment of all positive cows in a herd) is commonly used to reduce prevalence of infection in herd.

**Control** Eradication is possible. Identify and treat infected quarters, cull incurable cows. Premilking teat and udder sanitation, postmilking teat dipping, and dry cow therapy

within a herd will be less than 10% of cows. Following the use of antimicrobial agents, *S. agalactiae* was superseded by *S. aureus* and coagulase-negative *Staphylococcus* spp. as the major cause of bovine mastitis. In herds with a high bulk tank milk SCC, the probability is high that *S. agalactiae* infection is the most prevalent pathogen.

### Source of Infection

*S. agalactiae* is a highly contagious obligate parasite of the bovine mammary gland. The main source of infection is the udder of infected cows, although when hygiene is poor contamination of the environment may provide an additional source. The teats and skin of cattle, milkers' hands, floors, utensils, and clothes are often heavily contaminated. Sores on teats are the most common sites outside the udder for persistence of the organism. The infection may persist for up to 3 weeks on hair and skin and on manure and bricks. The importance of environmental contamination as a source of infection is given due recognition in the general disinfection technique of eradication. Spread of infection between herds is most often associated with purchase of infected cows and heifers but can also result from hiring of relief milkers.<sup>1</sup>

### Transmission of Infection

Transmission from animal to animal is most common from the medium of milking machine liners, hands, udder cloths, and possibly bedding.

The streak canal is the portal of entry, although there is doubt as to how invasion into the teat canal and then gland occurs. Suction into the teat during milking or immediately afterward does occur, but growth of the bacteria into the canal between milking also appears to be an important method of entry. It is difficult to explain why heifers that have never been milked may be found to be infected with *S. agalactiae*, although suckling between calves after ingestion of infected milk or contact with infected inanimate materials may be sources of infection.

### Risk Factors

There is no particular breed susceptibility, but infection does become established more readily in older cows and in the early part of lactation. Poor hygiene, incompetent milking personnel, and faulty or maladjusted machinery are important risk factors. **The most important risk factors are the failure to use postmilking teat dip and the selective or nonuse of dry cow therapy.** The use of a common washrag or sponge is also a risk factor. Inadequate treatment of clinical cases of mastitis is also a frequent risk factor in infected herds.

*S. agalactiae* has the ability to adhere to the mammary gland tissue, and the specific microenvironment of the udder is necessary for growth of the organism. The virulence of

various strains of the organism is related to differences in their ability to adhere to the mammary epithelium. Bacterial ribotyping has been used to characterize strains of the organism to determine their geographic distribution. The physical characteristics of the teat canal may influence the susceptibility to streptococcal infection. The mechanisms used by *S. agalactiae* to penetrate the teat canal are influenced more by the diameter of the teat canal lumen, as reflected by the peak flow rate, than by teat canal length.

### Economic Importance

The disease is of major economic importance in milk production. In individual cows, the loss of production associated with *S. agalactiae* mastitis is about 25% during the infected lactation, and in affected herds the loss may be of the order of 10% to 15% of the potential production. Reduction of the productive life represents an average loss of one lactation per cow in an affected herd. Deaths caused by *S. agalactiae* infection rarely if ever occur, and complete loss of productivity of a quarter is uncommon; the losses are incurred in the less dramatic but no less important fashion of decreased production per cow.

### PATHOGENESIS

When the primary barrier of the streak canal is passed, if bacteria are not flushed out by the physical act of milking they proliferate and invasion of the udder tissue follows. There is considerable variation between cows in the developments that occur at each of the three stages of invasion, infection, and inflammation. The reasons for this variation are not clear, but resistance appears to depend largely on the integrity of the lining of the teat canal. After the introduction of infection into the teat, the invasion, if it occurs, takes 1 to 4 days and the appearance of inflammation 3 to 5 days. Again there is much variation between cows in the response to tissue invasion, and a balance may be set up between the virulence of the organism and undefined defense mechanisms of the host so that very little clinically detectable inflammation may develop despite the persistence of a permanent bacterial flora.

The **development of mastitis** associated with *S. agalactiae* is essentially a process of invasion and inflammation of lobules of mammary tissue in a series of crises, particularly during the first month after infection. Each crisis develops in the same general pattern. Initially there is a rapid multiplication of the organism in the lactiferous ducts, followed by passage of the bacteria through the duct walls into lymphatic vessels and to the supramammary lymph nodes, and an outpouring of neutrophils into the milk ducts. At this stage of initial tissue invasion, a short-lived systemic reaction occurs, and the milk yield falls sharply as a result of inhibition and stasis of secretion caused by damage to acinar and ductal epithelium.

### ETIOLOGY

*Streptococcus agalactiae* infections with environmental streptococci are described in the next section.

### EPIDEMIOLOGY

#### Occurrence and Prevalence of Infection

*S. agalactiae* was the major cause of mastitis before the antimicrobial era and is still a significant cause of chronic mastitis in which control procedures for contagious mastitis are not used. Herd prevalence rates of infection range from 11% to 47%. Typically, in a herd infected with the pathogen, the prevalence of infection could be as high as 50% of cows, but more recent surveys indicate much lower within-herd prevalences, ranging from 8% to 10%. Where good hygienic measures and the efficient treatment of clinical cases are in general use, the prevalence of infection

Fibrosis of the interalveolar tissue and involution of acini result even though the tissue invasion is quickly cleared. Subsequently, similar crises develop and more lobules are affected in the same way, resulting in a step-wise loss of secretory function with increasing fibrosis of the quarter and eventual atrophy.

The **clinicopathologic findings** vary with the stage of development of the disease. Bacterial counts in the milk are high in the early stages but fall when the SCC rises at the same time as swelling of the quarter becomes apparent. In some cases bacteria are not detectable culturally at this acute stage. The SCC rises by 10 to 100 times normal during the first 2 days after infection and returns to normal over the next 10 days. The febrile reaction is often sufficiently mild and short-lived to escape notice. When the inflammatory changes in the epithelial lining of the acini and ducts begin to subside, the shedding of the lining results in the clinical appearance of clots in the milk. Thus the major damage has already been done when clots are first observed. At the stage of acute swelling, it is the combination of inflamed interalveolar tissue and retained secretion in distended alveoli that causes the swelling. Removal of the retained secretion at this stage may considerably reduce the swelling and permit better diffusion of drugs infused into the quarter. Inflammatory reactions also occur in the teat wall of affected quarters.

The variations in resistance between cows and the increased susceptibility with advancing age are unexplained. Hormonal changes and hypersensitivity of mammary tissue to streptococcal protein have both been advanced as possible causes of the latter. Local immunity of mammary tissue after an attack probably does not occur, but there is some evidence to suggest that a low degree of general immunity may develop. The rapid disappearance of the infection in a small proportion of cows in contrast to the recurrent crises that are the normal pattern of development suggests that immunity does develop in some animals. The antibodies are hyaluronidase inhibitors and are markedly specific for specific strains of the organism. A nonspecific rise in other antibodies may occur simultaneously, and this is thought to account for the field observations that coincident streptococcal and staphylococcal infections are unusual and that the elimination of one infection may lead to an increased incidence of the other.

### CLINICAL FINDINGS

In the experimentally produced disease, there is initially a sudden episode of acute mastitis, accompanied by a transient fever, followed at intervals by similar attacks, which are usually less severe. In natural cases fever, lasting for a day or two, is occasionally observed with the initial attack, but the inflammation of the gland persists and the

subsequent crises are usually of a relatively mild nature. These degrees of severity may be classified as **abnormal cow** when the animal is febrile and off its feed; **abnormal gland** when the inflammation of the gland is severe, but there is no marked systemic reaction; and **abnormal secretion** when the gland is not greatly swollen, pain and heat are absent, and the presence of clots in watery foremilk may be the only apparent abnormality. Induration is most readily palpable at the udder cistern and in the lower part of the udder and varies in degree with the stage of development of the disease.

The milk yield of affected glands is markedly reduced during each crisis but, with proper treatment administered early, the yield may return to almost normal. Even without treatment the appearance of the milk soon becomes normal, but the yield is significantly reduced and subsequent crises are likely to reduce it further.

### CLINICAL PATHOLOGY

The **CAMP test**, which has served as the universally used means of identifying *S. agalactiae* for many years, has been displaced by a commercial **latex agglutination test**, which contains specific reagents necessary for the identification of *S. agalactiae* and is suitable for general laboratory use. When used on isolates of samples from bulk tank milk, the sensitivity and specificity are 97.6% and 98.2%, respectively. An ELISA test correlates well with the bulk tank milk SCC and provides a suitable alternative.

The critical judgment to be made is deciding when the quarter infection rate is so high that control or eradication measures are necessary. A decision can be made on the basis of the bulk tank milk SCC as an indicator of the prevalence of mastitis on a quarter basis and on culture of the bulk tank milk sample to indicate that *S. agalactiae* is the important pathogen, but this approach is too inaccurate to be recommended. There seems to be no alternative to performing bacteriologic culture and determining SCC on milk samples from individual cows or quarters. Milk samples collected for bacteriologic examination for the presence of *S. agalactiae* can be stored in the frozen state. The number of samples that will be culturally positive when the stored frozen samples are thawed will either be unchanged or enhanced up to 200%; the latter response is attributing to fracturing of cellular debris containing *S. agalactiae*.

### Culture From Bulk Tank Milk Samples

The presence of the organism in bulk tank milk is caused by shedding of bacteria from infected quarters, and cyclic shedding is typical. The specificity of culture from bulk tank milk is very high; the sensitivity is more variable and typically much lower but can be increased by using selective media. A rapid, real-time quantitative PCR assay, the

PathoProof mastitis PCR, provides a useful herd test when performed on bulk tank milk, because the test detects both growth-inhibited and nonviable bacteria.<sup>2</sup> When used at a cycle threshold of <40 this PCR test can be considered as a positive; however, for cycle thresholds >40 bacteriologic culture is recommended to confirm the presence of infection. A quantitative PCR assay specific for *S. agalactiae* has been developed.<sup>3</sup>

### Total Bacterial Count

The total bacterial count in bulk tank milk can be markedly increased because of the presence of *S. agalactiae* mastitis in the herd. Samples of bulk tank milk from infected herds commonly contain bacterial counts in the range of 20,000 to 100,000 CFU/mL, because a cow in the early stages of infection can shed up to 100,000,000 bacteria/mL. The standard plate count can drop from 100,000 to 2,000 CFU/mL after implementation of a modified blitz therapy and control program to control *S. agalactiae*.

### Culture From Individual Cow Samples

Composite milk samples are satisfactory, because the number of cows identified as positive does not increase by quarter sampling. The sensitivity and specificity of a single culture from individual cows ranges between 95% and 100%.

### Somatic Cell Count

*S. agalactiae* produces high SCC in individual cows, which has a significant influence on the bulk tank milk SCC.

### NECROPSY FINDINGS

The gross and microscopic pathology of mastitis associated with *S. agalactiae* are not important in the diagnosis of the disease.

### DIFFERENTIAL DIAGNOSIS

The clinical diagnosis of *S. agalactiae* mastitis depends entirely on the isolation of *S. agalactiae* from the milk. Differentiation from other types of acute and chronic mastitis is not possible clinically.

### TREATMENT

*S. agalactiae* is **very sensitive to intramammary therapy** using a wide variety of commercially available intramammary infusion preparations. Systemic therapy is also effective but offers no advantages over the intramammary route. Clinical cases should be treated whenever they occur because of the need to prevent transmission to uninfected quarters and cows. Subclinical cases identified at any stage of lactation should be treated immediately because of the excellent response to treatment. Treatment of *S. agalactiae* mastitis with intramammary infusions will result in a high percentage of infections being eliminated economically

and with few residual concerns, provided the milk withholding times are observed.

Infections at all stages of lactation have 90% to 100% cure rates with penicillin, erythromycin, cloxacillin, and cephalosporins. Gentamicin, neomycin, nitrofurazone, and polymyxin B have poor activity. Procaine penicillin G is universally used as a mammary infusion at a dose rate of 100,000 units. Higher dose rates have the disadvantage of increasing penicillin residues in the milk. A moderate increase in efficiency is obtained by using procaine penicillin rather than the crystalline product, and by using 100,000 units of penicillin in a long-acting base the cure rate (96%) is significantly better than with quick-acting preparations (83%).

To provide a broader spectrum of antimicrobial efficiency penicillin is often combined with other drugs that are more effective against gram-negative organisms. A mixture of penicillin (100,000 units) and novobiocin (150 mg) provides a cure rate ranging from 89% to 98%. It is necessary to maintain adequate milk levels for 72 hours: three infusions at intervals of 24 hours are recommended, but dosing with two infusions 72 hours apart, or one infusion of 100,000 units, in a base containing mineral oil and aluminum monostearate, gives similar results. As a general rule clinical cases should be treated with three infusions, and subclinical cases, particularly those detected by routine examination in a control program, with one infusion. Recovery, both clinically and bacteriologically, should be achieved in at least 90% of quarters if treatment has been efficient. Intramuscular administration of ceftiofur is not efficacious as a treatment to eliminate the organism, compared with intramammary infusion of penicillin (100,000 units) and novobiocin (150 mg) daily for two treatments. Likewise, intramuscular administration of penethamate hydriodide (5 g) was not as effective as a treatment to eliminate *S. agalactiae* compared with intramammary infusion of ampicillin (75 mg) and cloxacillin (200 mg) twice daily for 3 days.<sup>4</sup>

Other antimicrobial agents used in the treatment of *S. agalactiae* infections include the tetracyclines and cephalothin, which are as effective as penicillin and have the added advantage of a wider antibacterial spectrum, an obvious advantage when the type of infection is unknown. Neomycin is inferior to penicillin in the treatment of *S. agalactiae* mastitis, whereas tylosin and erythromycin appear to have equal efficacy. A single treatment with 300 mg of erythromycin is recommended as curing 100% of quarters infected with *S. agalactiae*. Lincomycin (200 mg) combined with neomycin (286 mg) and administered twice at 12-hour intervals also has good efficacy. In a study of 1927 cases of subclinical *S. agalactiae* mastitis in New York, all commercially available intramammary infusions were more effective than

untreated controls (27% bacteriologic cure), with the following bacteriologic cure rates: amoxicillin (86%), erythromycin (81%), cloxacillin (77%), cephalirin (66%), penicillin (63%), hetacillin (62%), pirlimycin (44%).

In dry cows, one infusion is sufficient, and milk concentrations of penicillin remain high for 72 hours. Cloxacillin eliminated the organism from 98% and 100% of infected cows in two different studies.

### Blitz Therapy

The prevalence of subclinical mastitis caused by *S. agalactiae* can be reduced more rapidly by treatment of infected cows during lactation than by dry cow therapy and postmilking teat dipping. *S. agalactiae* is one of the few pathogens causing subclinical mastitis that can be treated economically during lactation and can be eliminated from herds with **blitz antimicrobial therapy followed by good sanitation procedures**. All cows are sampled, and those that are positive are treated simultaneously with penicillin and novobiocin. Cows not responsive to the first treatment are identified and retreated or culled. Failure to institute sanitation procedures for the control of the pathogen may result in subsequent outbreaks of mastitis.

If blitz therapy of all infected cows is not possible because of the short-term effect of lost milk production on income, a modified treatment protocol is recommended. The herd is divided into two groups, based on a composite milk SCC of 500,000. Those cows in the high category are treated with 300 mg of erythromycin, intramammarily. When lactating cow numbers reach their lowest point, all animals are treated with the same product. At drying off, cows are treated with 500 mg of cloxacillin and 250 mg of ampicillin.

### CONTROL

Eradication on a herd basis of mastitis associated with *S. agalactiae* is an accepted procedure and has been undertaken on an area scale in some countries. The control measures as outlined later in this chapter are designed especially for this disease and should be adopted in detail. If suitable hygienic barriers against infection can be introduced and if the infection can be eliminated from individual quarters by treatment, the disease is eradicable fairly simply and economically.

The control program consists of

- Identifying infected quarters
- Treating infected quarters on two occasions if necessary
- Culling incurable cows

The control program is particularly applicable in herds in which an unacceptable level of clinical cases is backed by a high incidence of subclinical infections. **Premilking teat and udder sanitation, postmilking teat dipping, and dry cow therapy** are vital aspects of the control program.

### Vaccination

Vaccination against *S. agalactiae* has been attempted and elicits systemic hyperimmunity but no apparent intramammary resistance. Development of an effective vaccine will be difficult because of the multiplicity of strains involved and the known variability between animals in their reaction to intramammary infection.

### Biosecurity

As with any eradication program a high degree of vigilance is required to maintain a "clean" status. This is particularly so with mastitis caused by *S. agalactiae*. Breakdowns are usually caused by the introduction of infected animals, even heifers that have not yet calved, or the employment of milkers who carry infection with them. Most dairy farms in the United States are in an ongoing process of herd expansion or replacement acquisition by the addition of purchased animals. Introduction of contagious mastitis associated with *S. agalactiae*, *S. aureus*, and *M. bovis* is a common result. It has been recommended that herd additions should be screened for these important pathogens; however, currently available screening tests do not have perfect sensitivity.

### TREATMENT AND CONTROL

#### Treatment

Treat clinical cases during lactation with penicillin G formulation (R-1).

Consider blitz therapy of herd using intramammary formulation during lactation (R-2).

Treat clinical cases during lactation with parenteral antimicrobial (such as penethamate hydriodide) (R-3).

#### Control

Implement 10-point mastitis control plan, including postmilking teat dip or spray (R-1).

Blanket dry cow therapy with intramammary formulation (R-1)

Eradicate infection from herd (R-1).

Vaccinate against *S. agalactiae* (R-3).

## CORYNEBACTERIUM BOVIS

### ETIOLOGY

*Corynebacterium* spp. are a common contagious cause of subclinical mastitis in dairy

cows, and 89% of isolates are *C. bovis*.<sup>1</sup> For this reason, mastitis isolates identified as *Corynebacterium* spp. are frequently termed *C. bovis*. It has been cultured from dairy cattle with clinical mastitis in 1.7% of cases and, in a herd that had controlled contagious mastitis pathogens, *C. bovis* was the only pathogen isolated in 22% of clinical mastitis episodes. There is considerable debate about the significance of *C. bovis* infections for mammary gland health and cow productivity. For this reason, *C. bovis* is classified as a **minor pathogen**.

## EPIDEMIOLOGY

The main reservoir of infection appears to be the teat canal region, but *C. bovis* is also isolated from the teat cistern, gland cistern, and mammary parenchyma.<sup>2</sup> *C. bovis* spreads rapidly from cow to cow in the absence of adequate teat dipping. It is extremely contagious, and the duration of intramammary infection is long (many months). The prevalence of *C. bovis* is typically low in herds using an effective germicidal teat dip, good milking hygiene, and dry cow therapy.

In vivo and in vitro studies have demonstrated that the bacteria has a predilection for the streak canal, and this predilection has been associated with a requirement for lipids (possibly in the keratin plug) for growth. It is possible that *C. bovis* infection in the streak canal may compete with ascending bacterial infections for nutrients, decreasing the new intramammary infection rate. Alternatively, the mild increase in SCC associated with *C. bovis* infection might increase the ability of the quarter to respond to a new intramammary infection. The *C. bovis* genome has been sequenced, and this indicated a bacteria that is well equipped to reside in the bovine udder, particularly the streak canal. The genome contains a number of genes related to lipolysis, including metabolism of glycerols and phosphoacylglycerols, and utilization of casein and lactose.<sup>3</sup>

Intramammary infection with *C. bovis* induces a higher than normal SCC,<sup>2</sup> increasing the resistance of the colonized quarter to invasion by a major pathogen. In particular, the lowest rate of intramammary infection with major pathogens is observed in quarters infected with *C. bovis*.

## CLINICAL FINDINGS

An intramammary infection with *C. bovis* is infrequently associated with clinical disease but usually causes a mild to moderate increase in the SCC and a small increase in the CMT score.<sup>4</sup> Milk production losses are usually not detectable, and the mastitis is typically a thicker than normal milk (abnormal secretion); occasional cases also have a large firm gland (abnormal gland), with systemic signs of illness being unusual (abnormal cow). There are clear herd-to-herd differences in the apparent clinical

pathogenicity of *C. bovis*, suggesting that strains of different virulence are present.

## TREATMENT

*C. bovis* is very susceptible to penicillin, ampicillin, amoxicillin, cephalixin, and erythromycin and most other commercially available intramammary infusions. There is no need for parenteral treatment. The duration of infection is prolonged (months) in animals not treated with antimicrobial agents.

## CONTROL

Long-term intensive programs of teat dipping and dry cow therapy will markedly reduce the prevalence of *C. bovis*. Because of its status as a minor pathogen, specific control measures (such as vaccination) are not indicated.

### TREATMENT AND CONTROL

#### Treatment

Treat *Corynebacterium bovis* clinical mastitis episodes during lactation with an intramammary formulation (R-1).

#### Control

Implement 10-point mastitis control plan, with particular emphasis on teat dipping/spraying and blanket dry cow intramammary treatment (R-1).

## M. BOVIS AND OTHER MYCOPLASMA SP.

### ETIOLOGY

A number of species of *Mycoplasma*, especially *M. bovis* and occasionally *Mycoplasma* species group 7, *Mycoplasma* F-38, *M. arginini*, *M. bovirhinis*, *M. canadensis*, *M. bovis genitalium*, *M. alkalescens*, *M. capricolium*, *M. californicum*, and *M. dispar*, have been isolated from clinical cases. Other mycoplasmas, not usually associated with the development of mastitis, also cause the disease when injected into the udder. There is also evidence of mastitis associated with *Ureaplasma* spp. A striking characteristic of the mycoplasmas is that they seem to be able to survive in the presence of large numbers of leukocytes in the milk. Antibodies to the bacteria have not been detectable in sera or whey from animals infected with some strains, but complement-fixing antibodies are present in the sera of animals recovered from infection with other strains.

### SYNOPSIS

**Etiology** *Mycoplasma bovis*, other *Mycoplasma* spp.

**Epidemiology** A highly contagious mastitis causing outbreaks of clinical mastitis. Most common in large herds with recent introductions. Transmitted within herds by bulk mastitis treatments and poor milking hygiene. Cows of all ages and any stage of lactation but those in early lactation are most severely affected.

**Clinical findings** Sudden onset of clinical mastitis in many cows, usually all four quarters, marked drop in milk production and may stop lactating, swelling of the udder and gross abnormality of the milk without obvious signs of systemic illness, eventually udders atrophy and do not return to production. Can cause clinical, subclinical, and chronic intramammary infections. Calves suckling milk from infected cows may develop otitis media/interna.

**Clinical pathology** Special culture and staining of milk techniques

**Necropsy findings** Purulent interstitial mastitis

**Diagnostic confirmation** Identification of pathogen in milk

**Differential diagnosis** Epidemiology and clinical findings are characteristic of *Mycoplasma* mastitis. May resemble other causes of chronic mastitis unresponsive to treatment

**Treatment** Not responsive to commonly used mastitis treatments protocols. Identify and cull affected cows for slaughter.

**Control** Prevent entry of infected cows into herd. Eradicate infection by culling affected cows.

*Acholeplasma laidlawii* is not a mastitis pathogen, but it has been observed that a high proportion of bulk tanks will give positive cultural tests for it, especially during wet, rainy weather. This increase is accompanied by an increase of clinical mycoplasma mastitis caused by pathogenic mycoplasma. *A. laidlawii* is considered to be a milk contaminant in these circumstances.

The group of diseases, including mastitis, that are associated with *Mycoplasma* spp. in sheep and goats are dealt with separately.

### EPIDEMIOLOGY

#### Occurrence and Prevalence of Infection

The disease was first reported in 1961 in the United States and since then has been recorded in Canada, Europe, Israel, and Australia. The quarter infection rate in infected herds varies widely.

#### Source of Infection

The epidemiology of the disease has been incompletely characterized. *Mycoplasma*

mastitis is most common in large herds and in herds in which milking hygiene is poor and when cows are brought in from other farms or from public saleyards. *Mycoplasma* mastitis usually breaks out subsequently after a delay of weeks or even months. The delay in development of an outbreak may be related to the long-term persistence of the organism (more than 12 months) in some quarters, and some cows become shedders of the organism without ever exhibiting signs of severe clinical mastitis.

*M. bovis* is capable of colonizing and surviving in the upper respiratory tract and the vagina, and extramammary colonization explains many of its epidemiologic paradoxes. An interesting epidemiologic observation is the detection of mycoplasmas and infectious bovine rhinotracheitis virus in affected udders at the same time. The virus could be the much sought after unknown factor in the etiology of the disease. Outbreaks of mastitis are recorded concurrently with outbreaks of vaginitis and otitis media/interna vestibulitis.

### Transmission

Entry of the disease to a herd is usually by the purchase of animals and their introduction without quarantine. Transmission within a herd is most common at milking via machine milking or the hands of milkers.<sup>1</sup> Transmission can also be through the use of bulk mastitis treatments administered through a common syringe and cannula. Although the disease occurs first in the inoculated quarter, there is usually rapid spread to all other quarters.

Hematogenous spread of *M. bovis* has been demonstrated. Colonization of body sites other than the mammary gland is common, and *M. bovis* isolates from the respiratory and urogenital systems are frequently the same *M. bovis* subtypes that cause mastitis.

*Mycoplasma* spp. group 7 has also been isolated from cases of pneumonia and polyarthritis in calves fed milk from cows with mycoplasmal mastitis.

### Risk Factors

Cows of all ages and at any stage of lactation are affected, and cows that have recently calved show the most severe signs and dry cows the least severe signs. There are several recorded outbreaks in dairy herds in dry cows, and one of them is immediately after mammary infusions of dry period treatment that affected all quarters of all cows.

Experimental production of the disease with *M. bovis* causes severe loss of milk production, a positive CMT reaction, and clots in the milk. Experimental infection produces little tissue necrosis, but *Mycoplasma* are detectable in many tissues, including blood, vagina, and fetus, indicating that hematogenous spread has occurred. It is also apparent that spread of infection between quarters in

one cow can be hematogenous. There are no significant pathologic differences between mastitis produced by *M. bovis* and *M. bovis*; however, *M. bovis* remains the most common cause of mycoplasmal mastitis in dairy cattle.

### Economic Importance

The disease is a disastrous one because of the high incidence in affected herds and the almost complete cessation of lactation. Many cows fail to ever return to milking; as many as 75% of affected cows may have to be culled.

### PATHOGENESIS

This is a purulent interstitial mastitis. Although infection probably occurs via the streak canal, the rapid spread of the disease to other quarters of the udder and occasionally to joints suggests that hematogenous spread may occur. The presence of the infection in heifers milked for the first time also suggests that systemic invasion may be followed by localization in the udder.

*M. bovis* appears to have a number of virulence attributes, with **variable surface lipoproteins** (Vsps) an important virulence factor. Some of these surface antigens are involved in the adherence of *M. bovis* to epithelial cells; adherence is important because the small genome of *M. bovis* means that the organism is dependent on the host for essential biosynthetic pathways, such as amino acids, lipids, and nucleotides. The Vsps also play an important role in interacting with the cow's immune system.

### CLINICAL FINDINGS

In lactating cows, there is a sudden onset of swelling of the udder, a sharp drop in milk production, and grossly abnormal secretion in one or more quarters. In most cases all four quarters are affected, and a high-producing cow may fall in yield to almost zero between one milking and the next. Dry cows show little swelling of the udder. Although there is no overt evidence of systemic illness, and febrile reactions are not observed in most field cases in lactating cows, those that have recently calved show the most obvious swelling of the udder and may be off their feed and have a mild fever. However, cows infected experimentally show fever up to 41°C (105.5°F) on the third or fourth day after inoculation, which is at the same time the udder changes appear. The temperature returns to normal in 24 to 96 hours. In some cases the supramammary lymph nodes are greatly enlarged. **The classic clinical presentation is severe clinical mastitis in multiple quarters of multiple cows with minimal systemic signs of disease.** A few cows, with or without mastitis, develop arthritis in the knees and fetlocks. The affected joints are swollen, with the swelling extending up and down the leg. Lameness may be so severe that the foot is not put to

the ground.<sup>2</sup> *Mycoplasma* may be present in the joint.

The secretion from affected quarters is deceptive in the early stages because it appears fairly normal at collection; on standing, however, a deposit, which may be in the form of fine, sandy material, flakes, or flocules, settles out leaving a turbid whey-like supernatant. Subsequently the secretion becomes scanty and resembles colostrum or soft cheese curd in thin serum. The secretion may be tinged pink with blood or show a gray or brown discoloration. Within a few days the secretion is frankly purulent or curdy, but there is an absence of large, firm clots. This abnormal secretion persists for weeks or even months.

Affected quarters are grossly swollen. Response to treatment is very poor, and the swollen udders become grossly atrophied. In infection with one strain of the *Mycoplasma*, many cows do not subsequently come back into production, although some may produce moderately well at the next lactation. With other strains there is clinical recovery in 1 to 4 weeks without apparent residual damage to the quarter.

Mycoplasma mastitis caused by *M. bovis* may be very mild and disappear from the herd spontaneously and without loss of milk production.

### CLINICAL PATHOLOGY

The causative organism can be cultured without great difficulty by a laboratory skilled in working with *Mycoplasma*. Samples for culture should be freshly collected and transported at 4°C (39°F), and concurrent infection with other bacteria is common. Diagnosis at the herd level can be made by culturing bulk tank milk or milk from cows with clinical mastitis or increased SCC. However, the sensitivity of bulk tank milk culturing is poor (33%–59%). A marked leukopenia, with counts as low as 1,800 to 2,500 cells/μL, is present when clinical signs appear and persists for up to 2 weeks. SCCs in the milk are very high, usually over 20,000,000 cells/mL. In the acute stages the organisms may be able to be visualized by the examination of a milk film stained with Giemsa or Wright-Leishman stain. Species identification of *Mycoplasma* isolates is usually done using immunofluorescence and homologous fluorescein-conjugated antibody or an indirect immunoperoxidase test (immunohistochemistry). Speciation of the causative *Mycoplasma* species is recommended.

### NECROPSY FINDINGS

Grossly, diffuse fibrosis and granulomatous lesions containing pus are present in the mammary tissue. The lining of the milk ducts and the teat sinus is thick and roughened. On histologic examination the granulomatous nature of the lesions is evident. Metastatic pulmonary lesions have been found in a few longstanding cases.

### Samples for Confirmation of Diagnosis

- Mycoplasma: chilled mammary tissue, regional lymph node (special media)
- Histology: fixed mammary tissue

### DIFFERENTIAL DIAGNOSIS

A presumptive diagnosis can be made based on the clinical findings, but laboratory confirmation by culture of the organism is desirable. Because the organism does not grow on standard media and other pathogenic bacteria are commonly present often lead to errors in the laboratory diagnosis unless attention is drawn to the characteristic field findings.

### TREATMENT

The majority of *M. bovis* strains isolated from cattle are susceptible in vitro to fluoroquinolones, florfenicol, and tiamulin. Approximately half of the isolates are susceptible to spectinomycin, tylosin, and oxytetracycline, and very few isolates are susceptible in vitro to gentamicin, tilmicin, ceftiofur, ampicillin, or erythromycin. The clinical relevance of these in vitro susceptibility data to treating mycoplasmal mastitis remains questionable.

Cows diagnosed with mycoplasmal mastitis should be considered to be infected for life. None of the common antimicrobial agents appear to be effective and oil-water emulsions used as intramammary infusions appear to increase the severity of the disease. Parenteral treatment with oxytetracycline (5 g intravenously, daily for 3 days) has been shown to cause only temporary improvement. A mixture of tylosin 500 mg and tetracycline 450 mg used as an infusion cured some quarters. Unless treatment is administered very early in the course of the disease, the tissue damage has already been done.

A puzzling observation in one study was that identification of infected cows and preferential culling of these cows was not associated with eliminating the infection from the herd, provided that good milking practices were followed.<sup>3</sup> Infection was eliminated from most herds in that study within 1 month of the initial diagnosis.<sup>3</sup>

### CONTROL

Prevention of introduction of the disease into a herd appears to depend on avoidance of introductions, or isolating introduced cows until they can be checked for mastitis. A popular biosecurity recommendation is to culture the milk of all replacement cows for *M. bovis*, but the sensitivity and specificity of milk culture in cows with subclinical infections appears to be low. The disease spreads rapidly in a herd, and affected animals should be culled immediately or placed in strict isolation until sale. Eradication of the disease can be achieved by culling infected cows

identified by culturing milk and nasal swabs, especially at drying off and calving. When eradication is completed the bulk tank milk SCC is the best single monitoring device to guard against reinfection. An alternative program recommended for large herds is the creation of an infected subherd that is milked last. There appears to be merit in the frequent culturing of bulk milk samples as a surveillance strategy for problem herds and areas. Frequent culturing overcomes the poor sensitivity of bulk tank milk culturing. Cows with infected quarters are segregated into the subherd, and cows developing clinical illness or decreased milk yield are culled.

Intramammary infusions must be performed with great attention to hygiene and preferably with individual tubes rather than multidose syringes. Most commercial teat dips are effective in control. Use of disposable latex gloves with disinfection of the gloved hands between cows may minimize transmission at milking.

Vaccination is a possible development but is unlikely to be a satisfactory control measure because the observed resistance of a quarter to infection after a natural clinical episode is less than 1 year. This may be because of the presence of variable surface proteins that enable the pathogen to evade host immunity or because mycoplasmas appear to activate the host immune system via secreted secondary metabolites.<sup>4</sup> An *M. bovis* bacterin is commercially available in the United States that contains multiple strains of *M. bovis*. Autogenous bacterins have also been made for specific herds; however, no vaccine has proven efficacy for preventing, decreasing the incidence of, or decreasing the severity of clinical signs of mycoplasmal bovine mastitis.

*Mycoplasma* are sensitive to drying and osmotic changes but more resistant than bacteria to the effects of freezing or thawing. Amputating the teats of affected quarters may result in heavy contamination of the environment and is not recommended. Because *M. bovis* can cause respiratory disease, otitis media/interna, and arthritis in calves, all colostrum and waste milk fed to calves should be pasteurized.

### TREATMENT AND CONTROL

#### Treatment

Identify, segregate, but do not treat infected cattle with confirmed subclinical or clinical mastitis caused by *Mycoplasma bovis* mastitis (R-1).

#### Control

Implement 10-point mastitis control plan (R-1).

Eradicate infection from herd as soon as practical (R-1).

Pasteurize waste colostrum or milk fed to suckling calves (R-2).

Screen purchased cows for intramammary infection with *M. bovis* (R-2).

Vaccinate using *M. bovis* bacterins (R-3).

## Mastitis of Cattle Associated With Teat Skin Opportunistic Pathogens

### COAGULASE-NEGATIVE STAPHYLOCOCCI

Because of the intense investigation of coagulase-positive staphylococcal mastitis (*S. aureus*), coagulase-negative staphylococcal intramammary infections have come under closer scrutiny and are now among the most common bacteria found in milk, especially in herds in which the major pathogens have been adequately controlled. There is considerable debate about the significance of these pathogens for the mammary gland and for cow productivity.<sup>1-3</sup> For this reason, these pathogens continue to be classified as **minor pathogens**.

### ETIOLOGY

CNS are common but minor contagious pathogens that include *S. epidermidis*, *S. hyicus*, *S. chromogenes*, *S. simulans*, and *S. warneri* that are normal teat skin flora, and *S. xylosum* and *S. sciuri* that come from an uncertain site. At least 10 different species of CNS have been isolated from cattle with mastitis. *S. simulans*, *S. chromogenes*, and *S. epidermidis* are the predominant CNS species in bovine mastitis and are associated with persistent intramammary infection<sup>4</sup>; *S. simulans* is a common isolate from older cows, whereas *S. chromogenes* is most frequently isolated from heifers before calving and during their first lactation.

### EPIDEMIOLOGY

CNS are predominantly **teat skin opportunistic pathogens** and cause mastitis by ascending infection via the streak canal. They appear to have a protective effect against colonization of the teat duct and teat skin by *S. aureus* and other major pathogens, with the exception of *E. coli* and the environmental streptococci. Sources of CNS, other than the mammary gland and teat skin, are suspected to be in the dairy environment for some species, and it is likely that further investigation on a species level will identify species that are predominantly found in the environment<sup>5</sup> or have close human contact.<sup>6</sup> Preliminary findings indicate that *S. chromogenes* and *S. epidermidis* may be more host adapted to the bovine mammary gland and therefore have contagious characteristics. In

comparison, *S. simulans* and *S. haemolyticus* may have environmental reservoirs; therefore their epidemiology may be more similar to that of environmental mastitis pathogens.<sup>5</sup> Large differences from farm to farm have been reported.<sup>7</sup>

Studies in the United States found that 20% to 70% of heifer quarters are infected before parturition with CNS, but these infections are usually eliminated spontaneously or with antimicrobial therapy during early lactation. A survey of the prevalence and duration of intramammary infection in heifers in Denmark in the peripartum period found *S. chromogenes* in 15% of all quarters before parturition, but this decreased to 1% of all quarters shortly after parturition. In Finland, CNS are the most commonly isolated bacteria from milk samples of heifers with mastitis. Infections with *S. simulans* and *S. epidermidis* occurred in 1% to 3% of quarters both before and after parturition. Infection with *S. simulans* persisted in the same quarter for several weeks, but intramammary infections with *S. epidermidis* were transient.

Coagulase-positive *S. hyicus* and *S. intermedius* have been isolated from some dairy herds and can cause chronic, low-grade intramammary infection and be confused with *S. aureus*. The prevalence of infection with *S. hyicus* was 0.6% of all cows and 2% of heifers at parturition; the prevalence of infection of *S. intermedius* was less than 0.1% of cows.

The major economic impact of CNS infection is that the mild to moderate increase in SCC, when coupled with a moderate to high prevalence of infection, may discount the price paid for milk.<sup>8</sup> *S. simulans*, *S. chromogenes*, and *S. xylophilus* appear to increase SCC to a much greater degree during subclinical infection than other CNS.<sup>7,9</sup> Intramammary infection with CNS does not appear to have an effect on milk yield or composition.<sup>3</sup> For heifers, the presence of a CNS intramammary infection at calving was associated with fewer cases of clinical mastitis and higher milk yield in their first lactation.<sup>1</sup> Based on these findings, the authors concluded that CNS intramammary infection around calving should not be a cause of concern.<sup>1</sup>

### CLINICAL FINDINGS

CNS are usually associated with mild clinical disease (abnormal secretion only and occasionally abnormal gland) and are commonly isolated from mild clinical cases of mastitis and subclinical infections. For example, *Staphylococcus* spp. have been cultured from dairy cattle with clinical mastitis in 29% of cases, and subclinical infections usually induce a moderate increase in SCC.

### CLINICAL PATHOLOGY

Intramammary infections by minor pathogens such as CNS result in a higher than

normal SCC, increasing the resistance of the colonized quarter to invasion by a major pathogen. Although these bacteria are capable of causing microscopic lesions, they are not nearly as pathogenic as *S. aureus*, and necropsy reports are lacking.

A small number of CNS isolates are methicillin resistant,<sup>10</sup> and 54% of CNS in one study were identified to have slime-producing ability.<sup>11</sup> The epidemiologic or clinical relevance of these observations are not known.

A major challenge with research into the role of CNS in bovine mastitis has been the lack of a sufficiently accurate but low-cost method for identifying CNS on the species level. Commercially available test kits that use biochemical tests do not appear to be sufficiently accurate to be used for research purposes, whereas analytical methods using MALDI-TOF technology and molecular methods involving PCR show promise.<sup>9</sup>

### TREATMENT

Spontaneous cure is common. CNS, including *S. chromogenes*, *S. hyicus*, and others, are very susceptible to ampicillin, amoxicillin, clavulanic acid, cephapirin, erythromycin, gentamicin, potentiated sulfonamides, and tetracyclines, with some studies reporting resistance to penicillin. In a study of 139 cases of subclinical coagulase-negative staphylococcal mastitis in New York, the bacteriologic cure rates of commercially available intramammary infusions were similar to that of untreated controls (72% bacteriologic cure), with the following bacteriologic cure rates: cephapirin (89%), amoxicillin (87%), cloxacillin (76%), and penicillin (68%). The current consensus view is that an intramammary treatment duration of 2 to 3 days should be used for cows with clinical signs of mastitis caused by CNS, because the mastitis usually responds well to treatment. Subclinical CNS infections usually do not need treatment because spontaneous elimination is common, and the presence of bacteria in a milk sample may reflect contamination of the sample with teat skin flora.

The use of a combination of novobiocin and penicillin, and cloxacillin as dry cow therapy for CNS gave cure rates of over 90%.

### CONTROL

Implementation of a mastitis control program will be very effective in decreasing intramammary infection and clinical mastitis episodes caused by CNS. Because of its current categorization as an opportunistic teat skin bacteria that can cause milk mastitis, attention should be focused on postmilking test dipping and optimizing teat skin condition, particularly around the teat orifice. Specific control measures (such as vaccination) are not indicated because of its status as a minor pathogen.

### TREATMENT AND CONTROL

#### Treatment

Treat clinical coagulase-negative staphylococci mastitis episodes during lactation with an intramammary formulation per label directions (R-1).

Treat subclinical coagulase-negative staphylococci intramammary infections during lactation with an intramammary formulation (R-3).

#### Control

Implement 10-point mastitis control plan, with particular emphasis on postmilking teat dipping/spraying and optimizing teat condition, particularly around the teat orifice (R-1).

## Mastitis of Cattle Associated With Common Environmental Pathogens

**Environmental mastitis** is associated with bacteria that are transferred from the environment to the cow rather than from other infected quarters. *E. coli*, *Klebsiella* spp., and **environmental streptococci** are the major pathogens causing environmental mastitis.

### COLIFORM MASTITIS ASSOCIATED WITH *ESCHERICHIA COLI*, *KLEBSIELLA* SP., AND *ENTEROBACTER AEROGENES*

#### ETIOLOGY

Many different serotypes of *E. coli*, numerous capsular types of *Klebsiella* spp. (most commonly *K. pneumoniae*), and *Enterobacter aerogenes* are responsible for coliform

mastitis in cattle. *E. coli* isolated from the milk of cows with acute mastitis cannot be distinguished as a specific pathogenic group on the basis of biochemical and serologic test reactions. The incidence of antimicrobial resistance is also low in these isolates because they are opportunists originating from the alimentary tract, from which antimicrobial resistant *E. coli* are rarely found in adults. Other gram-negative bacteria that are not categorized as coliforms but can cause mastitis include *Serratia*, *Pseudomonas*, and *Proteus* spp.

## SYNOPSIS

**Etiology** Many different serotypes of *Escherichia coli*, numerous capsular types of *Klebsiella* spp., and *Enterobacter aerogenes*. These are commonly called coliform bacteria; other gram-negative bacteria (such as *Pseudomonas aeruginosa*) can cause environmental mastitis but are not categorized as coliform bacteria.

**Epidemiology** Dairy cattle housed in total confinement or drylot; uncommon in pastured cattle. Most important mastitis problem in well-managed, low-SCC herds. Quarter infection rate low at 2%-4%. Incidence highest in early lactation. Eight percent to 90% of coliform infections result in clinical mastitis; 8%-10% are peracute. Causes clinical mastitis rather than subclinical mastitis. Source of infection is environment between milkings, during dry period and prepartum in heifers. Isolates of *E. coli* are opportunists. Sawdust and shavings bedding contaminated with *E. coli* and *Klebsiella* spp. (particularly *K. pneumoniae*) are a major source of bacteria; much worse when wet (rainfall or high humidity). Coliform intramammary infection highest during 2 weeks following drying off and in 2 weeks before calving. Animal risk factors include:

- Low SCC
  - Decrease of neutrophil function in periparturient cow
  - High susceptibility in early lactation
  - Contamination of teat duct
  - Selenium and vitamin E status
- Outbreaks of coliform mastitis do occur, and are commonly associated with major change in management of the environment (introduction of sawdust for bedding may result in outbreaks of *Klebsiella* mastitis).

### Clinical findings

**Acute:** Swelling of gland, watery milk with small flakes, mild systemic response, recovery in a few days

**Peracute:** Sudden onset of severe toxemia, fever, tachycardia, impending shock; cow may be recumbent. Quarter may or may not be swollen and warm, secretions thin and serous and contain very small flakes. May die in few days

**Clinical pathology** Culture milk. Somatic cell count. Marked leukopenia, neutropenia, and degenerative left shift. Bacteremia may occur, particularly in severely affected cattle.

**Necropsy findings** Edema, hyperemia, hemorrhages and necrosis of mammary tissue. Major changes in teat and lactiferous sinuses and ducts; invasion of organism into parenchyma is not a feature of *E. coli*.

**Diagnostic confirmation** Culture of organism from milk and high SCC

### Differential diagnosis:

- Parturient hypocalcemia paresis
  - Carbohydrate engorgement lactic acidosis
- Other causes of acute and severe mastitis (must culture milk):
- Environmental streptococci
  - *Staphylococcus aureus* and *Streptococcus agalactiae*

**Treatment** Must consider status and requirements for each case based on severity. Use of antimicrobial agents is indicated in moderately to severely affected animals; efficacy uncertain in mild cases. Some infections become persistent if antibiotics are not administered. Severely affected cattle also need supportive fluid and electrolyte therapy (such as hypertonic saline), and possibly NSAIDs for endotoxemia.

**Control** Manage outbreaks by examination of environment. Improve sanitation and hygiene. Regular cleaning of barns. Dry bedding. Avoid crowding. Keep dry cows on pasture if possible. Replace sawdust and shavings with sand for bedding. Emphasize premilking hygiene, including premilking germicide teat dipping and keep cows standing for at least 30 minutes after milking. Core lipopolysaccharide antigen vaccine in dry period and early lactation to reduce incidence of clinical mastitis caused by gram-negative bacteria

## EPIDEMIOLOGY

### Occurrence of Clinical Mastitis

The occurrence of coliform mastitis has increased considerably in recent years and is a cause for concern in the dairy industry and among dairy practitioners. Coliform mastitis occurs worldwide and is most common in dairy cattle that are housed in total confinement during the winter or summer months. Where cows are kept in total confinement in a drylot, outbreaks of coliform mastitis may occur during wet, heavy rainfall seasons. The disease is uncommon in dairy cattle that are continuously in pasture, but it has been reported in pastured dairy cattle in New Zealand.

In contrast to contagious mastitis, environmental mastitis associated with coliform bacteria is primarily associated with clinical mastitis rather than subclinical

mastitis. Clinical mastitis associated with environmental pathogens (including the environmental streptococci) is now the most important mastitis problem in well-managed, low-SCC herds. In a survey of the incidence of clinical mastitis and distribution of pathogens in dairy herds in the Netherlands, the average annual incidence was 12.7 quarter cases per 100 cows per year. The most frequent isolates from clinical cases were *E. coli* (16.9%), *S. aureus* (14.4%), *S. uberis* (11.9%), and *S. dysgalactiae* (8.9%).

The incidence of clinical coliform mastitis is highest early in lactation and decreases progressively as lactation advances. The rate of intramammary infection is about four times greater during the dry period than during lactation. The rate of infection is also higher during the first 2 weeks of the dry period and during the 2 weeks before calving. Eighty percent to 90% of coliform infections result in varying degrees of clinical mastitis in the lactating cow; approximately 8% to 10% of coliform infections result in peracute mastitis, usually within a few days after calving. The disease also is common in herds that concentrate calving over a short period of time.

### Prevalence of Infection

The prevalence of both intramammary infection and the incidence of clinical mastitis caused by coliform bacteria has increased, particularly in dairy herds with a low prevalence of infection and incidence of clinical mastitis caused by *S. aureus* and *S. agalactiae* as a result of an effective mastitis control program. Compared with other causes of mastitis, coliform infections are relatively uncommon and, in databases on herd surveys, the percentage of quarters infected with these pathogens is low. The percentage of quarters infected at any one time is generally low, at about 2% to 4%.

In the UK, about 0.2% of quarters of cows may be infected at any one time. Surveillance of a dairy herd in total confinement in the United States indicated that infection with coliform bacteria by either day of lactation or day of the year never exceeded 3.5% of quarters, and this maximum was reached on the day of calving. However, coliform infections may cause 30% to 40% of clinical mastitis episodes. In herds with a problem, up to 8% of cows have been infected with coliform bacteria, and 80% of the cases of clinical mastitis may be caused by coliform infections.

### Duration of Infection

Coliform intramammary infections are usually of short duration. Over 50% last less than 10 days; about 70% less than 30 days; and only 1.5% exceed 100 days in duration.

### Source of Infection and Mode of Transmission

The primary reservoir of coliform infection is the dairy cow's environment (environmental

pathogen); this is in contrast to the infected mammary gland, which is the reservoir of major contagious pathogens (*S. aureus* and *S. agalactiae*) and the main reservoir of infection in cattle with *M. bovis*. Exposure of uninfected quarters to environmental pathogens can occur at any time during the life of the cow, including during milking, between milkings, during the dry period, and before calving in heifers.

### Morbidity and Case Fatality

In dairy herds with low bulk tank milk SCCs the average herd incidence of clinical mastitis is 45 to 50 cases per 100 cows annually, with coliforms isolated from 30% to 40% of the clinical cases. This is similar to an average incidence of 15 to 20 cases of coliform mastitis per 100 cows in herds with low bulk tank milk SCCs. Other observations indicate that the number of clinical cases of coliform mastitis varies from 3 to 32 per 100 cows per year, but the average incidence in dairy herds can be as low as 6 to 8 per 100 cows per year.

Coliform mastitis is one of the most common causes of fatal mastitis in cattle. The case-fatality rate from peracute coliform mastitis is usually high and may reach 80% in spite of intensive therapy. Outbreaks of the disease can occur with up to 25% of recently calved cows affected within a few weeks of each other.

### Risk Factors

#### Pathogen Risk Factors

The isolates of *E. coli* from bovine mastitic milk are simply opportunist pathogens and represent a number of different strains that mostly lack known *E. coli* virulence factors.<sup>1-3</sup> This finding suggests that specific cow factors probably play a more important role in determining the severity of clinical signs after intramammary infection.<sup>3</sup> The isolates that cause coliform mastitis possess lipopolysaccharides (endotoxin), which form part of the outer layer of the cell wall of all gram-negative bacteria. Coliform bacteria isolated from the milk of cows or from their environment have different degrees of susceptibility to the bactericidal action of bovine sera, and the majority of isolates that cause severe mastitis are serum resistant in some, but not all studies.<sup>4,5</sup> Serum-sensitive organisms are unable to multiply in normal glands because of the activity of bactericidins reaching milk from the blood. Of the strains of *E. coli* isolated from cases of mastitis in cattle in England and Wales, only those that were serum resistant were reisolated from expressed milk following intramammary inoculation of lactating cows. Other observations indicate that serum-resistant coliforms have no selected advantage over serum-susceptible coliforms in naturally occurring intramammary infections. Strains of *Klebsiella* that cause mastitis were resistant to bovine serum in one study.

There are also somatic and capsular factors of coliforms that affect resistance to bovine bactericidal activity. The presence of long polar fimbriae and an enteroaggregative heat-stable enterotoxin are also prevalent in the majority, but not all, of the strains isolated from cattle with clinical *E. coli* mastitis.<sup>5</sup> The fibronectin binding property of *E. coli* from bovine mastitis may be an important virulence factor that allows the organism to adhere to the ductular epithelium. *E. coli* isolates from clinical mastitis cases were able to resist phagocytosis by neutrophils, multiply faster, and ferment lactose more quickly than environmental *E. coli* isolates from the environment.<sup>4</sup>

A minority of *E. coli* intramammary infections result in persistent infection. *E. coli* strains that are more likely to result in persistent infections are better able to invade and replicate within mammary epithelial cells than strains that do not result in persistent infections and were more likely to be resistant to multiple antibiotics.<sup>6,7</sup>

#### Environmental Risk Factors

All the environmental components that come in contact with the udder of the cow are considered potential sources of the organisms. The coliform bacteria are opportunists, and contamination of the skin of the udder and teats occurs primarily between milkings when the cow is in contact with contaminated bedding rather than at the time of milking. Feces, which are a common source of *E. coli*, can contaminate the perineum and the udder directly or indirectly through bedding, calving stalls, drylot grounds, udder wash water, udder wash sponges and cloth rags, teat cups, and milkers' hands. Cows with chronic coliform mastitis also provide an important source of bacteria, and direct transmission probably occurs through the milking machine. Inadequate drying of the base of the udder and the teats after washing them before milking can lead to a drainage of coliform-contaminated water down into the teat cups and subsequent infection.

#### Bedding

Sawdust and shavings used as bedding that are contaminated and harbor *E. coli*, and particularly *K. pneumoniae*, are major risk factors for coliform mastitis. Cows bedded on sawdust have the largest teat-end population of total coliforms and klebsiellae; those bedded on shavings have an intermediate number, and those on straw have the least. Experimentally, the incubation of bedding samples at 30°C to 44°C (86°F–111°F) resulted in an increase in the coliform count; at 22°C (71°F) the count was maintained, and at 50°C (122°F) the bacteria were killed. Wet bedding, particularly sawdust and shavings, promotes the growth of coliform bacteria, especially *Klebsiella* spp.

The relationship between the bedding populations of Enterobacteriaceae was studied over a 12-month period in a dairy herd. The analyses revealed that rainfall bedding populations of *E. coli* and coliform mastitis incidence were statistically independent, whereas there was a strong association between rainfall and *K. pneumoniae* bedding populations and the incidence of *K. pneumoniae* mastitis. The lack of an association between bedding population of *E. coli* and coliform mastitis, along with the observation that cows are most susceptible immediately after parturition, suggest that the ability of the bacteria to penetrate the streak canal may be a factor of resistance in the cow and not a characteristic of the organism. Also, it appears that the cow in early lactation is not as susceptible to *K. pneumoniae* as to *E. coli*.

The ability of several different bedding materials to support the growth of environmental pathogens has been outlined under controlled conditions. Bedding materials vary in their ability to support growth of different pathogens, and under barn conditions it appears that high bacterial counts are influenced by factors more complex than the type of bedding alone. Even clean damp bedding may support bacterial growth.

High populations of coliform bacteria on the teat end, unless accompanied by actual chronic quarter infection, are probably transitory and represent recent environmental contamination that would usually be eliminated by an effective sanitation program at milking time. However, any teat skin population, whether associated with infection in another quarter, from contaminated teat cup liners or from other environmental sources, must be considered as a potential source of new infection.

#### Animal Risk Factors

Factors that influence the susceptibility of cows to coliform mastitis include the SCC of the milk, the stage of lactation, and the physiologic characteristics and defense mechanisms of the udder (particularly the speed of neutrophil recruitment), teat characteristics, and the ability of the cow to counteract the effects of the endotoxins elaborated by the organisms.

#### Somatic Cell Count

Experimentally, an SCC of 250,000 cells/mL in the milk of a quarter may limit significant growth of bacteria and development of mastitis when small inocula of coliform organisms are experimentally introduced into the gland. SCCs of 500,000 cells/mL provided complete protection. Thus cows in herds with a low incidence of streptococcal and staphylococcal mastitis have a low milk SCC and are more susceptible to coliform mastitis. Dairy herds with low herd bulk tank milk SCCs may have a greater incidence of severe toxic mastitis than herds with higher counts.

### Neutrophil Recruitment and Function

Increased susceptibility to coliform mastitis in the periparturient cow is primarily caused by impaired neutrophil recruitment to the infected gland. In fatal cases of peracute mastitis in cows within 1 week after parturition there may be large numbers of bacteria in mammary tissues and an absence of neutrophilic infiltration. Other observations indicate a high correlation between poor preinfection chemotactic activity of blood neutrophils and susceptibility to intramammary *E. coli* challenge exposure. Experimentally, in periparturient cows the inability to recruit neutrophils rapidly into the mammary gland following intramammary infection is associated with an overwhelming bacterial infection and peracute highly fatal mastitis. The periparturient cows are unable to control bacterial growth during the first few hours after bacterial inoculation and, consequently, the bacterial load is much higher when neutrophils finally enter the milk. The lack of neutrophil mobilization could be caused by

- Failure to recognize bacteria
- Lack of production of inflammatory mediators
- A defect in the ability of the cells to move into the milk compartment

In ketonemic cows, experimental *E. coli* mastitis is severe, regardless of preinfection chemotactic response.

High levels of cytokines are present in the milk of cows that lack the ability to recruit leukocytes, which is evidence that the cells recognized the bacteria. All of this suggests that the critical defect is in the neutrophils of the periparturient cow. Certain cell-surface receptors on leukocytes may be important defense mechanisms against *E. coli* polysaccharides. Bovine mammary neutrophils possess cell surface C14 and C18 and lectin—carbohydrate interactions mediating nonopsonic phagocytosis of *E. coli*—which may be important in controlling these infections.

### Selenium and Vitamin E Status

The positive effects of supplemental vitamin E and selenium on mammary gland health are well established. An adequate dietary level of selenium enhances the resistance of the bovine mammary gland to infectious agents. Experimentally induced intramammary *E. coli* infections are significantly more severe, and of longer duration, in cows whose diets have been deficient in selenium than in cows whose diets were supplemented with selenium. The enhanced resistance is thought to be associated with a more rapid diaporesis of neutrophils into the gland of cows fed diets supplemented with selenium, which limits the numbers of bacteria in the gland during infection.

Vitamin E is especially important to mammary gland health during the periparturient period. Plasma concentrations of  $\alpha$ -tocopherol begin to decline at 7 to 10 days before parturition, reach nadir at 3 to 5 days

after calving, and then start increasing. When plasma concentrations are maintained during the periparturient period by injections of  $\alpha$ -tocopherol, the killing ability of blood neutrophils is improved. The supplementation of the diets of dry cows receiving 0.1 ppm of selenium in their diets with vitamin E at 1000 IU/day reduced the incidence of clinical mastitis by 30% compared with cows receiving 100 IU/day. The reduction was 88% when cows were fed 4000 IU/day of vitamin E during the last 14 days of the dry period.

There are also marked effects of dietary selenium on milk eicosanoid concentrations in response to an *E. coli* infection, which may be associated with the altered pathogenesis and outcome of mastitis in a selenium-deficient state.

### Stage of Lactation and Defense Mechanism

Coliform mastitis occurs almost entirely in the lactating cow and rarely in the dry cow. The disease can be produced experimentally in lactating quarters much more readily than in dry quarters. The difference in the susceptibility may be caused by the much higher SCCs and lactoferrin concentrations in the secretion of dry quarters than in the milk of lactating quarters. Cows with known uninfected quarters at drying off may develop peracute coliform mastitis at calving, suggesting that infection occurred during the dry period. New intramammary infections can occur during the nonlactating period, especially during the last 30 days, remain latent until parturition, and cause peracute mastitis after parturition.

The **rate of coliform intramammary infection** is highest during the 2 weeks following drying off and in the 2 weeks before calving. The fully involuted mammary gland appears to be highly resistant to experimental challenge by *E. coli*, but it becomes susceptible during the immediate prepartum period. More than 93% of *E. coli* intramammary infection associated with the nonlactating period originated during the second half of that period.

Several physiologic factors may influence the level of resistance of the nonlactating gland to coliform infection. The rate of new intramammary infection is highest during transitions of the mammary gland from lactation to involution and during the period of colostrum production to lactation. There can be a sixfold increase in coliform infections from late lactation to early involution, but 50% of these new infections do not persist into the next lactation. Also, the rate of spontaneous elimination of minor pathogens is high during the nonlactating period. The difference in susceptibility or resistance to new intramammary infection may be due, in part, to changes in concentration of lactoferrin, IgG, bovine serum albumin, and citrate, which are correlated with *in vitro* growth

inhibition of *E. coli*, *K. pneumoniae*, and *S. uberis*.

There is also a slower increase in polymorphonuclear neutrophils in milk after new intramammary infection in early lactation than in mid and late lactation. These conditions may explain the occurrence of peracute coliform mastitis in early lactation. This suggests latent infection or, more likely, that infection occurred at a critical time just a few days before and after calving, when the streak canal became patent and the population of coliform bacteria on the teat end was persistently high because the cow was not being milked routinely and thus would not be subjected to udder washing and teat dipping. Coliform bacteria can pass through the streak canal unaided by machine milking; this may be associated with the high incidence of coliform mastitis in high-yielding older cows, which may have increased patency of the streak canal with age.

Newly calved cows can be classified as moderate or severe responders to experimentally induced coliform mastitis. Following infection there is a diversity of responses varying from very mild to very acute inflammation of the gland and evidence of systemic effects such as fever, anorexia, and discomfort. Losses in milk yield and compositional changes are most pronounced in inflamed glands and, in severe responders, milk yield and composition did not return to preinfection levels. It is proposed that the severe and long-lasting systemic disturbances in severe responders can be attributed to absorption of endotoxin.

In summary, coliform mastitis is more severe in periparturient cows because of the inability to slow bacterial growth early after infection. This inability is associated with low SCC before challenge and slow recruitment of neutrophils. There may also be deficits in the ability of leukocytes to kill bacterial pathogens.

### Contamination of Teat Duct

The sporadic occurrence of the disease may be associated with the use of contaminated teat siphons and mastitis tubes and infection following traumatic injury to teats or following teat surgery. Several teat factors are important in the epidemiology of *E. coli* mastitis. It is generally accepted that *E. coli* is common in the environment of housed dairy cows and that mastitis can be produced experimentally by the introduction of as few as 20 organisms into the teat cistern via the teat duct. However, the processes by which this occurs under natural conditions are unknown. *E. coli* does not colonize the healthy skin of the udder or the teat duct.

The teat duct normally provides an effective barrier to invasion of the mammary gland by bacteria. As a result of machine milking there is some relaxation of the papillary duct, followed by gradual reduction in the duct lumen diameter in the 2 hours

following milking. This period of relaxation after milking may be a risk factor predisposing to new intramammary infection.

Experimental contamination of the teat ends with a high concentration of coliform bacteria by repeated wet contact; however, this does not necessarily result in an increase in new intramammary infection. The experimental application of high levels of teat-end contamination with *E. coli* after milking repeatedly led to high rates of intramammary infection, which suggests that penetration of the teat duct by *E. coli* occurs in the period between contamination and milking. Milking machines that produce cyclic and irregular vacuum fluctuations during milking can result in impacts of milk against the teat ends, which may propel bacteria through the streak canal and increase the rate of new infections caused by *E. coli* and outbreaks of peracute coliform mastitis.

#### Downer Cows

Cows affected with the downer cow syndrome following parturient paresis, or recently calved cows that are clinically recumbent for any reason, are susceptible to coliform mastitis because of the gross contamination of the udder and teats with feces and bedding.

#### Other Defense Factors

**Lactoferrin and Citrate.** The failure of lactoferrin within mammary secretions to prevent new infections and mastitis near and after parturition may be caused by a decrease in lactoferrin before parturition. Lactoferrin normally binds the iron needed by iron-dependent organisms; these multiply excessively in the absence of lactoferrin. Also, citrate concentrations increase in mammary secretions at parturition and may interfere with iron binding by lactoferrin.

**Serum Antibody to *E. coli*.** The serum IgG<sub>1</sub> ELISA titers recognizing core lipopolysaccharide antigens of *E. coli* J5 in cattle are associated with a risk of clinical coliform mastitis. Titers less than 1:240 were associated with 5.3 times the risk of clinical coliform mastitis. Older cattle in the fourth or greater lactations were also at greater risk, even though titers increased with age. There is a titer-independent age-related increase in clinical coliform mastitis. Active immunization of cattle with an Rc-mutant *E. coli* (J5) vaccine resulted in a remarkable decrease in the incidence of clinical coliform mastitis.

#### PATHOGENESIS

After invasion and infection of the mammary gland, *E. coli* proliferates in large numbers and releases endotoxin on bacterial death or during rapid growth when excess bacterial cell wall is produced. Endotoxin causes a change in vascular permeability, resulting in edema and acute swelling of the gland

and a marked increase in the number of neutrophils in the milk. The neutrophil concentrations may increase 40 to 250 times and strongly inhibit the survival of *E. coli*. This marked diapedesis of neutrophils is associated with the remarkable systemic **leukopenia** and **neutropenia** that occurs in peracute coliform mastitis. Large numbers of epithelial cells are sloughed into the glandular secretion very early in infection before the influx of immune cells into the affected gland and probably contribute to the breakdown in the blood-milk barrier.<sup>8</sup> The severity of the disease is influenced by the

- Degree of the preexisting neutrophils in the milk
- Rate of invasion and total number of neutrophils that invade the infected gland
- Susceptibility of the bacteria to serum bactericidins that are secreted into the gland
- Amount of endotoxin produced<sup>9</sup>

#### Stage of Lactation

The severity of disease is dependent on the stage of lactation. Experimental infection of the mammary gland of recently calved cows with *E. coli* produces a more severe mastitis compared with animals in midlactation. This may be caused by a delay in diapedesis of neutrophils into the mammary gland of recently calved cows. Furthermore, because of this delay there may be no visible changes in the milk for up to 15 hours after infection, but the systemic effects of the endotoxin released by the bacteria are evident in the cow (fever, tachycardia, anorexia, rumen hypomotility or atony, and mild diarrhea). The net result is endotoxemia, which persists as long as bacteria are multiplying and releasing endotoxin. This persistent endotoxemia is probably a major cause of failure to respond to therapy compared with the transient endotoxemia in the experimental inoculation of one dose of endotoxin.

#### Neutrophil Response

The final outcome is highly dependent on the degree of neutrophil response. If the neutrophil response is delayed and growth of the organisms is unrestricted, the high levels of toxin produced could cause severe destruction of udder tissue and general toxemia. If the animal responds quickly there is often little effect on milk yield because the injury is confined to the sinuses without involvement of secretory tissues. The ability of the neutrophils to kill *E. coli* varies among cows. Experimental infection of the mammary gland of cows with *E. coli* results in the stimulation of a long-lasting opsonic activity for the phagocytosis and killing of the homologous strain of the organism by neutrophils. Thus it is not opsonic deficiency that is the problem in early lactation; rather, it is a **failure of rapid migration of neutrophils into the gland cistern.**

The rapidity and efficiency of the neutrophil response are major factors in determining the outcome. If the neutrophil response is rapid, clinical disease will be mild or go undetected, self-cure will occur, and the cow returns to normal; the milk may be negative for the bacteria. This may be one important cause of an increase in the percentage of clinical mastitis cases in which no pathogens can be isolated from the milk. Failure of the cow to mount a significant neutrophil response results in the multiplication of large numbers of bacteria, the elaboration of large amounts of endotoxin, and severe highly fatal toxemia. In these cases, bacteria are readily cultured from the milk. In less serious and nonfatal cases, the recruitment of neutrophils does not fail but is delayed; this results in acute clinical mastitis with progressive inflammation and permanent loss of secretory function. The bacteria are not always readily eliminated from the infected gland by the neutrophils. Coliform bacteria may remain latent in neutrophils and, in naturally occurring cases, it is not uncommon to be able to culture the organism from the mammary gland during and after both parenteral and intramammary antibacterial therapy.

#### Numbers of Bacteria in Milk

The numbers of bacteria in the milk also influence the outcome. If bacterial numbers exceed 10<sup>6</sup> CFU/mL, the ability of the neutrophil to phagocytose is impaired. If the bacterial count is less than 10<sup>3</sup> CFU/mL at 12 hours postinfection, the bacteria will be rapidly eliminated and the prognosis will be favorable. This response is seen as a subacute form of the disease with spontaneous self-cure. If the neutrophil response is slow or delayed, the cow will exhibit more severe signs of coliform mastitis caused by toxemia. This is most common in recently calved cows and is characterized clinically by a serous secretion in the affected quarter that later becomes watery along with fever, depression, ruminal hypomotility, and mild diarrhea. The prognosis in these cases is unfavorable. These more severe forms of coliform mastitis usually occur after calving and in the first 6 weeks of lactation. Cows with coliform mastitis in mid to late lactation generally generate a rapid neutrophil response rate, and their prognosis is likely to be favorable.

#### Experimental Endotoxin-Induced Mastitis

In an attempt to further understand the pathogenesis of coliform mastitis, the effect of experimentally introducing *E. coli* endotoxin into the mammary gland has been examined. The intramammary infusion of 1 mg *E. coli* endotoxin induces acute mammary inflammation and transient, severe shock from which cows recover within 48 to 72 hours. Udder edema is apparent within 2 hours but begins to subside in 4 to

6 hours. The SCC increases within 3 to 5 hours, and at 7 hours the count is 10 times normal. A mild systemic reaction with a transient fever occurs in some cows. High concentrations of IL-1 and IL-6 are detectable in the milk of infused glands, beginning 3 to 4 hours after infusion. Milk concentrations of bovine serum albumin are increased from baseline levels to peak levels within 2 hours, indicating increased vascular permeability induced by inflammatory mediators. The infusion of endotoxin into the teat cistern of cows induces a rapid local inflammatory response of short duration with an influx of neutrophils into the teat cistern.

The intramammary infusion of endotoxin results in a sequential increase of immunoglobulin in milk whey and of phagocytosis of staphylococci by milk polymorphonuclear cells. This is consistent with spontaneous recovery of cows with acute coliform mastitis. Endotoxin infusion can also result in increases in arachidonic acid metabolites such as thromboxanes, and cytokines, which may be involved in mediation of local quarter inflammation, and the systemic signs observed in acute coliform mastitis. Histamine, serotonin, leukotrienes, and arachidonic acid metabolites are also released following experimental *K. pneumoniae* mastitis. There is also a marked increase in prostaglandin concentrations, which indicates that they may play a role in the pathogenesis of endotoxin-induced mastitis and that the use of NSAIDs may be of value therapeutically.

In **peracute coliform mastitis**, severe toxemia with fever, shivering, weakness leading to recumbency in a few hours, and mild diarrhea are common and probably caused by the absorption of large quantities of endotoxin. For many years it was thought that bacteremia did not occur in severe cases of coliform mastitis. However, **bacteremia is present in 32% to 48% of naturally occurring cases of coliform mastitis**. In experimental endotoxemia in cattle there is profound leukopenia (neutropenia and lymphopenia), a mild hypocalcemia, and elevation in plasma cortisol concentration. Hypocalcemia also occurs in naturally occurring cases and is thought to be caused by a decreased abomasal emptying rate associated with the endotoxemia. Experimentally infused endotoxin is detoxified very rapidly after absorption into the circulation.

In the acute form, the systemic changes are usually less severe than in the peracute form. However, in both forms, there is marked agalactia and the secretions in the affected quarter become serous and contain small flakes. Coliform organisms are not active tissue invaders, and in affected cattle that survive the systemic effects of the endotoxin the affected quarter(s) will usually return to partial production in the same lactation, and even full production in the next. However, in some cows that survive the

peracute form, subsequent milk production in the current lactation is inadequate and cows are commonly culled.

A retrospective analysis of cows with clinical and laboratory features of coliform mastitis revealed that 60% returned to produce a milk-like secretion in the affected quarters in the current lactation and 40% did not. However, only 63% of the former group and 14% of the latter group remained in the herd and produced milk in the next lactation. Some cows were culled during the current lactation for low milk production and other reasons, some died, and others were culled for mastitis. Of the original 88 cows with coliform mastitis, only 38 (43%) remained in the herd and produced milk in the next lactation.

### CLINICAL FINDINGS

**Peracute coliform mastitis** in the cow is a severe disease characterized by a sudden onset of agalactia and toxemia. The cow may be normal at one milking and acutely ill at the next. Complete anorexia, severe depression, shivering and trembling, cold extremities (particularly the ears), and a fever of 40°C to 42°C (104°F–108°F) are common. Within 6 to 8 hours after the onset of signs the cow may be recumbent and unable to stand. At that stage, the temperature may be normal or subnormal, all of which may superficially resemble parturient paresis. The heart rate is usually increased up to 100 to 120 beats/min, the rumen is static, there may be a mild watery diarrhea, and dehydration is evident. Polypnea is common, and in severe cases an expiratory grunt may be audible because of pulmonary congestion and edema.

The **affected quarter(s)** is usually swollen and warm but not remarkably so, and for this reason coliform mastitis may be missed on initial clinical examination. The cow may be severely toxemic, febrile, and have cold extremities before there are visible changes in the mammary gland or the milk. The mammary secretion is characteristic, and there are changes from the consistency of watery milk initially to a thin, yellow serous fluid containing small meal-like flakes that are barely visible to the naked eye; these are best seen on a black strip plate used for gross examination of milk. Additional quarters may become affected within a day or two of the initial infection.

**The course of peracute coliform mastitis is rapid.** Some cows will die in 6 to 8 hours after the onset of signs, and others will live for 24 to 48 hours. Those that survive the peracute crisis will either return to normal in a few days or remain weak and recumbent for several days and eventually develop the complications associated with prolonged recumbency. Intensive intravenous fluid therapy may prolong the life of the cow for up to several days, but significant improvement may not occur and eventually

euthanasia may appear to be the desirable course of action.

**Acute coliform mastitis** is characterized by varying degrees of swelling of the affected gland and variable systemic signs of fever and inappetence. The secretions of the gland are watery to serous in consistency and contain flakes. Recovery with appropriate treatment usually occurs in a few days. During the first day of infection affected cows spend approximately 10% less time lying than when they were healthy. This small difference would not be clinically detectable unless the animal was monitored with an activity monitor.<sup>10,11</sup>

A clinically useful disease severity scoring system is helpful in directing treatment protocols.<sup>12</sup> The most useful and easily understood system uses three easily identified categories of clinical mastitis: (1) abnormal secretion only, (2) abnormal secretion combined with abnormal gland (such as swelling, heat, erythema, pain, and decreased quarter milk production), and (3) abnormal cow (systemic signs of illness, such as fever, tachycardia, decreased rumen contraction rate, and depression) combined with abnormal secretion and abnormal gland.

### Accuracy of Clinical Diagnosis

Various diagnostic schemes that use clinical parameters to differentiate cows with clinical mastitis caused by gram-negative bacteria from those with clinical mastitis associated with gram-positive bacteria have been developed. Generally, all these schemes predict gram-negative bacteria as the cause if the milk is watery or yellow, if the mastitis episode occurs in summer, and if rumen motility is decreased or absent. Experienced clinicians are not much better at predicting the causative agent than inexperienced clinicians. The conclusion from all of these studies is that **clinical observations do not allow sufficiently accurate prediction of clinical mastitis pathogens** and should not be used as the sole criteria for deciding whether cows are treated with antibiotics, or even the class of antibiotic to be administered. Even the best predictive algorithm was wrong 25% of the time if the prevalence of gram-negative mastitis was 50%, which is too high an error rate to be used to guide treatment. In comparison, flipping a coin to attribute the causative agent as being gram-positive or gram-negative is wrong only 50% of the time.

An increase in the ability of a positive test to predict a gram-negative bacterial infection as the cause for a clinical mastitis episode is provided by examining for the presence of endotoxin in milk (sensitivity [Se] = 0.72; specificity [Sp] = 0.95), whether the **segmented neutrophil count** is less than 35% of the total leukocyte count (Se = 0.87; Sp = 0.71), whether the segmented neutrophil count is less than 3200 cells/μL (Se = 0.93; Sp = 0.89; Fig. 20-5), and by culturing

**Fig. 20-5** Scatter plot of blood leukocyte count (left panel) and segmented neutrophil count (expressed on a logarithmic scale; right panel) for 108 lactating dairy cattle with acute clinical mastitis caused by Gram-negative bacteria or Gram-positive bacteria. The hatched area represents the reference range, and data are expressed as mean  $\pm$  standard deviation. Cattle with acute Gram-negative mastitis are much more likely to be leukopenic and neutropenic. (Reproduced with permission from Smith GW, Constable PD, Morin DE. *J Vet Intern Med* 2001;15(4):394-400.)

on selective media (Se = 0.60; Sp = 0.98). The **endotoxin test** is a cowside test (Limast-test) that was commercially available in Scandinavia. Assessment of the white blood cell count and differential count is widely available in veterinary practice but is not a cowside test and is therefore not ideal. Both the milk endotoxin test and blood neutrophil count have adequate sensitivity and specificity for use to guide treatment decisions.

**Chronic coliform mastitis** is characterized by repeated episodes of subacute mastitis, which cannot be readily clinically distinguished from other common causes of mastitis.

**Subclinical coliform mastitis** is characterized by the presence of coliform organisms in the milk samples of cows without clinical evidence of mastitis. The prevalence of intramammary infection in quarters with coliform bacteria is low relative to contagious mastitis pathogens, ranging from 0.9 to 1.2%.

## CLINICAL PATHOLOGY

### Culture of Milk

Milk samples should be submitted for culture to identify the causative agent, but antimicrobial susceptibility testing has not been validated and is currently not recommended to guide treatment decisions. In the peracute case, the milk samples will yield a positive culture. In less acute cases, the milk sample may be negative because the neutrophils have cleared the bacteria.

Application of newer methods for bacterial identification suggest that *K. variicola* may be misidentified as *K. pneumoniae* in dairy cattle with clinical mastitis culture using routine procedures.<sup>13</sup>

## Somatic Cell Count and California Mastitis Test Scores

In the experimental disease the SCC of milk from the inoculated quarter ranges from 14,000,000 to 25,000,000 cells/mL at 5 hours after inoculation. The CMT on secretions from affected quarters is usually +3.

## Hematology

In peracute coliform mastitis there is hemoconcentration, a marked leukopenia, neutropenia, and a degenerative left shift caused by the margination of large numbers of neutrophils in response to endotoxin. There is also a moderate lymphopenia, monocytopenia, and thrombocytopenia (see Fig. 21-5). If the degenerative left shift, leukopenia, neutropenia, and thrombocytopenia become worse on the second day after the onset of clinical signs, the prognosis is unfavorable.<sup>14</sup> An improvement in the differential white count on the second day is a good prognostic sign.

## Endotoxin Presence in Milk and Plasma

A commercially available cowside test (Limast-test) for endotoxin was available in Scandinavia. The test required at least  $10^4$  to  $10^5$  CFU of gram-negative bacteria for a positive test result. The test took 15 minutes to run on milk samples and was able to detect the presence of endotoxin and therefore gram-negative bacteria, but it did not differentiate between *E. coli* and *K. pneumoniae*.

## Serum Biochemistry

The biochemical abnormalities observed in naturally occurring cases include uremia,

high aspartate aminotransferase activity, and strong ion (metabolic) acidosis in fatal cases, whereas in surviving cases there were decreased concentrations of sodium, potassium, and chloride, and strong ion (metabolic) alkalosis.<sup>14,15</sup> In acute cases there is a transient early hyperglycemia.<sup>16</sup>

## NECROPSY FINDINGS

There is edema and hyperemia of the mammary tissue. In severe cases hemorrhages are present and are accompanied by thrombus formation in the blood and lymphatic vessels; there is necrosis of the parenchyma.

A study of the progressive pathologic changes in experimental and natural cases of *E. coli* mastitis in cows reveals that damage is most marked in the epithelium of the teat and lactiferous sinuses and diminishes rapidly toward the ducts. In hyperacute cases, the organisms are largely confined to the ductular and secretory lumen and there is little invasion of the parenchyma, despite the presence of large numbers of organisms. In some cases there may be intense neutrophil infiltration, subepithelial edema, and epithelial hyperplasia of the sinuses and large ducts. In hyperacute cases in the immediate postpartum period, infiltration of neutrophils may be negligible. Bacteremia can occur in dairy cattle with coliform mastitis.

## Samples for Confirmation of Diagnosis

- Bacteriology: chilled mammary tissue, regional lymph node
- Histology: formalin-fixed mammary tissue

### DIFFERENTIAL DIAGNOSIS

- **Peracute coliform mastitis** in cattle is characterized clinically by a sudden onset of toxemia, weakness, shivering, often recumbency, fever in the early stages followed by a normal temperature or hypothermia in several hours, and characteristic gross changes in the milk, which usually is watery and contains some particles barely visible to the unaided eye. The peracute form of the disease is most common in recently calved cows.
- **Parturient hypocalcemia paresis** occurs in recently calved cows. The weakness and recumbency resembles peracute coliform mastitis but the marked increase in heart rate, and dehydration and mild diarrhea if present, are not characteristic of parturient paresis and should prompt further clinical examination, particularly of the udder. In the early stages of coliform mastitis the changes in the milk may be just barely visible. Those clinical findings that are most useful to predict peracute coliform mastitis include watery consistency of milk, shivering, firmness of udder, tachycardia, polypnea, fever, weakness, and mastitis of less than 24 hours' duration. A marked leukopenia and neutropenia are characteristic of coliform mastitis, whereas in parturient paresis there is usually a neutrophilia and stress leukon (neutrophilia, no left shift, lymphopenia, monocytosis, and eosinopenia). The differential diagnosis of recumbency in the immediate postpartum period is discussed under parturient paresis.
- **Carbohydrate engorgement lactic acidosis** causes rapid onset of weakness, recumbency, diarrhea, dehydration, and ruminal stasis and resembles the clinical findings of shock in peracute coliform mastitis. However, the rumen contains an excess of watery fluid, and the pH is below 5.0.
- **Acute coliform mastitis** cannot be accurately differentiated from all other common causes of acute mastitis with abnormal gland and abnormal milk, including the environmental streptococci *S. uberis* and *S. dysgalactiae*, and the contagious pathogens *S. aureus* and *S. agalactiae*. Culture of the milk is necessary.

### TREATMENT

The treatment of coliform mastitis in cattle has been controversial, but recent studies have clarified the **important role that antimicrobial agents play in treating severely affected cattle**. Historically, the treatment of coliform mastitis was based on the principles of treating a bacterial infection with varying degrees of inflammation. A combination of broad-spectrum antimicrobial agents administered parenterally and by intramammary infusion, fluid and electrolyte therapy, frequent stripping out of the

affected glands with the aid of oxytocin, and antiinflammatory drugs have been used with varying degrees of success based on empirical and anecdotal experience. Only a handful of clinical trials have evaluated the efficacy of therapeutic agents used in naturally occurring cases of coliform mastitis, especially for the peracute form of the disease.

Most of the controversy has centered on the rational use of antimicrobial agents. The use of antimicrobial agents for the treatment of coliform mastitis has been questioned for several reasons:

- Clinical signs are primarily caused by the effects of endotoxin in the mammary gland, with formation of endogenous inflammatory mediators within the udder and their subsequent release into the systemic circulation.
- The severity of clinical signs is correlated with the number of bacteria in the affected gland.
- Most mild cases of coliform mastitis (abnormal milk but normal gland and cow) are self-limiting and resolve without antimicrobial therapy. However, a small percentage of these mild clinical cases develop persistent infection.
- There is speculation that the use of bactericidal antimicrobial agents may result in the bolus release of large quantities of lipopolysaccharides in the mammary gland associated with a rapid kill of bacteria, but this has not been observed in any study. In contrast, endotoxin release occurs from rapid bacterial growth alone, which will be prevented by administration of an effective antibiotic.
- Many, but not all, of the broad-spectrum antimicrobial agents currently approved for use in lactating cattle do not result in high enough concentrations in the milk when given parenterally.

Most of the antimicrobial agents currently used for the treatment of coliform mastitis in lactating dairy cows are not approved for use in food-producing animals. Because of this extralabel use and the lack of pharmacokinetic data for adequate withholding times, the risk of drug residues in milk and meat is increased.

The prognosis in the peracute form of the disease is unfavorable if severe clinical toxemia is present. Severe depression, weakness, diarrhea and dehydration, recumbency, and a heart rate over 120 beats/min are indicators of an unfavorable prognosis. The successful treatment of peracute coliform mastitis requires the earliest possible action and clinical surveillance until recovery is apparent.

### Treatment Trials Using Antimicrobial Agents and Untreated Controls

Treatment trials with **experimentally induced** coliform mastitis in cattle during lactation have failed, for the most part,

to demonstrate efficacy of antimicrobial therapy. This is because all experimental models do not accurately reproduce the naturally occurring disease, and not because antibiotics are ineffective. Accordingly, treatment efficacy should be based on the results of randomized field trials. The major considerations for antimicrobial use in coliform mastitis include:

- Early administration to decrease the exposure of the cow to endotoxin
- The severity of clinical signs are positively associated with the bacterial and endotoxin concentration in the affected quarter.<sup>9</sup>
- Ensuring appropriate withholding periods for milk and meat
- The benefit:cost ratio

The antimicrobial susceptibilities of *E. coli* isolates from coliform mastitis vary considerably; drug susceptibility determination is not routinely recommended because the breakpoints have not been validated and the bacteria come from diverse sources in the environment.

### Parenteral Antimicrobial Agents

Broad-spectrum antimicrobial agents should be administered parenterally to cattle with systemic signs of disease (abnormal cow), preferably by the intravenous route initially, followed by intramuscular administration to maintain appropriate plasma concentrations. The first reason to administer parenteral antibiotics is that the **severity of clinical signs is correlated with the numbers of bacteria in milk from the affected gland**. The second main reason to administer parenteral antibiotics is to **combat bacteremia, which is present in 32% to 48% of severely affected cattle**. Based on pharmacokinetic/pharmacodynamic values, the results of experimentally induced and naturally acquired infections, and in vitro antimicrobial susceptibility testing (if this has any relevance to in vivo susceptibility), most *E. coli* isolated from the mammary glands of cattle are theoretically susceptible to third-generation cephalosporins (such as ceftiofur), fourth-generation cephalosporins (such as cefquinome), fluoroquinolones, gentamicin, amikacin, trimethoprim-sulfonamide, and oxytetracycline. Of these antimicrobials, third-generation cephalosporins, fourth-generation cephalosporins, fluoroquinolones, and potentiated sulfonamides have documented efficacy in naturally acquired or experimentally induced cases of acute *E. coli* mastitis, with moderate evidence supporting the efficacy of intravenous oxytetracycline.

- **Ceftiofur** is a third-generation cephalosporin that is resistant to  $\beta$ -lactamases and has excellent in vitro activity against *E. coli*. When given parenterally to cows with experimental coliform mastitis, ceftiofur did not produce drug concentrations in milk

above the reported MICs for coliform bacteria. However, when administered to cows with naturally occurring coliform mastitis, ceftiofur-treated cows (2.2 mg/kg BW intramuscularly every 24 hours) were three times less likely to die or be culled from the herd and had more saleable milk than nontreated cattle.

- **Cefquinome** is a fourth-generation cephalosporin that is resistant to  $\beta$ -lactamases and has excellent in vitro activity against *E. coli*. Parenteral cefquinome therapy (1 mg/kg BW intramuscularly twice at 24 hours apart), with or without intramammary cefquinome (75 mg, three times at 12-hour intervals), increased the bacteriologic cure rate and significantly improved clinical recovery and return to milk production in experimentally induced *E. coli* mastitis.
- **Danofloxacin**, a fluoroquinolone with excellent in vitro activity against *E. coli*, given intravenously once at 6 mg/kg BW was effective in treating experimentally induced *E. coli* mastitis.<sup>17</sup>
- **Enrofloxacin**, a fluoroquinolone with excellent in vitro activity against *E. coli*, given intravenously initially then subcutaneously once (5 mg/kg BW) was effective in treating experimentally induced *E. coli* mastitis, but had minimal efficacy in treating naturally acquired *E. coli* mastitis in a randomized clinical trial.<sup>18</sup> Generally, parenterally administered enrofloxacin increased the rate of initial *E. coli* clearance from the infected mammary gland. In a randomized clinical trial, a lower dose of enrofloxacin (2.5 mg/kg intramuscularly daily for 3 days) did not improve the survival rate of cows with *E. coli* mastitis, but it did result in a lower SCC at the first monthly herd recording after treatment.<sup>19</sup>
- **Gentamicin** has been used on an extralabel basis for the treatment of acute and peracute coliform mastitis because more than 90% of isolates from milk from affected cows are susceptible in vitro. However, the parenteral administration of gentamicin at 2 g intramuscularly every 12 hours until the appetite improved to dairy cows with mastitis predicted to be associated with gram-negative bacteria did not result in significant improvement compared with cows with similar mastitis that did not receive an antimicrobial or received erythromycin.
- **Trimethoprim-sulfadiazine** (trimethoprim 4 g, sulfadiazine 20 g, intramuscularly every 24 hours for 3–5 days) is efficacious in treating naturally acquired cases of coliform mastitis. The recovery rate of cows with clinical mastitis caused by coliform bacteria

susceptible to sulfonamide-trimethoprim was 89% compared with 74% in cows infected with coliforms resistant to the combination given parenterally, combined with NSAIDs and complete milking of affected quarters several times daily. Sulfadiazine or sulfamethazine (sulfadimidine) are preferred to sulfadoxine because the latter produces much lower milk concentrations after parenteral administration.

- **Oxytetracycline** (16.5 mg/kg BW intravenously every 24 hours for 3–5 days), combined with intramammary cephalirin (200 mg) and supportive care (intravenous or oral fluids, flunixin meglumine, and stripping of the mammary gland) was more effective in treating coliform mastitis than similar treatment without antibiotics in cattle with naturally acquired mastitis.

### Intramammary Antimicrobial Agents

Intramammary preparations of antimicrobial agents can be infused into the affected quarters after they have been stripped out completely at the start and end of the day. Evidence supporting the use of intramammary treatment for naturally acquired mild to moderate cases of *E. coli* mastitis (abnormal secretion and abnormal gland) is available for ceftiofur (125 mg daily for 5 consecutive days)<sup>20</sup> and cephalirin (200 mg per treatment). On theoretical grounds mild to moderate *Klebsiella* spp. mastitis episodes should also respond to intramammary ceftiofur or cephalirin treatment, because the spontaneous cure rate appears to be lower than that for *E. coli*.<sup>20</sup> The initial choice of antimicrobial will depend on previous experience of treatment efficacy in the herd.

- **Ceftiofur**: Based on clinical response and the results of antimicrobial susceptibility testing of coliform isolates from cows with naturally occurring mastitis (if relevant to in vivo performance), ceftiofur is an excellent choice for intramammary infusion in suspected cases of coliform mastitis.
- **Cephalirin**: Based on clinical response in lactating dairy cattle with experimentally induced *E. coli* mastitis, intramammary infusion of cephalirin (300 mg per quarter) at 4-, 12-, 24-, and 36-hour postinfection inhibited bacterial growth in milk decreased the inflammatory response.<sup>21</sup> The relevance of these findings to the treatment of naturally occurring cases of *E. coli* mastitis remains to be determined. This is because treatments were applied 4 hours after intramammary inoculation of *E. coli* when clinical signs of mastitis are usually not evident or are very mild.
- **Gentamicin**: The intramammary infusion of 500 mg of gentamicin did not affect the duration or severity of

experimentally induced coliform mastitis. The numbers of *E. coli* in the milk after intramammary inoculation were not affected by the intramammary infusion of gentamicin, despite maintaining a mean minimal gentamicin concentration in milk of 181  $\mu$ g/mL between dose intervals. The infusion did not affect the body temperature or the magnitude and duration of the inflammatory process in the glands as measured by the SCCs and peak albumin and immunoglobulin concentrations in the milk. It should be noted that gentamicin is not approved for use in the treatment of bovine mastitis, and in some jurisdictions it is not approved for any use.

A study of the efficacy of intramammary antibiotic therapy for the treatment of naturally occurring clinical mastitis associated with environmental pathogens found no difference in the short-term clinical or bacteriologic cure rates between quarters infused with 62.5 g of amoxicillin every 12 hours for three milkings or 200 mg of cephalirin every 12 hours for two milkings and those treated with 100 units of oxytocin intramuscularly every 12 hours immediately before milking for two or three milkings alone. However, the cost per episode of mastitis associated with the use of cephalirin was higher than the other two treatments, partly because of the longer milk withdrawal time (96 hours) associated with the drug. The percentage of relapses was higher for cows in the oxytocin treatment group, especially when the mastitis-associated pathogen was an environmental *Streptococcus* sp.

### Stripping of the Affected Quarter

An artificial intramammary environment has shown that milking 12 times daily could lead to elimination of *E. coli*, suggesting that frequent stripping would be an effective treatment. Indeed, stripping (augmented by oxytocin) is a popular but largely unsubstantiated recommendation for treating severe cases of coliform mastitis. There is one report of cattle with acute coliform mastitis that suggests irrigation of the affected quarter with 1 to 3 L of 0.9% NaCl resulted in a higher recovery rate 30 days later.<sup>22</sup>

Oxytocin at 10 to 20 units per adult cow given intramuscularly, followed by vigorous hand massage and hourly stripping of the affected quarter, may assist in removing inflammatory debris. Oxytocin doses higher than this are not needed, and intravenous administration is not needed because oxytocin is rapidly absorbed when injected intramuscularly. Oxytocin can be repeated and used as long as an effect is obtained.

Effective removal of coliform bacteria and endotoxin will minimize their local effects in the mammary gland and decrease the systemic signs of endotoxemia. The main problems with stripping are the labor

involved, the small volumes produced, the potential for creating additional pain and discomfort for the cow (and the producer when the cow kicks), and potential contamination of the environment if the secretion is stripped onto the ground. The role of frequent stripping, if any, in the treatment of clinical mastitis remains to be determined.

### Fluid and Electrolyte Therapy

Fluid and electrolyte therapy are essential for the treatment of acute and peracute coliform mastitis to counteract the effects of the endotoxemia. Isotonic polyionic electrolyte solutions (such as Ringer's solution) are given at 80 mL/kg BW for the first 24 hours by continuous intravenous infusion and at a slower rate than that over the following days. For a mature dairy cow (400–600 kg) a total of 32 to 48 L is therefore needed in the first 24-hour period, with 20 L given during the first 4 hours and the remainder over the next 20 hours. A favorable response is usually clinically evident in 6 to 8 hours. If the animal has not improved after 5 days of intensive fluid therapy (the 5-day rule for clinical improvement), the prognosis for survival is poor.

The large amounts of isotonic fluids and electrolytes that have been advocated and used are expensive to administer by continuous intravenous infusion and require monitoring over many hours. A possible alternative is the use of small volumes of hypertonic saline, which can be transported easily and administered rapidly. **Hypertonic saline** can be safely administered to cattle with endotoxin-induced mastitis. Hypertonic saline (7.2% NaCl) is given intravenously at 4 to 5 mL/kg BW intravenously over 4 to 5 minutes followed by immediate access to drinking water. The changes following administration of hypertonic saline include transient expansion of the plasma volume, hypernatremia, and hyperchloremia. The intravenous administration of hypertonic saline to clinically normal cows with access to water increases circulatory volume rapidly, induces slight strong ion (metabolic) acidosis, and increases glomerular filtration rate. Fluid therapy is covered in detail in Chapter 5.

### Antiinflammatory Agents

NSAIDs are frequently administered as adjunctive therapy in coliform mastitis, particularly in the peracute form of the disease. **Ketoprofen**, a cyclooxygenase type 1 and type 2 inhibitor and lipoxygenase inhibitor, is the only currently available NSAID with documented efficacy in naturally acquired cases of coliform mastitis.

Ketoprofen has been evaluated as adjunctive therapy for the treatment of acute clinical mastitis in dairy cows, most cases of which were associated with gram-negative pathogens. All cases were treated with 20 g of sulfadiazine and 4 g of trimethoprim

intramuscularly followed by one-half dose daily until recovery. Ketoprofen was given at 2 g intramuscularly daily for the duration of the antimicrobial therapy. Recovery rates for the nonblind contemporary controls and the blind placebo controls were 84% and 71%, respectively. In the nonblind controlled ketoprofen and placebo-controlled ketoprofen treatment groups, recovery rates were 95% and 92%, respectively. The odds ratio (OR) of recovery was significantly high in the placebo-controlled study (OR = 6.8), and high but not significant in the nonblind controlled study (OR = 2.6). It was concluded that ketoprofen significantly improved recovery rate in clinical mastitis. Oral ketoprofen (4 mg/kg in 500 mL of water and administered orally) was similarly effective in lactating dairy cattle to intramuscular ketoprofen (3 mg/kg) administered 2 hours after intramammary endotoxin infusion.<sup>23</sup> This does not necessarily translate to efficacy in the treatment of field cases of acute *E. coli* mastitis because bacterial multiplication is not present following endotoxin infusion, and overt clinical signs were not apparent when treatments were applied.

A similar clinical field trial evaluating the efficacy of phenylbutazone and dipyrone for the treatment of mastitis caused mostly by coliforms revealed a beneficial effect but no difference between the efficacies of the two drugs. Neither phenylbutazone nor dipyrone is permitted for use in lactating dairy cattle in the United States, but their use is permitted in some countries.

A single administration of flunixin meglumine (2.2 mg/kg, intravenously) to lactating dairy cattle when clinical mastitis was evident after intramammary infusion of *E. coli* increased dry matter intake on day 1 and milk yield on days 3 and 4 after treatment.<sup>24</sup> The antiinflammatory effect of either flunixin meglumine or dexamethasone was evaluated compared with controls in experimentally induced coliform mastitis. Dexamethasone at 0.44 mg/kg intravenously and flunixin meglumine at 1.1 mg/kg intravenously were both given 2 hours after inoculation of the quarter with *E. coli*, which is essentially a pretreatment administration because clinical signs are not evident at this time. Flunixin meglumine was also administered once 8 hours after the initial dose. Dexamethasone reduced the rectal temperature and the mammary surface temperatures and prevented further increase in rectal temperature above 39.2°C (102.5°F). The response to flunixin meglumine was less than expected, which suggested that a higher dose of 2.2 mg/kg may be necessary in lactating dairy cattle. The administration of flunixin meglumine at 2.2 mg/kg intramuscularly or flurbiprofen at 2 mg/kg intravenously before clinical signs appeared in experimental *E. coli* mastitis abolished the febrile response during the first 9 hours after infection and lessened the decrease in rumen

motility. In a separate study flunixin meglumine at 1.1 mg/kg intravenously 4 hours after inoculation of the *E. coli* mitigated the small reduction in lying time seen with acute *E. coli* mastitis;<sup>11</sup> this finding has minimal clinical relevance because this protocol is effectively a pretreatment administration because clinical signs of mastitis are usually not evident or very mild at this time.

The intramammary administration of prednisolone (20 mg) in conjunction with intramammary cephalixin (300 mg) had an antiinflammatory effect in cattle with experimental *E. coli* mastitis, as indicated by lower density of leukocytes in mammary tissue, lower IL-4 concentration in the glandular secretion of infected quarters, and a faster restoration of milk quality.<sup>21</sup> The relevance of these findings to the treatment of naturally occurring cases of *E. coli* mastitis is questionable because treatments were applied 4 hours after intramammary inoculation of *E. coli* when clinical signs of mastitis are usually not evident or very mild.

Carprofen, a long-acting NSAID, reduced the fever, tachycardia, and udder swelling associated with *E. coli*-endotoxin-induced mastitis. The long-acting properties of carprofen may be considered a therapeutic advantage over flunixin meglumine, which requires frequent dosing.

### Combination Therapy

Fluid and electrolyte therapy and flunixin meglumine, in combination and individually, have been evaluated in a 3-year study of a large number of cows with toxic mastitis. Cows were allotted to one of three groups:

- Fluid therapy (45 L of intravenous isotonic electrolyte solution) and flunixin meglumine at 2 g
- Fluid therapy intravenously only
- Flunixin meglumine only

All cases were treated with parenteral and intramammary antimicrobial agents, oxytocin, and calcium borogluconate. There was no significant difference in the rate of survival between the treatment groups, and 54% of the cows survived.

### CONTROL

The control of coliform mastitis is characteristically difficult, unreliable, and frustrating. Several cases of fatal peracute coliform mastitis may occur in a herd of 100 cows during a period of a year, in spite of the existence of apparently excellent management. The general principles of mastitis control that have been effective for the control of *S. aureus* and *S. agalactiae* mastitis have been unsuccessful for the control of coliform mastitis because infection of the mammary gland occurs by direct contact with the environment, usually between milkings. For the control of coliform mastitis, the emphasis is on the prevention of new infection. Core lipopolysaccharide antigen vaccines are useful and are discussed later.

## Management of Outbreaks

When an outbreak of peracute coliform mastitis is encountered the following procedures are recommended in an attempt to prevent new cases:

- Culture milk samples and obtain a definitive etiologic diagnosis (in other words, **put a name to the causative pathogen**).
- Examine the bedding for evidence of heavy contamination with coliform bacteria. If sawdust or wood shavings are being used, replace with sand, if possible, or change more frequently.
- Conduct a general clean-up of the stall and lounging areas.
- Improve premilking hygiene.
- Examine milking machine function.
- Allow cows access to fresh feed immediately after milking to ensure that they remain standing for at least 30 minutes to allow time for the streak canal to close.

## Housing and Environment

The normal presence of coliform bacteria in every aspect of the cow's environment must be recognized, but every effort must be made to avoid situations that allow a buildup of bacterial numbers. This is especially important in dairy herds that have been on an effective mastitis control program, resulting in a high percentage of cows with low SCCs in their milk, which increases their susceptibility to coliform mastitis. The overall level of sanitation and hygiene must be improved and maintained in these herds.

## Bedding

Dairy cows lay down for 12 to 14 hours each day, and during this time their teats are in direct contact with a contaminated environment. The key to control is to minimize the number of bacteria in the bedding environment that are mastitis pathogens. Most coliform infections in periparturient cows occur very early in the dry period or just before calving, so efforts to prevent infection should be centered on these periods. Management of the dry cow environment may provide the best opportunity for prevention of infection. Although no reliable recommendations are available, cows that are housed during part or all of the day or night should be bedded on **clean** and **dry** bedding and not overcrowded to prevent heavy fecal contamination. When possible, dry and preparturient cows are best maintained on pasture. There remains an urgent need for the determination of optimum space and bedding requirements for the lounging areas of dairy cows kept under loose housing. Bedding should be kept as dry as possible. Excessively wet bedding should be removed from the back one-third of the stalls daily and replaced with fresh bedding. The addition of lime may decrease bacterial growth. Sawdust and shavings harbor more coliform bacteria than

straw and require special attention. The buildup of high numbers of coliform bacteria in the bedding of cow cubicles can be controlled by the daily removal of the sawdust from the rear of the cubicle and rebedding with clean sawdust, which is usually of low coliform count. The use of a paraformaldehyde spray on sawdust bedding reduced the coliform count for 2 to 3 days, but it returned to its predisinfection level in 7 days. When outbreaks of coliform mastitis are encountered that are possibly associated with heavily contaminated sawdust or shavings, the bedding should be removed immediately and replaced with clean, fresh, dry straw. The use of sawdust or shavings as bedding should be avoided if possible. Sand is now considered to be the "gold standard" and the most suitable alternative.

## Regular Daily Cleaning of Barns

This is necessary to minimize contamination of teats. In free-stall and loose-housing dairy barns, every management technique available must be used to ensure that cows do not defecate in their stalls and increase the level of contamination. This requires daily raking of the bedding in free-stall barns and adjusting head rails to ensure that cows do not lie too far forward in the stall and to ensure that they defecate in the alleyway.

In dairy herds that are confined for all or part of the year, the level of contamination usually increases as herd size increases; and usually the ventilation is inadequate. This leads to excessively humid conditions, which promote the development of coliform bacteria in wet bedding. This will require increased attention to sanitation and hygiene.

## Milking Procedures

Postmilking teat dipping with a disinfectant has little effect on reducing the incidence of coliform mastitis because contamination of the teats occurs between milkings rather than at milking. Thus one logical approach to the control of coliform mastitis is to reduce environmental contamination. In the event of gross fecal contamination of the udder and teats, additional time and care will be required at milking time. Premilking udder preparation can significantly influence milk quality. Lowest bacterial counts in milk are observed when the teats of cows are cleaned with water followed by thorough drying with paper towels, or when a teat disinfectant is applied to the teats followed by drying with paper towels. In addition, premilking teat disinfection in association with good udder preparation reduces the rate of intramammary infections by environmental pathogens by about 51% compared with good udder preparation only.

## Premilking Teat Disinfection

Many dairy producers have now incorporated premilking teat disinfection into their mastitis control strategy, and many different

teat dips are used. Premilking teat dips containing 0.25% iodine, 0.1% iodophor, 0.25% iodophor, and 0.55% iodophor with 1.9% linear dodecylbenzene sulfonic acid (LDBSA) have been evaluated and have provided consistent results. Premilking and postmilking teat disinfection, in association with good udder preparation, are significantly more effective in prevention of environmental pathogen intramammary infection than good udder preparation and postmilking teat disinfection. No chapping or irritation of teats was observed. However, premilking teat disinfection has not been shown to decrease the incidence of clinical mastitis.

## Postmilking Barrier Teat Dips

Barrier test dips include latex, acrylic, and polymer-based products that create a physical seal between the teat and the environment and theoretically decrease the exposure of the teat end to environmental mastitis pathogens, decreasing the incidence of new coliform intramammary infections during lactation. The efficacy of this barrier product was thought to be caused by the persistency of the dip on teats between milkings; however, barrier dips were not consistently successful. In summary, barrier teat dips with germicidal agents are no more effective in decreasing the incidence of environmental mastitis than postmilking germicidal teat dips.

## Nutrition

Vitamin E or selenium deficiency decreases neutrophil chemotaxis into the mammary gland and decreases the intracellular killing of bacteria by neutrophils. It is therefore important to ensure that vitamin E and selenium intakes are adequate; this is best achieved by daily ingestion of 1000 IU of vitamin E and 3 mg of selenium for dry cows and daily ingestion of 400 to 600 IU vitamin E and 6 mg of selenium for lactating cows.

Vitamin C is the most important water-soluble antioxidant in mammals and, consequently, plasma vitamin C concentration may impact neutrophil function.<sup>25</sup> Daily ingestion of Vitamin C (30 g/day orally) had no effect on neutrophil phagocytosis, bacterial killing, or the severity of mastitis in dairy cattle following intramammary infusion of endotoxin.<sup>25</sup> The current data do not support the administration of Vitamin C in the diet as part of the control measures for *E. coli* mastitis.

## Prevention of Infection During Dry Period

Considerable movement of coliform bacteria can occur from the teat apex into the teat sinus in cows that are not being milked, so cows that are ready to calve should be kept on grass or moved into a clean area at least 2 weeks before calving, their udders and teats washed daily if necessary, and teat dipping with a teat disinfectant begun 10 days before

calving. This is particularly necessary for older cows and those that are known to be “leakers.” The teats of those cows that are “leakers” just before calving may have to be sealed with a barrier teat dip or collodion to minimize the chance of infection.

### Recumbent Cows

Cows that are recumbent and unable to stand (e.g., the downer cow) should be well bedded on clean dry straw; their udders should be kept clean and dry, and the teats should be dipped with a teat disinfectant. Strict hygiene must be practiced when using teat siphons and teat creams, and strict asepsis should be observed when doing teat surgery.

### Milking Machine

Irregular vacuum fluctuations in the milking machine may induce coliform mastitis in quarters exposed to a high level of contamination. The operation and sanitation of the milking machine, especially those parts in direct contact with the teats, must therefore be examined.

### Vaccination

#### Core Lipopolysaccharide Antigen Vaccine

The vaccination of cows during the dry period and early lactation with core lipopolysaccharide antigen vaccine (such as the Re mutant *Salmonella typhimurium* or the Rc mutant *E. coli* O111:B4, named the J5 vaccine) provides one tool to reduce the incidence and severity of clinical coliform mastitis. These vaccines are available in the United States and are based on mutated gram-negative bacteria with exposed core antigens of lipopolysaccharide. The core antigen (lipid A component) is uniform between bacterial species possessing lipopolysaccharide and is immunogenic. On theoretical grounds, the Re mutant (*S. typhimurium*) should provide better protection than the Rc mutant (*E. coli* J5) because the lipid A component is more accessible to the immune system; however, comparative studies of vaccine efficacy have not been performed. Generally, core lipopolysaccharide vaccines are weakly immunogenic, and frequent dosing (hyperimmunization) appears to increase vaccine efficacy. However, the economic benefits of hyperimmunization have not been determined.

The Re and Rc mutant vaccines are protective against natural and experimental challenge to gram-negative bacteria, and in most, but not all studies, **reduce the incidence and severity of clinical gram-negative bacterial mastitis in lactating dairy cows.**<sup>26–29</sup> In a prospective cohort study in two commercial dairy herds, during the first 90 days of lactation, cows vaccinated with *E. coli* J5 vaccine were at five times lower risk of developing clinical coliform mastitis than unvaccinated cows. This is

corroborated with the observation that cows with naturally occurring serum IgG ELISA titers higher than 1:240 against the gram-negative core antigen of *E. coli* J5 had 5.3 times lower risk of developing clinical coliform mastitis than cows with lower titers. Vaccination reduced the severity of clinical signs following intramammary experimental challenge with a heterologous *E. coli* strain. In cows vaccinated with the J5 bacterin at drying off, at 30 days after drying off and within 48 hours after calving, and challenged 30 days after calving with a strain of *E. coli* known to cause mild clinical mastitis, the duration of intramammary infection and local signs of mastitis were reduced compared with controls. Also, the concentrations of bovine serum albumin in milk 24 hours after challenge were greater in control cows than in vaccinated cows.

A partial budget analysis of vaccinating dairy cattle with one core lipopolysaccharide antigen vaccine (the Rc mutant of *E. coli* or J5 strain) indicated that herd vaccination programs were predicted to be profitable when more than 1% of cow lactations resulted in clinical coliform mastitis and predicted to be profitable at all herd milk production levels.

Core lipopolysaccharide antigen vaccines have the potential to have deleterious effects because of their endotoxin content. For instance, vaccination of late lactation and dry cattle with the *S. typhimurium* Re mutant transiently decreased leukocyte and blood-segmented neutrophil concentration, but the decrease is probably clinically insignificant. This response is typical for endotoxin administration. Vaccination of lactating dairy cattle with the *E. coli* Rc mutant decreased milk production by 7% at the second and third milkings after vaccination. These two studies indicate that core lipopolysaccharide antigen vaccines should not be administered to diseased cattle or to healthy cattle in hot and humid weather because of their decrease in cardiovascular reserve. Moreover, to minimize the total bolus exposure to endotoxin, core lipopolysaccharide vaccines should not be administered at the same time as other gram-negative vaccines.

### TREATMENT AND CONTROL

#### Treatment

Treat mild and moderate *Escherichia coli*, *Klebsiella* spp., and *Enterobacter aerogenes* clinical mastitis episodes (abnormal secretion and abnormal gland) during lactation with a  $\beta$ -lactamase-resistant intramammary formulation with activity against gram-negative bacteria per label directions (R-1).

Treat severe *E. coli*, *Klebsiella* spp., and *E. aerogenes* clinical mastitis episodes (abnormal secretion, abnormal gland, and

abnormal cow) during lactation with parenteral third- or fourth-generation cephalosporins, fluoroquinolones, potentiated sulfonamides, or intravenous oxytetracycline per label directions, in conjunction with intramammary treatment that may be extended to 5 days or 8 days per label directions (R-1).

Administer intravenous small-volume hypertonic saline or large-volume isotonic crystalloid solutions to severe clinical mastitis episodes (R-1).

Administer nonsteroidal antiinflammatory agents (ketoprofen, possibly flunixin meglumine) to cattle with systemic signs of illness (R-2).

Treat subclinical intramammary infections during lactation with an intramammary formulation (R-3).

#### Control

Implement 10-point mastitis control plan, with particular emphasis on ensuring cows are housed in a clean dry environment and that clean dry teats are milked (R-1).

Ensure cows remain standing for at least 30 minutes after milking (R-1).

Ensure adequate vitamin E and selenium intake in periparturient dairy cattle (R-1).

Consider implementing premilking teat disinfection (probably with 0.1%–0.5% iodophor formulation) (R-2).

Administer core-lipopolysaccharide antigen vaccine (Re mutant *Salmonella typhimurium* or Rc mutant *E. coli* O111:B4) at least every 6 months in herds with a high incidence of coliform mastitis (R-2).

## ENVIRONMENTAL STREPTOCOCCI

### SYNOPSIS

**Etiology** *Streptococcus uberis*, *S. dysgalactiae*, other *Streptococcus* spp. are most common; occasionally *Enterococcus* spp.

**Epidemiology** Common cause of subclinical and clinical mastitis in herds and countries that have controlled contagious mastitis. Responsible for approximately one-third of all cases of clinical mastitis in herds without contagious pathogens. Rate of infection high during first 2 weeks following drying off and 2 weeks before calving. Duration of infection usually short (<8 days). Prevalence of infection at calving: 11% of cows and 3% of quarters. Bedding materials (high in straw bedding) most important source of environmental streptococci; bacteria can be isolated from many different feedstuffs and several locations on cow (teats, rumen, feces, saliva, lips, and nares). Bacterial numbers low in sand, which is bedding of choice

**Clinical findings** Abnormal secretion, abnormal gland, usually no systemic signs. Recovery in two to three milkings with intramammary treatment

**Clinical pathology** Culture of milk

**Necropsy findings** Not applicable

**Diagnostic confirmation** Culture bacteria from milk and milk somatic cell count

**Differential diagnosis** Cannot differentiate from other causes of subacute and acute mastitis without culture of milk

**Treatment** Antimicrobial intramammary infusions increase bacteriologic cure rate and decrease percentage of relapses. Intramammary antibiotics should be routinely administered to all clinical cases of mastitis caused by environmental streptococci.

**Control** Decrease exposure of teat end to pathogens by attention to environment, dry bedding, sand for bedding, premilking hygiene, and premilking germicide teat dipping. Dry cow therapy with penicillin G, cloxacillin, erythromycin, and first-generation (cephapirin) or third-generation (ceftiofur) cephalosporins. Application of an internal teat sealant of bismuth subnitrate at dry off may decrease new infection rate in dry period.

### ETIOLOGY

*S. uberis* and *S. dysgalactiae* and the enterococci are the most commonly isolated environmental streptococci from intramammary infections. Other uncommon environmental streptococci involved in bovine mastitis include *S. equi* var. *zooepidemicus*, *S. viridans*, *S. equinus* (*S. bovis*), *Streptococcus* spp. group G, *S. pyogenes*, and *S. pneumoniae*. Both *S. uberis* and *S. dysgalactiae* are widespread in the animal's environment and on the skin of the teats. *Enterococcus* spp. are also a common cause of environmental intramammary infections.

### EPIDEMIOLOGY

#### Occurrence and Prevalence of Infection

In countries in which the prevalence of intramammary infections caused by the contagious pathogens *S. agalactiae* and *S. aureus* has been reduced or eradicated, the proportion of intramammary infections associated with **environmental streptococci** has increased markedly; in some areas these organisms are the leading or second leading cause of both subclinical and clinical mastitis in dairy cattle. *S. uberis* is now a common cause of intramammary infection occurring during the dry period, with most clinical cases occurring during the first part of lactation. Many infections acquired during the dry period persist to lactation and contribute to the incidence of clinical mastitis in early lactation. *S. uberis* has become the most commonly isolated pathogen from clinical mastitis episodes in grazing dairy cattle in Australia and is present in 33% of submitted samples in southeast Australia.<sup>1</sup>

The rate of new infection caused by environmental streptococci is elevated during the first 2 weeks following drying off and the 2 weeks before calving; the rate of new infections is greater during the first month of lactation than during the remainder of the lactation. Approximately 50% of new infections occur during the dry period and 50% in the early part of lactation. The rate of new infections during the dry period is about five times greater than during lactation. Based on data from surveys of milk samples over a 10-year period, the point prevalence of infection of environmental streptococci was 4% of quarters and 12% of cows. The percentage in heifers at calving is similar to that in cows. The prevalence of environmental streptococci isolation at drying off and calving was 2.5% and 3.0%. Environmental streptococcal intramammary infections are usually short-lived (<28 days), with only a small percentage becoming chronic.

The most important change in the epidemiology of bovine mastitis over the past decade has been the rise in the importance of environmental pathogens, mainly causing clinical mastitis, relative to contagious pathogens. Remarkable increases in both the coliforms and environmental

streptococci as causes of clinical mastitis have occurred. The percentage of clinical cases of mastitis from which environmental streptococci can be isolated ranges from 14% in Ontario to 26% in the UK. When expressed as a percentage of clinical cases from which a major pathogen was isolated, environmental streptococci are isolated in 37% to 45% of cases.

### Source of Infection

The environmental streptococci, especially *S. uberis*, have been isolated from bedding materials and the lips and tonsils of cows, with the abdominal skin of cows often harboring the largest population. Some cows are permanently colonized with *S. uberis* and may pass large numbers of the bacteria in the feces. Fecal shedding is thought to play an important role in the maintenance of *S. uberis* populations on dairy farms, and is the likely source of large numbers of the organism in straw bedding on farms in which this form of mastitis persists. The numbers of environmental streptococci in organic bedding materials vary with the type of bedding. Large numbers of *S. uberis* are found in straw bedding and much lower numbers in sawdust and wood shavings. The numbers of streptococci recovered from the teats of cows bedded on sawdust are lower than those bedded on straw. Long straw used in calving box stalls or as bedding in loose housing can be a source of considerable exposure to environmental streptococci.

*S. dysgalactiae* can also be found in the environment of dairy cattle and has been isolated from the tonsils, mouth, vagina, and the mammary glands. It has characteristics of both a contagious and an environmental pathogen, and some categorization schemes place it in the contagious category, although it is primarily an environmental pathogen. *S. dysgalactiae* is also associated with summer mastitis, which affects dry cows and heifers during the summer months. It has been isolated from the common cattle fly *Hydrotoea irritans*, which may be involved in the establishment and maintenance of bacterial contamination of teats. *S. dysgalactiae* may colonize the teat before infection with *T. pyogenes* and anaerobic bacteria such as *P. indolicus* and *E. necrophorum*.

### Risk Factors

#### Environmental Risk Factors

The major risk factor for environmental streptococci infection is **exposure of the teat end to mastitis pathogens in the environment**. Transmission is predominantly from the environment. Exposure of uninfected teats to environmental streptococci can occur during the milking process, between milkings, during the dry period, and before parturition in first-lactation heifers. The rate of new infections is greatest during the summer months in North America.

Housing and management practices on dairy farms may contribute to contamination of bedding materials and exposure of teats to environmental streptococci. Housing facilities that predispose to the accumulation of feces on cows will increase the rate of exposure of the teat end to the pathogens. Straw bedding appears to increase the risk of *S. uberis* mastitis, and an increase in *S. uberis* mastitis cases occurs when cows are housed in deep straw pack.

Pastured cattle are generally at reduced risk for environmental streptococcal mastitis compared with cows in confinement housing. However, certain pasture conditions, such as areas under shade trees, poorly drained ground surfaces, ponds and muddy areas, may result in a high rate of exposure to the pathogens, particularly to *S. uberis*. The environmental streptococci are the most significant environmental pathogen in New Zealand dairy herds in which cows spend almost 100% of their time on pasture.

*S. dysgalactiae* is commonly isolated from heifers and cows in the dry period and is one of the most prevalent pathogens isolated from cases of summer mastitis. The spread of *S. dysgalactiae* between cows within dairy herds may occur directly or by way of the milking machine or environment.

### Animal Risk Factors

*S. uberis* is the most common cause of clinical mastitis at calving in cattle in pasture-based dairy systems.<sup>2</sup> The risk of new infections is influenced by the stage of lactation and parity of the cow. The **rate of new infection is highest during the 2 weeks following drying off and the 2 weeks before calving**. The high rates of new infection following drying off may be associated with the lack of flushing action of milking, changes in the composition of the mammary secretion, which may enhance the growth of the pathogens, and the lack of a keratin plug in the streak canal. The primary defense mechanisms for *S. uberis* are the length of the teat canal and the amount of keratin in the lining. Antimicrobial dry cow therapy reduces the infection rate in the early part of the dry period but has little or no effect on preventing infection with *S. uberis* at the end of the dry period. The increase in susceptibility to infection just before parturition may be associated with the lack of milking when the gland is accumulating fluid, loss of keratin plugs from streak canals, or immunosuppression of the periparturient period. The **rate of infection is also higher in older cows** than for either heifers or cows in second lactation, and highest during the summer months for both cows in lactation and cows in the dry period. This is in contrast to contagious pathogens, in which exposure occurs primarily during the milking process. A small percentage of animals have highly resistant phenotypes for *S. uberis* infection.<sup>2</sup>

### Pathogen Risk Factors

*S. uberis* is ubiquitous in the cow's environment with multiple environmental habitats. Consequently, the mammary gland is exposed continuously to the pathogen during lactation and the dry period, and infections are associated with a large variety of strains, some of which are not capable of inducing clinical mastitis or prolonged infections of subclinical mastitis.<sup>3</sup> Several virulence factors of *S. uberis* have been identified that are important in the pathogenesis of environmental mastitis. Antiphagocytic factors allow *S. uberis* to infect and multiply in the gland and to adhere to and invade the mammary tissue. Bovine mammary macrophages are capable of phagocytosis of the organism, but certain strains of *S. uberis* are capable of resisting phagocytosis by neutrophils because of their **hyaluronic acid capsule**. The ability of *S. uberis* to invade the bovine mammary epithelial cells could result in chronic infection and protection from host defense mechanisms and the action of most antimicrobial agents, which may explain the intractable response to therapy in some cases. However, most apparently "intractable" infections are caused by an inappropriately short duration of treatment.

*S. dysgalactiae* behaves like both a contagious and an environmental pathogen<sup>4</sup> and can invade bovine mammary epithelial cells, which may explain the persistence of infection. Different biotypes of *S. dysgalactiae* have been identified, and strains can possess several antiphagocytic factors, including M-like protein,  $\alpha$ -2-macroglobulin, capsule and fibronectin binding, and virulence factors, including hyaluronidase and fibrinolysin.

An existing intramammary infection caused by *C. bovis* is a risk factor for environmental streptococcal infection through an unidentified mechanism.

### Economic Importance

The major economic losses associated with environmental streptococcal mastitis are caused by clinical mastitis resulting in lost production, milk withholding, premature culling, increased labor, and costs of therapy and veterinary services. Eighty-eight percent of the loss associated with clinical mastitis is attributed to loss of milk production and milk withholding. Pluriparous cows lost 2.6 times as much as first-calf heifers, and cows less than 150 days in milk lost 1.4 times more than cows more than 150 days in milk. Intramammary infection with *S. uberis* at calving in heifers resulted in a decreased lactational milk yield, even with subclinical infections, which means that *S. uberis* infections at calving should be routinely treated.<sup>5</sup>

### PATHOGENESIS

The current consensus is that environmental streptococci (with the possible exception

of *S. dysgalactiae*) are not contagious pathogens.<sup>4</sup>

In experimental infection of dairy cows with *S. uberis* there is acute inflammation, resulting in the accumulation of large numbers of neutrophils in the secretory acini in 24 hours. Adherence to mammary epithelial cells followed by internalization appears to be important in the establishment of infection.<sup>6,7</sup> Infection also leads to the recruitment of activated T cells that are able to kill *S. uberis* and appear to play an important role in an effective immune response.<sup>8</sup> After 6 days of infection, the neutrophil response is still evident, but there is cellular infiltration, septal edema, extensive vacuolation of secretory cells, focal necrosis of alveoli, small outgrowths of the secretory and ductular epithelium, and widespread hypertrophy of the ductular epithelium. The organism is present free or phagocytosed, in macrophages in the alveolar lumina, adherent to damaged secretory or ductular epithelium, in the subepithelium and septal tissue, and in lymphatic vessels and lymph nodes. The macrophage and activated T cells are important as the primary phagocytic cells,<sup>7,8</sup> but the marked neutrophil response may be ineffective as a defense mechanism. It is hypothesized that the marked neutrophil response following infection with *S. uberis*, rather than the organism, may be responsible for most of the effects of the mastitis. At least 11 virulence-associated genes have been identified in *S. uberis*, but it is not clear which are of major importance.<sup>9</sup>

### CLINICAL FINDINGS

Approximately 50% of environmental streptococcal intramammary infections cause clinical mastitis during lactation. Clinical abnormalities occur in 42% to 68% of these infections in the same herd in different years. The clinical findings are usually limited to abnormal secretion or abnormal gland. In about 43% of cases the findings are limited to abnormal milk, 49% involve abnormal secretion and an enlarged (abnormal) gland, and in only 8% of cases do systemic signs include a fever and anorexia (abnormal cow). Clinical recovery commonly occurs in 24 to 48 hours. Natural infections with *S. uberis* appear to be more severe than natural infections with *S. dysgalactiae*, based on higher milk SCC for *S. uberis* mastitis episodes during the 4-month period after treatment.<sup>4</sup>

### CLINICAL PATHOLOGY

The laboratory diagnostic tests for these pathogens are the same as for *S. agalactiae*. All the environmental streptococci except *S. dysgalactiae* hydrolyze esculin on blood agar. Species can be differentiated with reasonable success using a variety of biochemical tests, such as the API20 Strep and serologic grouping using specific antisera of Lancefield groups; however, this approach is laborious, time-consuming, and does not accurately

differentiate every streptococcal mastitis pathogen. Biophysical analytical techniques have recently been applied with success to accurately differentiate streptococcal mastitis pathogens, including MALDI-TOF MS, which is mainly based on ribosomal proteins, and Fourier transform infrared spectroscopy, which covers the entire biochemical composition of a bacterial cell.<sup>10</sup>

## DIFFERENTIAL DIAGNOSIS

*Streptococcus uberis* mastitis in dry cows may be sufficiently severe to resemble mastitis associated with *Trueperella pyogenes*. Diagnosis depends on cultural examination of the milk.

## TREATMENT

### Antimicrobial Agents

The in vitro susceptibility of environmental streptococci to antimicrobial agents is high. Most isolates of *S. uberis* and *S. dysgalactiae* are susceptible to penicillin, novobiocin, amoxicillin, and cephalirin. A high percentage (96%) are also susceptible to tetracycline, but susceptibility to aminoglycosides is much lower. Most cases of clinical mastitis associated with *S. uberis* and *S. dysgalactiae* respond well to intramammary infusions of penicillin, cephalosporins, cloxacillin, erythromycin, and tetracyclines. Spontaneous cures can also occur. Clinical cases in lactating cows should be treated by at least two intramammary infusions 12 hours apart; this may produce a clinical cure but fail to produce a bacteriologic cure. Subclinical infections in **late lactation** may be left until the dry period. For clinical cases in the first 100 days of lactation there is substantial economic benefit from intramammary treatment. Some cases associated with strains of *S. uberis* appear intractable to treatment; extended treatment is necessary in these animals. Failure of treatment may be caused by epithelial cell invasion and movement of the bacteria into subepithelial layers, possibly reducing the effectiveness of the antimicrobial. Apparently recurrent episodes of clinical mastitis caused by *S. uberis* despite adequate treatment are more likely from a subsequent infection with a new strain, rather than ineffective treatment.<sup>1</sup> Parenteral treatment is rarely needed to treat cattle with confirmed *S. uberis* clinical mastitis.

Extended therapy (for 5 days or 8 days) with intramammary ceftiofur (125 mg), pirlimycin (50 mg), or penethamate hydriodide, dihydrostreptomycin sulfate, and framycetin sulfate, every 24 hours, increases the bacteriologic cure rate for cattle with experimentally induced *S. uberis* mastitis. In a study of 1148 cases of subclinical environmental streptococci mastitis in New York, commercially available intramammary infusions were more effective than untreated

controls (66% bacteriologic cure), with the following bacteriologic cure rates: amoxicillin (90%), penicillin (82%), and cloxacillin (79%).

Treatment using oxytocin and frequent stripping of the affected glands without intramammary antibiotic administration is not recommended because cure rates are much lower. Moreover, not administering antimicrobial agents results in a higher relapse rate. Many of the relapses were associated with the environmental streptococci; therefore **intramammary antimicrobial treatment should be routinely performed**. In particular, because clinical mastitis with an abnormal gland or abnormal cow induces some pain and discomfort in the cow, **withholding an effective treatment (intramammary antimicrobials) cannot be condoned on animal welfare grounds**.

Meloxicam (250 mg subcutaneously once) was administered to dairy cows in New Zealand with mild clinical mastitis receiving three daily intramuscular injections of penethamate hydriodide (5 g). In this population, *S. uberis* was the most common isolate, and the addition of meloxicam to the treatment protocol decreased the posttreatment SCC and decreased culling from the herd from 28% to 16%.<sup>11</sup>

## CONTROL

The control of mastitis caused by environmental streptococci is achieved by **decreasing the exposure of pathogens to the teat end** and by increasing the resistance to intramammary infections. A specific control recommendation for environmental streptococci mastitis is **not to bed on straw**, but this may not be a practical or economic recommendation for some producers. If straw bedding is used, a reduction in the teat-end exposure to *S. uberis* can result from frequent (daily) replacement of bedding. The key factor promoting environmental streptococci mastitis is bedding on wet or damp straw.

**Reducing the exposure of the teat end to manure and dirt depends on maintenance of a clean and dry environment.** The alleys and holding pens should be frequently scraped, and places in which cows lie down should be dry. Special attention must be directed to the dry cow and close-up heifer housing, the calving area, lactating cow housing, and the milking parlor and milking hygiene. Organic bedding materials such as straw that support large numbers of environmental pathogens when wet should be kept dry. Sand is the ideal bedding material because it has the lowest number of coliform and environmental pathogens. Milking time hygiene should emphasize milking of clean, dry teats and udder, with a properly functioning milking machine. Predipping with a teat dip germicide may reduce environmental mastitis by as much as 50%, but this reduction does not occur in all herds.

**Dry cow therapy** to prevent new infections has not been as successful for the control of all causes of environmental mastitis as it has been for contagious mastitis. However, dry cow therapy is more effective against the environmental streptococci than against coliform bacteria. Application of an **internal teat sealant** of bismuth subnitrate at dry off is effective in preventing infections associated with *S. uberis* during the dry period. Combined administration of a dry cow intramammary formulation and an internal teat sealant has become routine in Australia as a fundamental plank in dairy herds with endemic *S. uberis* mastitis.<sup>12</sup>

A long-acting intramammary infusion dry cow therapy containing 250 mg of cephalonium administered after the last milking of lactation reduced the incidence of new infections caused by *S. uberis* from 12.3% to 1.2%. Clinical infections during the dry period were most prevalent in quarters identified as having open teat canals. Fewer open teat canals were observed among treated quarters over the first 4 weeks of the dry period. It is proposed that the teat canal of treated quarters closed earlier than those of untreated quarters. Most of the new infections in the untreated controls occurred within the first 21 days of the dry period. Normally, the teat canal is dilated for up to 7 days after drying off, with a keratin plug then forming over the following 14 to 21 days. It is suggested that once a physical keratin seal has formed in the teat canal after drying off, an uninfected quarter has a very low risk of infection over the remainder of the dry period. Treated quarters had a lower incidence of new clinical infections during the next lactation and lower SCCs.

## Vaccination

Experimentally, multiple intramammary vaccinations with whole killed *S. uberis* cells resulted in complete protection against experimental infection in cattle. Bacteria could not be isolated from the quarters after challenge, and protection occurred in the absence of a marked neutrophil response. Preparations containing plasminogen activator or recombinant *S. uberis* adhesion molecule may form the basis of a vaccine against *S. uberis*.<sup>13</sup>

Vaccines are presently commercially unavailable, and vaccination is not currently recommended as part of the control program for mastitis caused by environmental streptococci.

## TREATMENT AND CONTROL

### Treatment

Treat clinical mastitis episodes during lactation with an intramammary formulation that is effective against gram-positive bacteria per label directions; consider extended

*Continued*

intramammary therapy in chronic cases (R-1).

Treat subclinical *S. uberis* intramammary infections at calving with an intramammary formulation that is effective against gram-positive bacteria per label directions (R-1).

Administer nonsteroidal antiinflammatory agents (meloxicam) to cattle with clinical mastitis that is predominantly caused by environmental streptococci (R-2).

#### Control

Implement 10-point mastitis control plan, with particular emphasis on ensuring cows are housed in a clean dry environment and that clean dry teats are milked (R-1).

Ensure cows remain standing for at least 30 minutes after milking (R-1).

Administer a long-acting intramammary formulation with activity against gram-positive bacteria at dry off to all cows, followed by infusion of an intramammary teat sealant (R-1).

## TRUEPERELLA PYOGENES

### ETIOLOGY

*T. pyogenes* (formerly *Arcanobacterium pyogenes*, *Actinomyces pyogenes*, and *Corynebacterium pyogenes*) causes two forms of severe clinical mastitis: sporadic cases of suppurative mastitis, mostly in housed cattle, referred to as **pyogenes mastitis**, and a clinically similar disease that occurs in outbreaks in cattle during the summer months in Europe and Scandinavia and is referred to as **summer mastitis**. Successful transmission of infection has been performed, but the bacteria is rarely present in pure culture in the naturally occurring disease and is not the specific cause of summer mastitis. When the organism is applied to the teat skin at the end of the teat, infection of the quarter does not occur unless the teat end is injured, which is when anaerobic bacteria are also involved in the infection.

### SYNOPSIS

**Etiology** *Trueperella pyogenes*, formerly known as *Arcanobacterium pyogenes*, *Actinomyces pyogenes*, or *Corynebacterium pyogenes*

**Epidemiology** Important cause of sporadic suppurative mastitis, most common in dry cows or pregnant heifers. Outbreaks occur in Europe in summer (called summer mastitis) associated with seasonally active biting flies, such as *Hydrotoea irritans*. Other bacteria (*Streptococcus dysgalactiae* and *Peptostreptococcus indolicus*) may be required to initiate clinical mastitis.

**Clinical findings** Gland is severely swollen and hard, usually only one quarter affected. Secretion from infected quarters is initially watery with clots and later purulent. Initially severe systemic signs including fever, inappetence, tachycardia, depression, and mortality rate up to 50%. In cattle surviving the initial infection, the affected quarter becomes abscessed, with drainage of purulent material at the base of the teat.

**Clinical pathology** Culture of milk

**Necropsy findings** Abscesses in one gland and severe systemic reaction are strong presumptive necropsy findings of *T. pyogenes* mastitis.

**Differential diagnosis** Cannot definitively differentiate from other causes of acute mastitis without culture of milk; however, the presence of abscesses in mastitis is strongly suggestive of *T. pyogenes*.

**Treatment** Responds poorly to treatment with parenteral procaine penicillin G or oxytetracycline and intramammary penicillin. Affected quarter is almost always lost for milk production.

**Control** Intramammary infusion with dry cow preparation every 3 weeks during the dry period. Control fly populations. Isolate cows with draining abscesses.

In summer mastitis the purulent material in the quarter usually contains *T. pyogenes* as a primary pathogen, but the severity of the disease is determined by the presence of anaerobes such as *P. indolicus*; *S. dysgalactiae*; *F. necrophorum*; *P. melaninogenica*; *Fusobacterium* spp.; a microaerophilic, gram-positive coccus (Stuart-Schwan coccus); and other Bacteroidaceae and *Micrococcus* spp. are also found. These bacterial species are found on the teats and conjunctiva and in the oral cavity of healthy cattle. *F. necrophorum* was recovered almost exclusively from the oral cavity, *P. indolicus* and *T. pyogenes* most frequently from teat skin, and isolates of *P. melaninogenica* subsp. *levii* were evenly distributed between conjunctiva and teat tip samples. There is also a distinct seasonal pattern of the isolation of the pathogens, which corresponds closely to the seasonal activity of the fly *H. irritans*.

It has also been proposed that *S. dysgalactiae* is the primary cause, and the others secondary invaders, but all these bacteria are capable of causing suppurative mastitis when infused into the udder. *T. pyogenes* alone establishes itself readily in mammary tissue after experimental introduction but causes only a subclinical disease, but inclusion of summer mastitis exudate provokes the classical syndrome of summer mastitis. Experimental infections with *T. pyogenes* and *P. indolicus* cause a much more serious disease, and are less responsive to treatment if the infection is introduced into a dry quarter instead of into a lactating one. The bacterial flora in cases of summer mastitis is quite variable. In some years in the UK, many cases are apparently caused by pure infections of *M. haemolytica*. In pyogenes mastitis, *T. pyogenes* is often found in pure culture, but the other bacteria listed in summer mastitis are also common accompaniments. *A. ulcerans* is an uncommon cause of a subacute mastitis.

## EPIDEMIOLOGY

### Occurrence and Prevalence of Infection

Bovine mastitis associated with *T. pyogenes* occurs sporadically and is most common in dry cows or pregnant heifers, although lactating cows may also be affected. A high prevalence is also recorded in heifer calves as young as 2 months. In the UK, Japan, northern Europe, Florida, and infrequently in a group of countries scattered all over the world, there is a much higher incidence of suppurative “summer mastitis” during the summer months when nonlactating females are left at pasture and not kept under close observation. In the UK 20% to 60% of farms are affected, the same herds are affected each year, and about 40% of farms never experience the disease.

### Source of Infection and Mode of Transmission

The portal of infection is unknown, although it is presumed to be via the streak canal. The method of spread is uncertain in sporadic cases but insects, especially biting ones such as *H. irritans*, appear to play an important role in outbreaks of summer mastitis in northern Europe. The prevalence of the disease is related to the peaks of the fly populations and the prevailing climate, especially the wind force and direction.

### Risk Factors

The incidence is much higher in wet summers and on heavily wooded and low-lying farms when the fly population is high. Dairy breeds are the predominant target, mostly at the end of gestation or in the first few days of the lactation. Heavy fly populations are a common accompaniment of an outbreak. It has been suggested that some triggering mechanism is needed before contamination

of the teat and invasion and infection of the gland can occur. The infection rate of *T. pyogenes* in udders is much less in housed cattle than in the same cattle at pasture. In Australia the disease occurs mostly in lactating cows and usually after injury or the development of black spot on the teat. Outbreaks are also recorded in association with outbreaks of foot-and-mouth disease and herpes mamillitis virus damage to the teats.

### Economic Importance

Summer mastitis is a serious disease because the mortality rate without adequate treatment is probably about 50%, and the affected quarters of surviving cows are always totally destroyed. In pyogenes mastitis the mortality rate is much less, but the loss of the quarter means that the cow is culled.

### PATHOGENESIS

It is suggested that the infection is carried from udder to udder by flies and that massive invasion of the mammary tissue occurs via the teat canal that is damaged. The greater part of the gland is affected at the first attack, causing a severe systemic reaction and loss of function of the entire quarter. The disease has been reproduced by inoculation of the mammary gland of pregnant heifers with *T. pyogenes*, *F. necrophorum*, and *P. indolicus*. All animals developed moderate to severe clinical mastitis: 4 out of 10 animals recovered completely and had a normal lactation after calving. In 6 of 10 animals, the course of the disease was severe and affected quarters failed to produce milk after calving.

### CLINICAL FINDINGS

Mastitis associated with *T. pyogenes* is usually peracute with a severe systemic reaction, including fever (40°C–41°C; 105°F–106°F), rapid heart rate, complete anorexia, and severe depression and weakness. Abortion may occur during this stage. In almost all cases only one quarter is affected, most commonly a front one. The teat is swollen and inflamed and the quarter is very hard, swollen, and sore; the secretion is watery with clots early and later purulent, with a typical putrid odor. The SCC from the secretion of affected cows is extremely high, and the secretion resembles a purulent process more than milk.<sup>1</sup> Affected cows usually carry a large fly population. If the cow survives the severe toxemia, the quarter becomes extremely indurated and abscesses develop, later rupturing through the floor of the udder, commonly at the base of the teat. These may be presented as chronic cases, but they are usually residual after an acute episode. True gangrene, such as occurs in staphylococcal mastitis, rarely if ever occurs in uncomplicated infections with *T. pyogenes*, but quarters may be so severely affected that sloughing occurs. Lameness in the hindlimb on the affected side occurs in some cases, and the limb joints may be

swollen. The function of the quarter is permanently lost, and cows that have calved recently may go completely dry. Severe thelitis with extreme thickening and obstruction of the teat is a common sequel. Partial or complete obstruction of the teat and damage to the teat cistern can also occur independently of an acute attack of mastitis. Fetal growth retardation is thought to be a feature of calves born to cows affected by summer mastitis during pregnancy.

### CLINICAL PATHOLOGY

Isolation of the bacteria is required. Freezing of milk samples reduces the number of samples giving a positive cultural result. MALDI-TOF MS provides a promising tool for the rapid identification of *T. pyogenes*.<sup>2</sup>

### NECROPSY FINDINGS

Details of the pathology of the disease are not available.

### DIFFERENTIAL DIAGNOSIS

The seasonal incidence of the disease in some areas, the acute inflammation of the quarter, the suppurative nature of the mastitis, the development of abscesses, and the severe systemic reaction make this form of mastitis one of the easiest to diagnose clinically in cattle.

### TREATMENT

Summer mastitis normally responds extremely poorly to treatment, and the affected quarter is almost always lost for milk production. Failure of therapy is caused by the extensive purulent processes in the udder and not to antimicrobial resistance. Bacterial isolates from cases of summer mastitis are susceptible to penicillin G and other  $\beta$ -lactam antimicrobials. However, penicillin G has limited distribution throughout the inflamed udder. Given parenterally to experimental cases of summer mastitis, it was effective in about 40% of cases if treatment was initiated within 32 hours after inoculation. In peracute cases parenteral treatment with sodium sulfadimidine or one of the tetracyclines is preferable and should be accompanied by repeated stripping of the quarter. Broad-spectrum antimicrobial agents are usually given by intramammary infusion, but the quarter is almost always rendered functionless.

Affected quarters can also be treated by permanently drying the quarter off. The best method for permanently drying off a quarter is infusion of 120 mL of 5% povidone iodine solution (0.5% iodine) after complete milk out and administration of flunixin meglumine (1 mg/kg BW, intravenously). This causes permanent cessation of lactation in the quarter but does not alter total milk production by the cow.

Clearing of proteinaceous debris from the affected quarter may be aided by the intramammary application of proteolytic enzymes, but the outcome as far as the quarter is concerned is unlikely to be much altered and amputation of the teat to facilitate drainage is a common treatment. Even with intensive therapy, at least 80% of quarters are rendered useless and many of those that respond are greatly reduced in productivity.

### CONTROL

The question of control of this form of mastitis centers largely on summer mastitis. Many prophylactic measures, including infusion of the quarter when the cow is dried off, sealing the teat ends with collodion, and vaccination with toxoid, have been tried but with inconclusive results. The most favored technique is intramammary infusion with a dry cow preparation (e.g., cloxacillin 500 mg and ampicillin 250 mg in a long-acting base) at 3-week intervals during the dry period. Less frequent administration offers less protection. An alternative intramammary infusion procedure is to use cephalonium at 4-weekly intervals.

Repeated spraying of the udder, for example automatically at watering points, with a contact insecticide is commonly performed during the fly season and is thought to be effective. An alternative to spraying is the use of insecticide-impregnated ear tags, or pour-ons. Careful daily examination of dry cows during the summer may enable affected quarters to be identified, the cows to be isolated, and the quarters treated at an early stage, limiting the spread of infection. In particular, cows with purulent material draining from an affected quarter need to be isolated from other cattle. Early treatment of teat lesions to limit bacterial colonization by bacteria, possibly transported by flies, is recommended. The known susceptibility of particular farms, and particular paddocks on those farms, demands proper care in planning the pasturing of dry cows during the danger period.

### TREATMENT AND CONTROL

#### Treatment

Treat clinical mastitis episodes immediately with intravenous oxytetracycline (R-1).

Permanently dry off affected quarters if cow is to remain in the herd (R-2).

#### Control

Isolate cow from the rest of the herd if spontaneous purulent discharge from udder is present (R-1).

Fly control during summer months for pastured cattle (R-1).

## Mastitis of Cattle Associated With Less Common Pathogens

### *PSEUDOMONAS AERUGINOSA*

Mastitis in cattle and sheep associated with *P. aeruginosa* is rare and occurs usually as sporadic cases after intramammary infusion with contaminated material.

### ETIOLOGY

*P. aeruginosa* is the most common cause, although other *Pseudomonas* spp. can cause disease. *P. aeruginosa* produces a number of extracellular toxins; hemolysin is cytotoxic for most cells and is considered the most potent toxin produced, lecithinase (phospholipase) can destroy cell membranes, and protease degrades proteins. In 25 *P. aeruginosa* isolates from the milk of cattle with mastitis in Egypt, 80% carried the hemolysin virulence factor, whereas 72% were lecithinase positive and 16% were protease positive.<sup>1</sup>

### EPIDEMIOLOGY

*P. aeruginosa* is common in the environment of cattle because of its innate ability to survive for long periods in dry and moist conditions. Occasionally a number of animals in the herd are affected with *P. aeruginosa* mastitis; the infection usually originates in contaminated water used for washing udders. The organism has the capacity to colonize inert materials such as loops of hose and the interior surface of water heaters, so that high bacterial concentrations may be in the water left in the hose between milkings. It may be an advantage in these circumstances to flush out the udder washing system before commencing each milking. Once the teats are contaminated, the entry of the organisms to the teats is facilitated by overmilking and by putting the milking cups on while the udder is still wet. Serious outbreaks in cows have also occurred in association with the use of a suspected contaminated mastitis infusion used as a dry period treatment. The cows became affected soon after calving. Prolonged herd outbreaks are rare.

Rarely, strains of this organism are highly virulent and cause fatal mastitis with generalized lesions. Less commonly there is a high level of infection in a herd caused by a contaminated water supply but with no clinical

cases. Reinfection is common unless the source of infection is removed.

### CLINICAL FINDINGS

The mastitis in cattle is usually mild, subacute, or chronic, but can be clinically severe with a mortality rate as high as 17% of affected cows. Clinically, there is a severe systemic reaction and acute swelling of the gland with the appearance of clotted, discolored milk; the function of the gland is usually completely lost at the first attack, but recurrent crises may occur.

### CLINICAL PATHOLOGY

Culture of the organism in milk is necessary to confirm the diagnosis.

### NECROPSY FINDINGS

The disease can be fatal, and the gross and histologic findings are similar to other causes of clinical mastitis in cows.

### DIFFERENTIAL DIAGNOSIS

Bovine mastitis associated with *Pseudomonas aeruginosa* must be differentiated from the many other forms of acute mastitis associated with this species; this can be done only by bacteriologic examination of the milk.

### TREATMENT

Treatment with antimicrobial agents is generally unsuccessful. *P. aeruginosa* is an intrinsically multidrug-resistant bacteria because it has decreased outer membrane permeability, efflux systems, and produces  $\beta$ -lactamase.<sup>2,3</sup> Most bovine mastitis strains are also strong biofilm producers that further decrease antimicrobial effectiveness.<sup>4</sup> However, *P. aeruginosa* isolates from cattle with mastitis are susceptible to a wider variety of antimicrobials than similar isolates from humans.<sup>2</sup> This has been attributed to a lack of selection pressure in the cow's environment.<sup>2</sup> Third-generation cephalosporins such as ceftiofur, aminoglycosides such as gentamicin and amikacin, and fluoroquinolones are most likely to be efficacious in treating affected animals,<sup>4</sup> but susceptibility testing may be helpful in identifying which antimicrobials not to administer on the basis of a very high MIC.

### CONTROL

The standard control program described later in the chapter should control the disease in cows. The oral administration of an organic iodine compound and vaccination with a killed autogenous vaccine are credited with bringing the disease under control in one herd.

## *MANNHEIMIA (PASTEURELLA) SPECIES*

Mastitis associated with *Mannheimia* (formerly *Pasteurella*) *haemolytica* and *Pasteurella multocida* is common in ewes, occurring in a peracute gangrenous form, but is comparatively rare in cattle and goats.

### ETIOLOGY

In cattle *M. haemolytica* and *P. multocida* are the causative organisms; *M. haemolytica* has also been isolated from many cases of summer mastitis in the UK.

### EPIDEMIOLOGY

In cattle the disease is encountered rarely, and usually sporadically, but it may be a problem in individual herds, particularly in which calves are reared by nurse cows.

### CLINICAL FINDINGS

In cattle the mastitis is severe with fever, profound toxemic shock, weak pulse, tachycardia, and recumbency. The affected quarter is very swollen and the milk is watery, red-tinged, and contains flakes. Disseminated intravascular coagulopathy may cause internal bleeding at many sites. All four quarters may be affected. There is complete cessation of milk flow in affected and unaffected quarters and subsequent fibrosis and atrophy. Newborn calves allowed to suck colostrum from affected cows may die of pasteurellosis.

### Clinical Pathology

Culture of the organism in the milk is necessary to confirm the diagnosis.

### NECROPSY FINDINGS

The disease is not fatal in cows.

### DIFFERENTIAL DIAGNOSIS

Bovine mastitis associated with *Pasteurella multocida* must be differentiated from the many other forms of acute mastitis associated with this species; this can only be done by bacteriologic examination of the milk.

### TREATMENT

In cattle, streptomycin administered by intramammary infusion is effective, but tetracycline is preferred. Recurrence in quarters that appear to have recovered is not infrequent, and response to treatment is often poor.

### CONTROL

The standard control program described later in the chapter should control the disease in cows.

## *NOCARDIA SP.*

Nocardial mastitis is an uncommon occurrence in cattle and is manifested as an acute

or subacute mastitis accompanied by extensive granulomatous lesions in the udder.

## ETIOLOGY

*Nocardia* are aerobic, gram-positive, filamentous, branching rods.<sup>1</sup> *Nocardia* spp. are ubiquitous environmental saprophytes with more than 30 named species.<sup>2</sup> *N. asteroides* can be cultured from the milk of affected quarters, and the disease can be produced experimentally by this organism. The most common species isolated from bovine mastitis are *N. nova* and *N. farcinica*.<sup>3</sup> Occasional cases of chronic mastitis associated with *N. africana*, *N. arthritidis*, *N. asteroides*, *N. brasiliensis*, *N. cyriacigeorgica*, *N. neocaledoniensis*, and *N. puris* have also been recorded.<sup>3</sup>

## EPIDEMIOLOGY

### Occurrence

With rare exceptions, nocardial mastitis in cattle has been recorded as a sporadic infection affecting only one or two cows in a herd. Accidental introduction of the causative bacteria into udders when infusions are being administered may create a herd problem. A large number of cases occurred in Canada from 1987 to 1989 because of intrinsic contamination of a neomycin-containing dry cow formulation with an amikacin-resistant strain of *N. farcinica*.<sup>4,5</sup> *N. neocaledoniensis* was isolated from the quarters of nine dairy cattle in Italy with chronic mastitis; intramammary infection was attributed to inadequate hygiene procedures during administration of intramammary therapy.<sup>2</sup> *Nocardia* is recorded as being a relatively common chronic mastitis in Cuba. Confinement of dairy cattle in muddy pens has been associated with an increased incidence of nocardial mastitis.

### Source of Infection and Mode of Transmission

The bacteria is a common soil contaminant and probably gains entrance to the udder when udder washing is ineffective or udder infusion is not performed aseptically. *Nocardia* can survive in ineffective teat dips and may be spread by their use. The disease is most common in freshly calved adult cows, particularly if infusion of the udder with contaminated materials is performed in the dry period. *N. farcinica* is capable of surviving in mixtures used for intramammary infusion for up to 7 weeks. There is one record of a massive outbreak with many deaths in dairy cattle that was probably caused by the use of a contaminated home-made udder infusion.

### Risk Factors

A sharp increase in isolations of *N. farcinica* in milk samples at veterinary diagnostic laboratories in Canada was related to the extensive use of a particular dry period treatment. Teat dips containing recommended concentrations of iodine or dodecylbenzene

are effective against *Nocardia*, whereas those containing chlorhexidine acetate are not effective. When the dip is contaminated during use it may spread the organism to other quarters and other cows.

### Economic Importance

The disease is a serious one because there is extensive destruction of tissue, loss of production, and occasionally death of a cow. Also, there is a possibility that human infection may occur, because the organism may not be destroyed by usual pasteurization procedures.

## PATHOGENESIS

The inflammation of the teat sinus and lower parts of the gland suggests invasion via the teat canal. Infection of mammary tissue results in the formation of discrete granulomatous lesions and the development of extensive fibrosis, and the spread of inflammation occurring from lobule to lobule. Infected animals are not sensitive to tuberculin.

When infection occurs early, in the first 15 days of lactation, the reaction is systemic with fever and anorexia. At other times the lesions take the form of circumscribed abscesses and fibrosis. There may also be infected foci in supramammary and mesenteric lymph nodes.

## CLINICAL FINDINGS

Affected animals may show a systemic reaction with high fever, depression, and anorexia, but an acute or subacute inflammation is more usual. Fibrosis of the gland and the appearance of clots in a grayish, viscid secretion that also contains small, white particles is the usual clinical picture. The fibrosis may be diffuse but is usually in the form of discrete masses 2 to 5 cm in diameter. Badly affected glands become grossly enlarged and may rupture or develop sinus tracts to the exterior. None of these cases recovers sufficiently to justify retention, and all are eventually culled.

Laboratory examinations of herds in which cases occur may also reveal subclinical cases that have intermittent flare-ups.

## CLINICAL PATHOLOGY

The bacteria can be detected on culture of the milk. Small (1-mm diameter) specks are visible in the milk and, on microscopic examination, these prove to be felted masses of mycelia. Herds containing infected cows have been readily identified by culture of bulk milk samples. A gentamicin–blood culture medium has good selectivity. The normal blood agar plates need to be kept for an extended period of time to detect growth. Colonies may not appear until 72 hours.

## NECROPSY FINDINGS

Grossly, diffuse fibrosis and granulomatous lesions containing pus are present in the

mammary tissue. The lining of the milk ducts and the teat sinus is thick and roughened. On histologic examination the granulomatous nature of the lesions is evident. Metastatic pulmonary lesions have been found in occasional longstanding cases.

### Samples for Confirmation of Diagnosis

- Bacteriology: mammary tissue, regional lymph node
- Histology: formalin-fixed mammary tissue for light microscopy

## DIFFERENTIAL DIAGNOSIS

The appearance of the milk is distinctive, but cultural examination is necessary for positive identification.

## TREATMENT

The disease does not respond well to treatment because of its chronic granulomatous nature. In vitro susceptibility tests suggest amikacin, gentamicin, and neomycin should be effective but will probably need to be administered for 1 to 2 weeks.

## CONTROL

Invasion probably occurs via the teat canal from a soil-borne infection; proper hygiene at milking and strict cleanliness during intramammary infusion are therefore necessary on farms in which the disease is enzootic. Treatment in late cases is unlikely to be of value because of the nature of the lesions, and in affected herds particular attention should be given to the early diagnosis of the disease.

## BACILLUS SP.

*Bacillus* spp. are considered part of the normal microflora of the bovine teat.<sup>1</sup> *Bacillus cereus* and *B. subtilis* are saprophytic organisms and only chance mastitis pathogens; they have been known to cause an acute hemorrhagic mastitis in cattle. *B. cereus* cases are often associated with contamination associated with teat injuries or surgery. The mastitis may also occur in cows at the time of calving and is associated with the feeding of brewers' grains in which the spores of *B. cereus* are present. Some strains of *Bacillus* spp. appear nonpathogenic and the strain isolated from the teat of clinically healthy cattle can change rapidly over time.<sup>1</sup>

The infection is thought to occur during the dry period following the use of dry cow therapy preparations that may have been contaminated with the organism. Infection probably occurs at the time of infusion, but the acute mastitis does not occur until after parturition. *B. cereus* is a spore former and may remain dormant in the mammary gland for long periods, unaffected by the presence of the antibiotic. In one outbreak, 62 of 67 cows infused with a dry cow infusion product contaminated with the organism developed acute hemorrhagic mastitis. Six cows died; the remainder survived but were subsequently culled and slaughtered because of recurrent mastitis, inadequate milk production, and loss of weight.

Clinically, there is peracute to acute mastitis affecting one or more quarters. There is severe swelling and pain and the secretions are red-tinged and serous in consistency. Initially there is a high fever (40°C–41°C; 104°F–106°F) and severe toxemia. Affected cows are weak and quickly become recumbent; death may occur in 24 to 36 hours. Gangrene may occur and, in cows that survive, portions of affected gland will slough out and a chronic relapsing mastitis will persist. Experimentally produced mastitis caused by *B. cereus* causes toxemia, acute swelling of the quarter, and clots in the milk. The mastitis persists in a chronic form, and the quarter eventually dries up.

The organism can be usually cultured from milk samples from affected quarters. At necropsy there is focal hemorrhagic necrosis of the mammary tissue, acute lymphadenitis, and disseminated intravascular coagulation.

Treatment consists of intensive fluid therapy, a broad-spectrum antibiotic intravenously, and vigorous massage and stripping of the affected gland. Intramammary infusion of the most suitable antibiotic determined by culture and sensitivity is indicated, but the results are often not good because of the presence of severe hemorrhage and necrosis and plugging of the lactiferous ducts. Prevention depends on the use of sterile techniques during teat surgery and the use of sterile intramammary infusions and instruments. In problem herds, autogenous bacterins have been prepared but not extensively evaluated. If *B. cereus* infection is identified in the mammary glands of dry cows the recommended prevention program is infusion of each quarter with 750 mg of neomycin and 375 mg of framycetin.

*B. subtilis* is recorded less frequently as a cause of acute mastitis. Infection is characterized by yellow or bloody milk, sometimes with clots, and the cow is febrile.

### **CAMPYLOBACTER JEJUNI**

Only one case of clinical mastitis has been recorded, but the incident is of some importance because of its zoonotic impact.

Infection of the udder by the organism is easy to establish, and the infection is persistent but subclinical for the most part. Other experimental cases have been recorded, and campylobacters that have not been further identified have also been observed in naturally occurring cases. These are characterized by fine granular clots in the milk, very high cell counts, and a transient episode of fever and swelling of the quarter.

### **CLOSTRIDIUM PERFRINGENS TYPE A**

This is a rare form of mastitis characterized by high fever, swelling, and superficial hyperemia of the affected quarter, followed later by gangrene, enlargement of the supramammary lymph nodes, a thin brown secretion containing gas, and subcutaneous emphysema. Early treatment with a broad-spectrum antibiotic can be successful, but advanced cases are uniformly fatal.<sup>2</sup>

### **FUSOBACTERIUM NECROPHORUM**

This is a rare type of mastitis but is likely to have a high incidence in the herd when it occurs. Mixed infections of *F. necrophorum* appear to play an important role in summer mastitis caused by *T. pyogenes* (see section earlier in this chapter). Affected quarters have a viscid, clotty, stringy secretion but there is little fibrosis. No systemic reaction occurs, but treatment with a variety of antibiotics is unsuccessful.

### **HISTOPHILUS SOMNI**

*Histophilus somni* (formerly *Haemophilus somnus*) has caused mild, chronic mastitis, including an acute form with high fever and bloodstained milk and a gangrenous form.

### **LISTERIA MONOCYTOGENES**

Udder infection with *L. monocytogenes* is reported more often in sheep and goats than cattle.<sup>3</sup> However, it is a gram-positive facultative anaerobe that is being recorded with increasing frequency as a cause of bovine mastitis because of the zoonotic importance of the organism in dairy products. Most cases in cattle are subclinical and abnormal milk is rare.<sup>3,4</sup> The SCC is usually greater than 10<sup>7</sup> cells/mL milk. An ELISA and PCR have been used to detect antibody or bacterial antigen, respectively, in milk. One cow in Ireland with clinically normal milk was persistently infected for 6 months with a serotype 1/2b strain.<sup>3</sup> The milking system can be exposed to a variety of *L. monocytogenes* strains, but only a small percentage of these strains are able to persist within the milking system, suggesting that these strains possess factors that promote survival in this

ecological niche.<sup>5</sup> Culture of bulk tank milk samples is an adequate means of locating herds with infected cows. Over a 23-year period in Denmark, the percentage of cows infected with the organism varied from 0.01% to 0.1% and that of herds with an infected cow from 0.2% to 4.2%.

Identifying listeriosis-infected cows is not easy because most infections are subclinical and clinical mastitis is usually mild; the milk is often normal in appearance, but the quarter does lose productivity and the milk carries a high SCC. The disease is characteristically unresponsive to treatment with penicillin, although the organism may be sensitive to the antibiotic in *in vitro* tests. The persistence of the clinical signs should arouse suspicion of *L. monocytogenes* as a cause.

### **MYCOBACTERIUM SP.**

Tuberculous mastitis is described under tuberculosis. Other mycobacteria, especially *M. lacticola*, have been isolated from cases of mastitis in cattle that occur after the intramammary infusion of therapeutic agents in oils. The disease can be reproduced by the intramammary injection of the organism in oil but not when it is in a watery suspension. Subsequent oily infusions exacerbate the condition. Clinically, there is tremendous hypertrophy of the quarter with the appearance of clots in discolored milk, but there is no systemic reaction. Affected animals do not show sensitivity to avian or mammalian tuberculin. No treatment is effective. It is suggested that the treatment of injured teats and quarters with oil-based intramammary preparations is inadvisable because of the risk of them already being infected with mycobacteria.

A mild, acute mastitis, self-terminating and unresponsive to treatment, has occurred in outbreak form. It may be associated with intramammary infusion but is apparently predisposed because of stress and associated with an unidentified mycobacterium.

*M. fortuitum* is encountered rarely as a cause of a severe outbreak of bovine mastitis. Infected quarters are seriously damaged and do not respond to treatment, and affected cows die or are salvaged. The disease can be reproduced experimentally, and affected animals show positive reactions to mammalian and avian tuberculosis and some sensitivity to johnin. Similar experiences are recorded with *M. smegmatis* and *M. chelonae*. The mammary secretion of affected quarters varies from pus to a watery fluid containing flakes, and there is a high milk loss and irreparable damage to quarters. *M. smegmatis* causes hypertrophy of the gland of such proportions that all cases need to be culled. At least 15 different unique mycobacterial species have been cultured from unpasteurized bovine milk in Brazil.<sup>6</sup>

## SERRATIA SP.

*S. marcescens* is the most common *Serratia* species causing mild chronic mastitis in cattle in which swelling of the quarters with clots in the milk appear periodically.<sup>7</sup> *Serratia* mastitis occurs naturally and has been produced experimentally.<sup>7</sup> *S. liquefaciens* has caused a similar mastitis. Most cases are sporadic, but herd outbreaks caused by the use of contaminated sawdust as bedding and inadequate cleaning of the teats before milking may occur. An epidemic in New York state was associated with the use of a chlorhexidine-containing teat disinfectant that permitted the growth of *Serratia* spp.<sup>8,9</sup> Generally, *Serratia* mastitis is not as severe as that caused by *E. coli* or *Klebsiella* spp.

*S. marcescens* is susceptible to a large number of antimicrobials in vitro with the exceptions being penicillin, ampicillin, and cephalixin.<sup>10</sup> Neomycin (2 g initially followed by 3 daily doses of 1 g by intramammary infusion) has provided a satisfactory treatment.

## FUNGI AND YEASTS

A larger variety of fungi and their unicellular form (yeasts) have been isolated from the glands of cattle with clinical mastitis, but the true pathogenic potential of a number of these isolates has yet to be determined.

*Cryptococcus neoformans*, the yeast that causes human cryptococcosis, has caused acute mastitis in cattle and buffaloes. Contaminated infusion material and spread from other infected quarters are the probable sources of infection. Infection in humans drinking the milk is unlikely to occur because the yeast does not withstand pasteurization, but there may be some hazard to farm families. Although there is no systemic reaction, the mastitis may be acute, with marked swelling of the affected quarter and the supramammary lymph node; a severe fall in milk yield; and the appearance of a viscid, mucoid, gray-white secretion. Clinical mastitis persists for some weeks and, in many cases, subsides spontaneously, but in others the udder is so severely damaged that the cow has to be slaughtered. Systemic involvement occurs rarely. At necropsy, there is dissolution of the acinar epithelium and in chronic cases a diffuse or granulomatous reaction in the mammary tissue and lymph node. Similar lesions have been found in the lungs.

Many other fungi, including *Candida* spp., *Saccharomyces* spp., *Pichia* spp., and *Torulopsis* spp. have also caused mastitis in cattle. A survey of 91 bovine cases of fungal/yeast mastitis in the United States showed that 78% belonged to *Candida* spp.; this genus contains at least seven different species that have been isolated from the bovine mammary gland.<sup>11</sup> Infection is probably introduced by contaminated intramammary

infusions or teat cup liners. Establishment of the infection is encouraged by damage to the mammary epithelium and stimulated by antibiotic therapy; for example, *Candida* spp. use penicillin and tetracyclines as sources of nitrogen.

A fever (41°C; 106°F) is accompanied by a severe inflammation of the quarter, enlargement of the supramammary lymph nodes, and a marked fall in milk yield. The secretion consists of large, yellow clots in a watery supernatant fluid. Lesions are limited to the walls of the milk cistern, and there is no invasion of the mammary gland itself. Usually the disease is benign and spontaneous recovery follows in about a week.

*Trichosporon* spp. can cause mastitis in cattle and is manifested clinically by swelling of the gland and clots in the milk. The infection rate is low, and the fungi disappear spontaneously. Experimental transmission of the disease has been effected. In cases of infection by *Aspergillus fumigatus* or *A. nidulans* there are multiple abscesses in the quarter. These are surrounded by granulation tissue, but the milk ducts are generally unaffected.

**None of these infections responds well to antimicrobial therapy** but treatment with iodides, either sodium iodide intravenously, organic iodides by mouth, or iodine in oil as an intramammary infusion, might be of value. A number of drugs, including cycloheximide, nystatin, polymyxin B, neomycin, and isoniazid, have been tested for efficiency against mastitis in cattle produced experimentally by the infusion of *C. neoformans* but did not alter the clinical course of the disease. Merthiolate (20 mL of a 0.1% solution) as an infusion daily for 2 to 3 days is reported to have a beneficial effect if administered early in the course of the disease. Actinomycotic agents tested in vitro against fungi, mostly *Candida* spp., from cases of mastitis showed sensitivity to clotrimazole, nystatin, polymyxin, miconazole, and amphotericin B, and least sensitivity to 5-fluorocytosine. Miconazole (200 mg as an intramammary infusion administered a total of 8 times at 12-hour intervals) was not effective in treating dairy cows with moderate to severe clinical mastitis.<sup>12</sup> Sulfamethoxypyridazine given parenterally (22 mg/kg BW for 2–3 days) has resulted in more than 50% clinical cures in quarters infected with *C. krusei*. A case of mastitis caused by *A. fumigatus* has been successfully treated by concurrent intraarterial injection and intramammary infusion of 100 mg of miconazole at each site. Clinical signs included fever, anorexia, and depression; a hard, swollen, hot gland with clots in the milk; and a negative response to treatment with intramammary antibiotics.

## ALGAE

The only known plants that cause infectious diseases in animals are unicellular round to

ovoid colorless algae in the genus *Prototheca*, which lack chlorophyll.<sup>13</sup> *Prototheca* is ubiquitous in the environment. It is a zoonotic disease that can be transmitted to humans when they ingest milk from infected cows.

*P. zopfi* and *P. blaschkeae* have been identified as causes of chronic bovine mastitis.<sup>14,15</sup> *P. zopfi* consists of different biotypes based on biochemical and serologic grounds, and all clinical and subclinical mastitis isolates are genotype 2,<sup>13,16–19</sup> or genotype 3, now renamed *P. blaschkeae*. Extremely strong herd-level risk factors identified associated with the presence of *Prototheca* in composite milk samples were intramammary infusions with a nonintramammary formulation (OR = 136.8), the use of a dry cow internal teat sealant (OR = 34.2), or the use of a dry cow external teat sealant (OR = 80.0).<sup>20</sup> These high OR estimates support the presence of a causal effect between poor teat hygiene practices and intramammary infection with *Prototheca* spp. Reduced milk yield, large white clots in watery milk, and induration of the affected quarter may be the only clinical signs. Cases of this disease are usually sporadic, but one severe outbreak is recorded. Experimental transmission of the disease causes a progressive pyogranulomatous lesion in the gland, and the organism can be isolated from draining lymph nodes. *Prototheca* spp. are commonly isolated from animal environments, particularly mud and standing water.

*P. zopfi* strains isolated from mammary glands are resistant to many antimicrobials, but are susceptible to kanamycin, gentamicin, amphotericin, and ketoconazole.<sup>19</sup> Treatment is usually unsuccessful, and affected cows should be culled; because of a high prevalence rate in many affected herds the loss to the farmer can be considerable.

Control measures should focus on implementing good hygiene practices at milking and identifying environmental sources for contamination. Iodine teat dip concentrations (0.16%–0.63%) and sodium hypochlorite teat dip concentrations (0.04%–0.16%) were effective in killing *Prototheca* in one study<sup>21</sup>; another study identified minimal microbiocidal concentrations of 0.3% to 1.3% for iodine and 0.005% to 0.020% for chlorhexidine.<sup>22</sup> *Prototheca* can form biofilms, even on stainless steel, and this may facilitate their persistence in the dairy environment.<sup>23</sup> Bedding type appears to impact growth of *Prototheca* spp.,<sup>24</sup> but the recommended strategy of housing cattle on clean dry bedding should decrease the risk of mastitis caused by *Prototheca* spp.

## TRAUMATIC MASTITIS

Injuries to the teats or udder that penetrate to the teat cistern or milk ducts, or involve the external sphincter, are commonly followed by mastitis. Any of the organisms that cause mastitis may invade the udder after

such injury, and in such cases mixed infections are usual. All injuries to the teat or udder, including surgical interference, **should be treated prophylactically with broad-spectrum antibiotics.**

## Control of Bovine Mastitis

Improvement in udder health has been a major initiative of the dairy industry for over 50 years. The thrust of these efforts has been on the implementation and use of management techniques to limit the spread of major mastitis pathogens, reducing the quarter infection rate. Detailed mastitis control strategies have been outlined and promoted by the National Institute for Research in Dairying (NIRD) and the NMC ([www.nmconline.org/](http://www.nmconline.org/)). With proper implementation, these programs result in a dramatic decrease in the prevalence of common contagious mastitis pathogens. Herds that have successfully implemented a comprehensive mastitis control program also need to develop strategies to control infection with environmental organisms, as well as using an effective monitoring system for new infections. Achievement of excellent udder health for the production of high-quality milk is a realistic and important goal for all aspects of the dairy industry.

The adoption of effective mastitis control programs has often been less than desirable, even with extensive research validation of

the recommended control practices and with major extension efforts at both national and local levels. The reasons for this slow adoption of proven mastitis control strategies are not well documented, even though producers look to the veterinary profession for information on mastitis and its control. Veterinarians usually become involved in mastitis control in one of the following circumstances:

- The herd is experiencing a higher than normal incidence of clinical cases.
- The milk processing plant reports a higher than permissible total bacterial count or bulk tank milk SCC.
- A farmer who is not performing the standard program of postmilking teat dipping and dry period treatment asks for advice—either as a single mastitis control program or, more probably, as part of a herd health management program.

The procedure is the same in all these situations, and any variation is in terms of speed and intensity. It consists of an assessment of the herd's mastitis status and the implementation of a recommended mastitis control program.

### Udder Health Improvement

The benefit of an integrated mastitis program is improved udder health; this improvement is progressive and can usually be observed within a few years after implementation at the herd level. Methods now exist to control contagious pathogens and reduce the bulk tank milk SCCs to below 400,000 cells/mL. With good management, the incidence of clinical mastitis can be kept low (7–21 cases per 100 cows per year) by culling any cow with chronic or recurrent mastitis and paying great attention to housing and management standards.

Although the rate of contagious mastitis has been decreased with implementation of an integrated mastitis program, the rate of infections and the incidence of mastitis associated with environmental pathogens such as *S. uberis* and the coliform bacteria have not decreased. Approximately 65% of clinical cases are now caused by environmental pathogens. Organisms prevalent in the cow's environment currently cause the most costly types of mastitis in the United States.

### Economic Benefits, Incentives, and Penalties

Mastitis is one of the most costly diseases in dairy herds. Some surveys indicate that the cost incurred by producers because of clinical mastitis is much higher than the cost of prevention. An integrated mastitis control program has always been an excellent investment for the dairy farmer, with a revenue to cost ratio of approximately 6:1; most of the additional revenue is from increased milk production.

Differential payments to farmers for milk quality are also an **economic** incentive to adopt a control program. The widespread adoption of bulk tank milk SCCs as a measure of milk quality, and the adoption of payment schemes of increasing severity, has stimulated farmers to reduce their cell count. Many milk marketing cooperatives have established both penalty and incentive programs based on bulk tank milk SCC and total bacterial counts as global measures of milk quality.

### Requirements

The requirements for a successful mastitis control program include a willing farmer, a capable diagnostic laboratory, an enthusiastic and knowledgeable veterinarian, a record keeping system, adequate milking machinery, and adequate housing facilities.

The farmer must have health and production goals and be willing to achieve them by making a commitment to invest the resources to control mastitis. Wide variations in the costs of controlling and monitoring mastitis in herds are evident because of lack of client compliance with accepted recommendations for mastitis control. There are also variations in the level of mastitis control procedures adopted by producers that affect the success of a program. Lack of adoption may result from a lack of awareness of the economic returns from a complete program, adoption of a new practice only in response to a problem, or competition for liquid financial resources from other aspects of the enterprise.

The veterinarian must be knowledgeable about all aspects of mastitis and be willing to invest the time and effort required to provide sound advice based on the health and production information obtained from monitoring the herd. A data recording system that records all the udder health and production data and the milk quality of each cow and the herd on a regular basis is a vital requirement. A diagnostic laboratory or milk recording agency that provides regular SCCs of individual cows is necessary to monitor udder health. The milking machine and the housing facilities must be adequate for the size of the herd. Farmworkers must be aware of the health and production goals of the herd and adhere to the principles of mastitis control.

## OPTIONS IN THE CONTROL OF MASTITIS

The broad options for control are either eradication or decreasing the infection rate, either by legislative control or implementing a voluntary program.

### Eradication

Complete eradication of bovine mastitis from a herd or geographic region is not a practicable target in most circumstances. The exception is mastitis caused by *S. agalactiae*,

which can be eradicated from individual herds by a blitz antibiotic technique. The difficulty in attempting to eradicate mastitis is that the contagious causes of mastitis, *S. agalactiae* and *S. aureus*, are so contagious, and the sources of infection so widespread, that adequate quarantine would be very difficult to maintain. In the case of *S. aureus* there is the additional difficulty of eliminating the infection from its intracellular sites in mammary tissue. The environmental infections, especially *E. coli*, pose an even greater problem. They are so ubiquitous that reinfection would be almost immediate in cows housed in economically practicable surroundings.

### Decreasing the Infection Rate

This is a practicable proposition; the degree of limitation is dependent on the need to maintain cost-effectiveness. One of the virtues deriving from this necessity is the concept that subclinical mastitis causes a continuous low-level leukocytosis in the milk that acts as a protective mechanism against other infections. Present-day knowledge about immunity in the mammary gland suggests that control programs that reduce milk SCCs to unrealistically low concentrations may reduce the gland's resistance to clinical mastitis. Correspondingly, the complete elimination of common udder pathogens such as *S. agalactiae* and *S. aureus* is thought to increase the susceptibility of the udder to environmental pathogens, especially coliform bacteria. Another relevant example is the commonly encountered minor pathogen *C. bovis*, which may be a significant microbial agent in maintaining the resistance of udders. The mastitic effect of this organism is too low to warrant specific action, but the infection rate with major pathogens is significantly lower in quarters that harbor *C. bovis* than in those that do not. An intensive program to disinfect udders could well eliminate *C. bovis* and increase susceptibility to other pathogens. *C. bovis* is likely to be more important where cows are housed, or confined in straw yards, and therefore more exposed to teat contamination with coliforms. The question of whether it is better practice to maintain some level of bacterial infection with innocuous organisms in the udder as a protection against more damaging pathogens, rather than to attempt complete bacterial sterilization, is still unresolved. For now it is generally agreed that decreasing the infection rate is the appropriate target.

### Legislative Control

Mastitis does not lend itself to eradication (as set out under the section Eradication), so legislative control of the disease is not widely implemented. Norway has implemented national control of mastitis, starting with a requirement in 1975 that records of mastitis treatments were to be maintained. This was

followed by implementation of the Norwegian Mastitis Control Program in 1982.<sup>1</sup>

### A Voluntary Program

Most of what is done in mastitis control in dairy herds is through voluntary involvement by producers in programs aimed at reducing the incidence of mastitis and maintaining the infection rate at a low level. The justification for control of the disease is purely economic, and a control program must therefore be based on its applicability on each individual farm. Area or national control can only be in the form of providing incentives by educational and laboratory assistance to individual farmers who wish to participate. The value of a mastitis awareness program, and the part played by the two-way flow of information between farmers and the program operators, is most apparent when an area campaign is conducted by a government or industrial sponsor. Once a control program is in place it is customary for milk processors, aided in some places by government agencies, to encourage participation by paying incentives for bulk tank milk with low SCCs or bacteria counts, or refusing to accept milk for processing or, in some cases, refusing to transport milk that does not satisfy statutory requirements. This could be the first step in incorporating the program into planned health and production programs that promote mastitis control and maintenance of milk production at financially optimal levels.

Mastitis infections in beef cattle herds are currently at too low a level for a mastitis control program to be financially advantageous.

## PRINCIPLES OF CONTROLLING BOVINE MASTITIS

### DYNAMICS OF INFECTION

The principles of a bovine mastitis control program are based on changing the dynamics of infection, which are as follows:

- **Prevalence of infection is a function of the rate of new infection minus the rate of elimination**
- **Rate of new infection is a function of the level of exposure times the number of susceptible quarters**
- **Rate of elimination is a function of the number of infections times the efficacy of treatment plus spontaneous cure**

Successful control occurs when the level of infection is held low or is decreased, either by preventing new infections or eliminating existing infections.

The dynamics are not, however, so simple in reality. They vary with the susceptibility of the individual animal, which changes with **age and stage of lactation** (Fig. 20-6) and is **season dependent**. The dynamics may vary with the pathogens involved, and the relative importance between herds can be very considerable and also vary with time. The

duration of infection may be extremely different for different pathogens. *E. coli* causes mild to severe acute clinical disease but usually self-eliminates quickly; it is rarely found in subclinical infections. *S. agalactiae* and *S. aureus* are very persistent, and *S. aureus* responds poorly to treatment. The rate of elimination and the persistency of these pathogens are highly variable. Similarly, there can be large variations in the rate of new infections, which is closely related to the identifiable risk factors, including rate of teat contamination, mechanisms aiding teat penetration, and effectiveness of establishment and growth of bacteria in the mammary gland.

The success of a control program can be measured by the decrease in level of infection and the speed with which this is achieved. The farmer must be able to appreciate progress within a year to remain enthusiastic about application of the methods. The level of infection can be controlled significantly by lowering the rate of new infections, but the speed of change really depends on the duration of the infection and is thus related more to the rate of elimination. No control procedures are available to prevent all new infections, and only culling of chronically infected cows is absolutely successful in eliminating infections. Control schemes therefore require both prevention and elimination to give optimal effect, and that optimum will vary with each pathogen.

The specific components of a mastitis control program must be devised to fulfill three basic principles: (1) **eliminate existing infections**, (2) **prevent new infections**, and (3) **monitor udder health**.

### 1. ELIMINATE EXISTING INFECTIONS

The control program must reduce the duration of infection in the cows. Antimicrobial therapy during the dry period remains the best method of achieving this objective (Fig. 20-7). Treatment during lactation can be useful to eliminate some existing infections, depending on the causative agent, and is often effective in resolving clinical mastitis episodes. Culling of chronic cases that are not eliminated with dry period treatment is also used to remove the most persistent existing infections. Further study needs to focus on development of treatment protocols and on cowside identification of the causative bacterial agent.

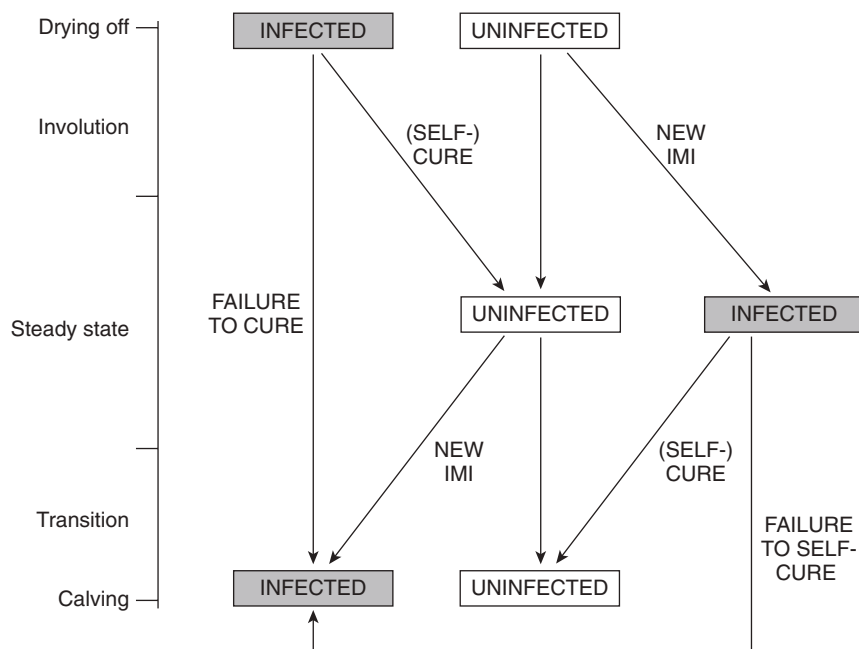

### 2. PREVENT NEW INFECTIONS

The control program must reduce the rate at which new infections occur. The dipping of all teats in an effective teat dip after each milking is the best method to reduce the new infection rate. Ensuring that the milking machine is functioning properly and used correctly will result in less spread of infection. The dry period is the time of greatest risk of new infection, and blanket dry cow

**Fig. 20-6** New infection rate in cows by stage of lactation. (Reproduced with permission from Natzke RP. *J Dairy Sci* 1981;64:1431-1441.)

**Fig. 20-7** A summary of the possible outcomes for individual quarters during the dry period. IMI, intramammary infection. (Reproduced with permission from Bradley A, Barkema H, Biggs A, et al. *Dairy Herd Health*, Wallingford, UK: CAB International 2012;144.)

therapy or application of an internal teat sealant is efficacious in preventing new infections during the dry period. Environmental and nutritional management have also become important for the prevention of new infections. Specific recommendations for methods of reducing new infection rate depend on the predominant pathogen in the herd.

A novel method for preventing new infections during the second half of the dry period and the start of lactation is to administer polyethylene glycol-conjugated **bovine granulocyte colony-stimulating factor (bG-CSF)** subcutaneously approximately 7 days before the anticipated calving date followed by a second injection immediately after calving. Administration of **bG-CSF** markedly increased the blood neutrophil count and decreased the number of clinical mastitis episodes caused by environmental pathogens.<sup>2</sup>

### 3. MONITOR UDDER HEALTH STATUS

An ongoing program to monitor the udder health status of individual cows as well as the herd is needed to evaluate the effectiveness of the control efforts. Monitoring methods should also assist with specific decision making, such as optimized treatment protocols or culling. In the five-point mastitis control programs recommended by the NIRD and the NMC, monitoring was not emphasized. As udder health status improves, and as milk quality premiums and penalty programs become meaningful, there is a need to continuously monitor udder health.

### MASTITIS CONTROL PROGRAMS

A major step forward in mastitis control occurred in 1970 with the publication of the results of controlled field studies performed by the NIRD. The **five-point control plan** was based on attacking the key areas in the dynamic processes of mastitis, and the individual components of the plan were evaluated as efficacious by field testing in dairy herds. Its success has been well documented. **The five-point plan has been highly successful for the control of contagious mastitis but is not adequate for the control of environmental mastitis.** The plan depends heavily on the motivation, education, and financial commitment of the milkers and the herd owner to achieve good and consistent results.

The five-point mastitis control program is as follows:

1. Udder hygiene and proper milking methods
2. Proper installation, function, and maintenance of milking equipment
3. Dry cow management and therapy
4. Appropriate therapy of mastitis cases during lactation
5. Culling chronically infected cows

Five additional management practices are recommended to make a **10-point mastitis control program**, which includes emphasis on an appropriate environment, particularly for the control of environmental mastitis, and the keeping of records, monitoring udder health, and setting goals for udder health status.

6. Maintenance of an appropriate environment
7. Good record keeping
8. Monitoring udder health status
9. Periodic review of the udder health management program
10. Setting goals for udder health status

The 10-point mastitis control program satisfies the basic needs of the farmers, which is an essential prerequisite in the implementation of a voluntary program. The program is profitable, within the scope of the producer's technical skill and understanding, capable of being introduced into current management systems, and encourages farmers to continue the program by rapidly reducing the occurrence of clinical mastitis and the rejection of milk by milk processors on the grounds of quality. Very helpful checklists that include all components of the recommended mastitis control program are available for North America and international dairy enterprises ([www.nmconline.org](http://www.nmconline.org); accessed July 2016).

The components of the recommended 10-point mastitis control program are the same for all situations. The exact level of severity at which it will be implemented depends on its cost-effectiveness; higher milk and cattle prices will justify higher financial inputs. The program has the virtues of simplicity, profitability, and widespread applicability, and most countries with a significant dairy industry have devised their own variant of it to suit their own local needs, especially the targets of freedom from infection and other quality-control criteria. The 10-point program was designed primarily for the control of the common contagious mastitis pathogens and may encounter difficulties unless measures to control the environmental infections receive special attention.

## TEN-POINT MASTITIS CONTROL PROGRAM

### 1. UDDER HYGIENE AND PROPER MILKING METHODS

The principles of a proper milking procedure include:

- Premilking udder hygiene
- Stimulation of milk letdown
- Efficient removal of the milk
- Postmilking teat disinfection

These principles are important for controlling the spread of contagious pathogens and for preventing new intramammary infections associated with environmental organisms. There is much farm-to-farm and region-to-region variation in how these

milking procedures are applied. Milking methods are often taught to milkers by observation of the current methods used on the farm, and milkers are seldom objectively evaluated, especially in family farm operations with only one or two farm employees.

Several important steps are necessary in establishing a milking management routine, including the following.

### Establish and Maintain a Regular Milking Schedule in a Stress-Free Environment

A management routine using twice-daily milking should strive for a 12-hour interval. In the same way, an 8-hour interval between milkings is necessary for thrice-daily milking. The milking schedule is obviously less important with robotic milking. Consistency is as important as maintaining these exact intervals. Any influence that may add stress to the milking environment is to be avoided. For example, harsh crowd gates, rough handling, barking dogs, and people shouting can be associated with epinephrine release, which will counteract the effect of oxytocin for efficient milk letdown.

### Ensure That Teats Are Clean and Dry Before Milking

The major objective of premilking udder preparation and teat sanitation is to reduce the microbial population of teat skin, particularly at the teat end. The aim of these techniques is to minimize the probability of new intramammary infection and have good milking performance. Milking time hygiene is extremely important because of the potential interaction between milking machine function and the microflora of teat skin. The incidence of intramammary infection is highly correlated with the number of mastitis pathogens on the teat end at milking.

### Udder Hygiene Score

An udder hygiene scoring system has been developed, with the udder viewed from behind. Score 1 is an udder free of dirt, score 2 has 2% to 10% of the surface area dirty, score 3 has 10% to 30% of the surface area covered with dirt, and score 4 has more than 30% of the surface area covered with caked-on dirt. A hygiene scoring system is repeatable and easy to use, but only hygiene scores for the udder and hindlimbs are associated with cow composite milk SCCs.

### Premilking Cow Preparation

Premilking cow preparation is a step in milking management in which there is considerable variability between what is recommended and what is actually practiced. **The goal is to milk clean and dry teats.** Current recommended procedures for premilking udder preparation range from water hose washing and manual drying of teats, to washing teats with a paper towel wetted in warm sanitized solution plus drying with a

single service paper towel, to the use of pre-milking teat dipping in germicide plus paper towel drying. The additional step of premilking teat disinfection (predipping) has been incorporated as part of the milking routine on many dairy farms. It is argued that manual teat washing improves stimulation and the release of oxytocin for milk letdown, in addition to cleaning debris from the teats and teat ends. However, with properly functioning milking equipment, there is little evidence that the manual massage is necessary for good milk letdown. In milking parlors in which handheld spray washers are used, it is important to avoid wetting the udder. Excessive water use can lead to bacterial contamination of the teat cups and to an increase in the incidence of mastitis. In addition to individual paper towels, the use of disposable latex or nitrile gloves is also recommended to minimize the transfer of mastitis pathogens from the milkers' hands to the teats. Gloves that become soiled with organic and fecal material should be replaced.

### Check Foremilk and Udder for Mastitis

Early clinical mastitis can be detected by physical examination of the udder for swelling, heat, or pain, and by using a strip cup or black plate to examine foremilk from each quarter of each cow before every milking. This step has been a standard NMC management recommendation, but the supporting evidence has been inconsistent. The rate of implementation of foremilk stripping (forestripping) is widely variable and depends on the management system used. Forestripping is more common in milking parlor situations.

Checking foremilk has three major advantages:

1. Detection of clinical mastitis (such as the presence of clots and stringy or watery milk), as early as possible: Detection of abnormalities is enhanced if the milk is evaluated against a dark surface such as a black strip plate.
2. Forestripping: This theoretically aids in preventing new infections of the mammary gland by flushing pathogens from the teat streak canal before milking. Bacterial colonization of the teat canal may not represent a problem until the organisms gain access to the teat sinus beyond the rosette of Furstenburg.
3. Stimulation of the milk letdown process: This could be helpful in systems in which minimal cow preparation is used, such as a premilking program consisting of only a dry wipe.

In tie-stall barns, a strip cup is necessary to avoid contaminating the stall bedding or the cow herself. In milking parlors, it is common to use the concrete floor surface for detection of abnormalities in the milk. In either case it is important to recognize the potential for

cow-to-cow transmission of pathogens by milk contact from one teat to another. For this reason, forestripping must be done before the predipping or udder washing step.

Foremilk stripping is often not done in pasture-based dairy industries, such as Australia and New Zealand, because it takes time and slows down the milking process. Moreover, if the clinical mastitis incidence is 2 cases per month per 100 lactating dairy cattle, then in herds milking twice a day, milkers have to forestrip 12,000 teats to identify one clinical case of mastitis. Despite the very low incidence of clinical mastitis detected by foremilk stripping, in seasonal calving herds that are pasture based it is probably helpful to examine the foremilk for the first 2 to 4 weeks after calving, because this is the highest incidence of clinical mastitis in this dairy system.

### Premilking Teat Disinfection

Premilking teat disinfection, more commonly referred to as **predipping**, is used by some dairy producers as a component of a mastitis control program. Premilking teat disinfection in association with good udder preparation and postmilking teat disinfection can further reduce the occurrence of new intramammary infections during lactation. The use of predipping is increasing as the predominant cause of mastitis shifts from contagious pathogens to environmental pathogens. Controlled studies on the effectiveness of predipping indicate significant merit in the use of iodine predipping for the reduction of udder infections caused by environmental pathogens in some, but not all studies. Some studies found that premilking teat dipping with 0.25% iodophor did not reduce the incidence of clinical mastitis caused by environmental pathogens, and the use of 0.5% iodophor plus good udder preparation did not affect the prevalence of infection of coagulase-negative *Staphylococcus* spp., but the rate of clinical mastitis in the control group was 1.38 cases per 1000 cow-days compared with 1.06 cases per 1000 cow-days in the predipped group. The benefit:cost ratio of 0.37 indicated that the benefit of reduced incidence of clinical cases of mastitis did not justify the added expense required to predip the herd. A study in New Zealand with pasture-based dairy cattle found that the addition of premilking chloramine-T teat disinfection provided no benefit to that obtained by postmilking chloramine-T teat disinfection applied as a spray.<sup>3</sup>

Although premilking teat dipping with iodine-based sanitizers may play a role in reducing new intramammary infections, there are some precautions that should be taken. The major concern is the potential for increased iodine residues in milk. Predipping with either 0.5% or 1% iodophor does not significantly increase milk iodine residues if a paper towel is used to dry the teats. Without drying, iodine residues are

significantly increased. In addition, predipping in combination with postmilking teat disinfection may increase the potential for residues.

Implementation of predipping into the cow preparation methods may require significant management changes, such as the drying of teats. Some, or possibly all, of the improvement in udder health associated with the implementation of a predipping program may be attributable simply to the milking of clean, dry teats. Before the commencement of predipping, attaching the unit to wet or dirty teats may have been common. Whatever management methods are adopted on a particular farm, premilking hygiene and udder preparation can have a significant effect on milk bacterial counts and on the incidence of mastitis. In summary, the current evidence supports the use of premilking teat disinfection as a routine procedure in dairy herds in which environmental pathogens are the predominant cause for mastitis. A 2008 survey in the United States indicated that the most commonly used germicidal predip formulations were iodine (60%), chlorhexidine (12%), unspecified (8%), chlorine (7%), fatty-acid based (2.5%), and quaternary ammonium (0.3%).

### Attach the Milking Unit Properly

The milking unit teat cups should be carefully attached to the udder within 90 seconds of starting udder preparation. The milk letdown process that follows the release of oxytocin after udder stimulation is at maximum for 3 to 5 minutes. Some effects of the oxytocin may last up to 8 minutes. It is important to use this physiologic event to its maximum for the most efficient removal of the milk. The proper timing of attaching the milking unit has been shown to shorten milk-out time and increase lactation productivity. However, consistency in the time interval from stimulation to attachment of the unit is as important as the exact time.

When attaching the teat cups, it is imperative to minimize the amount of air drawn into the system. Excessive air inlet could result in vacuum fluctuations, which may predispose to milk aerosol impacts of the teat end and machine-induced infections.

The machine position and support should be adjusted as necessary during milking. This will ensure that quarters milk out properly. The milking unit should hang on the cow as straight and level as possible. Improperly adjusted support could contribute to uneven milk out and to an unbalanced udder on some cows; in addition, there is an increased probability of liner slips and squawking, which in turn will increase the risk of new intramammary infections. The mechanics and importance of liner slips will be discussed with milking machine function later in this chapter.

The use of proper milking machine attachment and adjustment methods affects

the number of milker units that can be efficiently handled per person. With a tie-stall barn pipeline milking system it is recommended that a maximum of three units per person be used. It is unlikely that producers who milk with more than three units in a tie-stall barn are using appropriate cow preparation and milking machine attachment methods.

### Minimize Machine Stripping and Avoid Liner Slips

The majority of milking-machine-induced intramammary infections occur near the end of milking. Liner slips occur with a greater frequency near the end of milking. During a liner slip, air sneaks in between the teat and liner (heard as a squawk), increasing the potential for small droplets of contaminated milk to be propelled backward against the end of the other teats (**teat-end impacts**). Over a sustained period of time, liner slips and milk impacts may result in an intramammary infection.

Machine stripping is the act of putting hand pressure on the milker unit at the end of milking to remove extra milk. Machine stripping is habit forming, and will eventually lead to increased milking time. It also increases the risk of squawking, liner slips, and milk impacts.

### Avoid Overmilking or Removing the Unit Under Vacuum

As soon as a cow is milked out, the vacuum to the milker unit should be shut off, and the teat cups should be removed. The milker unit should gently “fall off” the teats, causing no irritation. This is best performed using automatic take-offs that detect a low flow of milk from the teat end and automatically detach the milking cluster from the udder. Removing the unit under vacuum will cause milk and air to impact onto the teat ends. Overmilking should be avoided to prevent teat-end irritation. The unit should be removed as soon as the first quarter is milked out. The risk of liner slip is also increased during overmilking, but there is little evidence that overmilking will result in an increased rate of intramammary infection, unless liner slips and teat-end impacts occur. The practice of removing teat cups individually is also discouraged.

### Use an Effective and Safe Postmilking Teat Germicide (Teat Dip) After Every Milking

Teat dipping or spraying with a germicidal solution immediately after every milking is an effective milking management practice to reduce the rate of new intramammary infections. **Postmilking teat antisepsis is regarded as the single most effective mastitis control practice in lactating dairy cows.** The prevalence of *C. bovis* in milk cultures usually reflects inadequate teat disinfection, because spread of *C. bovis* is easily

controlled by postmilking test disinfection. Quarters colonized with *C. bovis* usually remain so until treated with an effective dry-cow intramammary formulation. In other words, the prevalence of *C. bovis* infection will usually not decrease for approximately a year after implementing an optimal postmilking disinfection protocol.

Teat dipping or spraying is a simple, effective, and economical means to reduce bacterial populations on teat skin. There is general agreement that the numbers and types of bacteria on teat skin have a direct relationship to the incidence and types of intramammary infections that develop in a herd. An effective teat dip, correctly used, will reduce the incidence of new udder infections by 50% to 90%.<sup>3</sup>

There are several major classes of postmilking teat sanitizer and many available products within each class. The classes of product vary widely in their composition, formulation, and mode of action. Each product should be evaluated for its safety, efficacy, advantages, and disadvantages. The most commonly used teat dips fall into several major classes, with geographic differences in availability. A 2008 survey in the United States indicated that the most commonly used germicide postdip formulations were iodine (69%), chlorhexidine (13%), fatty-acid based (7%), unspecified (4%), chlorine (2%), and quaternary ammonium (0.6%).

### Iodine Formulations

Iodine teat dips are used extensively and marketed in a variety of formulations, ranging from 0.1% to 1.0% available iodine. Iodine formulations are active against bacteria, viruses, and fungi, and ideally they should be used at a minimum 0.5% available iodine concentration. The safety and efficacy of these products are well established, and it is difficult to identify a reason why iodine formulations should not be the preferred choice for postmilking teat antisepsis. They were historically called iodophor teat dips because many contained phosphoric acid, which is no longer the case.

### Chlorhexidine

Chlorhexidine teat dips are also widely used and effective for reducing new infections. They are more efficacious in the presence of organic material than other classes of product. Chlorhexidines have a broad spectrum of antimicrobial activity and excellent persistence on teat skin, but they are minimally effective against viruses and fungi. Commercial preparations are formulated with a dye to make the product visible and with glycerin to minimize teat skin irritation.

### Linear Dodecyl Benzene Sulfonic Acid Products

LDBSA teat dips contain an organic acid and are formulated with emollients. They are generally nonstaining, tolerant of organic

matter, and less irritating than most other products; their efficacy against major mastitis organisms is well established.

### Quaternary Ammonium Compounds

A variety of quaternary ammonium chemicals, in combination with lanolin or glycerin, are available as teat dip germicides and are safe and effective. They are readily broken down in the environment and depend heavily on proper formulation for effectiveness.

### Sodium Hypochlorite

Many dairy farmers prepare their own teat dip by dilution of commercial laundry bleach to a final concentration of 4% sodium hypochlorite. It is effective and extremely low cost. However, these dips are not government approved, have a strongly disagreeable odor, and can be inactivated by organic material. There is also a risk of mixing errors, resulting in the potential for irritation of teats and milkers' hands.

### External Teat Sealants (Barrier Teat Dips)

A goal that has yet to be achieved is development of a barrier teat dip that provides an effective teat sealant for use in lactating cows and withstands environmental contamination but is easily removed with minimal pre-milking udder preparation. Latex and acrylic latex-based products have been developed to act as a physical barrier to the entrance of mastitis pathogens into the udder. These products were aimed at the prevention of coliform mastitis. However, it has proved to be difficult to remove the residual product from teats. Furthermore, the barrier product alone is not intended to be effective against other major mastitis organisms.

External teat sealants have been formulated in combination with disinfectants to provide protection as both a barrier and a germicide. A postmilking teat disinfectant containing 0.64% sodium hypochlorite in a gel formulation was an effective and safe teat dip preparation. However, in experimental studies, barrier teat dips were no more efficacious in preventing new intramammary infections caused by *S. aureus* and *S. agalactiae* than no teat dip or the use of a nonbarrier product. In contrast to their current use in lactating dairy cows, external and internal teat sealants are increasingly applied at dry off (see the section [Dry Cow Management and Therapy](#)).

### Selection and Use of Teat Disinfectants

With the extensive array of commercially available postmilking teat germicidal preparations, producers need some guidelines to make an appropriate selection for use on their farms. Manufacturers of teat dips should provide the producer with documentation of the efficacy and safety of each product. In the United States, teat dip

products must be listed with the Food and Drug Administration (FDA). The FDA regulates teat dips for compliance with label accuracy and manufacturing quality, but efficacy data are not required for registration. In Canada, teat dips must be approved by the Bureau of Veterinary Drugs. This approval process requires extensive data on human safety, animal safety, and the efficacy of each new teat dip submission. Standard protocols have been endorsed for the evaluation of teat dip efficacy under conditions of experimental challenge with mastitis pathogens, as well as under conditions of natural exposure in commercial dairy herds.

In the United States, iodine-based teat dips are the most commonly used product for postmilking disinfection, and an **iodine-based teat dip in 10% glycerin is generally regarded as the gold standard teat dip** against which all other teat dips are compared. Dairy producers should request information on effectiveness when selecting a teat dip. Veterinarians should assist producers with interpretation of the data. There is no evidence that changing teat dips on a regular basis is necessary to prevent the development of resistant mastitis bacteria. Monitoring several measures of udder health status will signal the need for a change in teat dip product. The teat dip selected must be compatible with other chemical preparations used in the milking management system.

Postmilking teat dips can be applied by dipping or spraying. In North America, **dipping has been the most popular method**. However, with the increase in herd size and parlor automation, there is an increase in the use of teat spraying because it is quicker and easier. Spray and dip application of the same product result in equal efficacy, when done appropriately; however, it is easier to do a bad job of teat coverage with spraying than dipping. Under field conditions, the effectiveness of either method will depend on adequate coverage of each teat. A general recommendation is that **as much of each teat should be covered as is possible and no less than the lower half**.

Teat dips should be stored in a cool dry place and not be allowed to freeze. Contamination should be prevented and expiry dates observed. For economic reasons, producers are tempted to dilute commercially available products; however, their effectiveness and safety may not be maintained. **At the end of milking, unused teat dip solution should not be poured back into the original container**. Dipping devices should be cleaned regularly.

In cold weather conditions, precautions should be taken with respect to teat dipping. A high emollient concentration product should be used. Dipped teats should be allowed to dry before cows are exposed to cold and windy conditions. This may be accomplished by allowing the dip 30 minutes of contact time, followed by removal of

excess disinfectant with a laundered dairy cloth or a single-use paper towel. Wind-breaks should be provided for cows that have access to outside areas. These combined strategies will minimize the occurrence of frostbite of wet teats.

### Establish Milking Order and Segregation Programs

In herds with a significant prevalence of contagious pathogens, such as *S. aureus*, establishing a specific milking order may be helpful to limit the rate of new infections. This is a popular veterinary recommendation that is **difficult to implement** because it usually requires massive disruption of the milking procedure. Generally, first-lactation heifers and fresh cows should be milked first. Cows with high SCCs, chronic clinical mastitis, and current clinical cases should be milked last. The maintenance and management of both SCCs and clinical mastitis records becomes important to make milking order programs work.

In larger herds, cows are usually grouped according to stage of lactation and production level. For nutritional management reasons, it is often suggested to have high-, medium-, and low-production groups. In herds with a high prevalence of *S. aureus* mastitis, it has been suggested that the problem of spread would be stopped by simply isolating infected cows and milking them last. In theory, segregation combined with culling and effective dry cow management should allow the prevalence of *S. aureus* to approach zero. However, the change in prevalence of *S. aureus* infection in unsegregated herds compared with herds using a segregated program indicates no significant difference. A more significant decrease in prevalence of *S. aureus* mastitis was found in herds that gave priority to a full milking hygiene program in combination with dry cow therapy and culling. Segregation is not a simple, stand-alone solution to a contagious mastitis problem.

### Disinfect Teat Liners

Disinfection of the milking machine teat cup liners between cows has the potential of limiting the spread of contagious organisms from cow to cow because bacterial populations in liners can be greatly reduced by sanitization. However, there is considerably less documentation that flushing liners will result in major reductions in contagious mastitis problems.

In tie-stall milking barns, **liner disinfection** is a laborious process that involves dipping the claw in a series of solutions. Liners must be put through a rinse, a disinfectant, and another rinse to remove the germicide. The solutions should be kept hot and replaced when they become overly contaminated. Only two liners can be dipped at one time if the milk hose remains connected to the pipeline to avoid an air lock in the claw, which will reduce the disinfection process.

However, if the milk hose is disconnected from the milk pipeline, then all four liners can be dipped at one time. Even with these limitations, dairy herds with intensive management, utilizing individual cow SCCs and culture information, can effectively use liner sanitization to limit the spread of contagious pathogens. Electric hot pails are commercially available to maintain the disinfection solution at a sterilization temperature.

In large milking parlor operations, automatic **backflushing** of milking units between cows is commercially available but expensive to install. In conjunction with automatic take-offs, the claw is flushed with rinse water, followed by disinfectant, and again rinsed, immediately after the unit detaches from a cow. An alternative procedure (**cluster dunking**) involves backflushing the milking units with water until a clear stream is obtained and then dunking the milking units in a bucket containing disinfectant while avoiding trapping of air in the dunking process. Large numbers of pathogens can be removed from teat cups by the backflushing process, but documented reductions in the new intramammary infection rate are not available. For instance, backflushing decreased the numbers of staphylococci and gram-negative bacteria on liners by 98.5% and 99.5%, respectively and caused a small decrease in the number of new infections by *C. bovis* but had no effect on the incidence of new infections by staphylococci, streptococci, or coliforms. Until backflushing has been demonstrated to decrease the new infection rate, the procedure cannot be a routine recommendation.

## 2. PROPER INSTALLATION, FUNCTION, AND MAINTENANCE OF MILKING EQUIPMENT

The milking machine plays an integral role in the efficiency of the operation of a dairy farm, and it has direct contact with teat tissue. It must perform properly and consistently, two or three times a day (or much more frequently in robotic milkers), day after day, year after year. For these reasons, it is important that the milking system is installed according to approved guidelines. Regularly scheduled maintenance should be performed, and machine function should be evaluated by periodic analysis of the system. All persons in the milking management process should thoroughly understand the basic components, function, and operation of the milking equipment. They should also be aware of the significance of regular equipment maintenance and of the importance of good milking techniques.

### Milking System Function and Objectives

The milking system performs several basic functions to achieve its objectives:

- Causing milk to flow from the teat by exposing the teat ends to a partial vacuum

- Massaging the teat in an effort to relieve the effects of a continuous milking vacuum
- Protecting the milk from contamination while it is transported to a storage device, which cools and stores the milk until it can be transported to the processing plant

### Components of a Milking System

To perform the basic functions and to achieve the objective of efficient removal of the milk with minimal opportunity for intramammary infection, milking and milk handling equipment requires three basic components:

- Vacuum system
- Milk pipeline system
- Bulk milk tank for milk cooling and storage

Considerable engineering expertise goes into the proper design, installation, and function of milking equipment. For the purposes of understanding the basic principles of machine milking, a brief description of these three components will be provided.

#### Vacuum System

##### *Vacuum Pump*

The function of milking equipment depends on the creation of a partial vacuum. A **vacuum pump** is used to continuously remove some of the air from the various lines in the milking system. The amount of air removed determines the system vacuum level, which is important for proper function. The vacuum level is monitored using a gauge that is read in either kilopascals (kPa), millimeters of mercury (mm Hg), or inches of mercury (in.Hg). If one-half of the air is removed from the system, then the vacuum gauge will read 50 kPa (15 in.Hg) vacuum. Vacuum pumps are rated on the basis of the volume of air they can move when the intake vacuum is at 50.7 kPa (15.0 in.Hg). Cubic feet per minute (CFM) is the standard air flow measurement used. The CFM rating of a vacuum pump determines the number of milking units that can be used on the system. For example, to operate 6 units, the minimum vacuum pump capacity is 52 CFM.

##### *Vacuum Reserve Tank*

Because the vacuum pump continuously removes a constant amount of air from the system, a **vacuum reserve tank** is placed between the pump and the vacuum supply line. The purpose of this tank is to provide a common site for connecting the vacuum header lines and to provide a reserve of vacuum to help buffer the sudden admission of air into the system. For example, when a milking unit falls off a cow, there should be enough reserve vacuum to maintain the system function. The amount of reserve vacuum needed in a system is a function of pump capacity, pump performance, regulator operation, and the degree of system

leakage. Vacuum reserve tanks are usually constructed of PVC plastic and should not be less than a 75-L capacity.

### Vacuum Regulator

A **vacuum regulator** or controller is an important component of the vacuum system. The function of the regulator is to keep the vacuum of the milking system at a preset level by responding to changing air admissions into the system. The regulator should be located in proximity to, or directly on, the vacuum reserve tank. It should be sensitive to handle a rapid response to changes in vacuum. Servo-diaphragm regulators are the most sensitive style available and are highly recommended. An increase in vacuum pump capacity cannot compensate for poor regulator function. Likewise, a sensitive regulator cannot compensate for a deficiency in pump capacity. The two components must work well together.

It is recommended that two vacuum gauges be installed in the system to monitor the system vacuum. One gauge should be located on the milking vacuum supply line near the regulator. A second gauge is best situated at the far end of the vacuum pulsation line. A portable mercury manometer should be used on a regular basis to calibrate the accuracy of the system vacuum gauges and to make adjustments to the vacuum regulator. The preferred vacuum system installation consists of two header lines from the vacuum reserve tank, continuing to form a completely looped pulsation line. The recommended vacuum lines are 76-mm diameter PVC pipe, adequately supported, and slightly sloped in the direction of air flow and with automatic drain valves. This line allows for attachment of the milking unit pulsators.

### Pulsation System

A properly functioning pulsation system is critical to teat and udder health. The pulsator causes the chamber between the teat cup shell and the liner to alternate regularly from vacuum to air source. Pulsators are either electromagnetic or pneumatic. In an electromagnetic system, all pulsators function together off an electrical signal. An electronic control circuit turns current on and off to the electromagnet. Pneumatic pulsators run off the vacuum system and use air to move a plunger or slide valve to cover and uncover the air passage, producing the pulsating action.

An understanding of the dynamics within the teat cup and the characteristics of pulsation is crucial to ensuring that the objectives of mechanical milking are achieved. The chamber between the teat cup shell and the liner is regularly subjected to a vacuum source, whereas the inside of the liner is under stable milking vacuum at all times. The pulsation cycle involves a milk phase and a rest or massage phase. When air is admitted between the shell and the liner, the liner

collapses around the cow's teat. The collapsed liner has a massaging action on the teat, which is called the **rest** or **massage phase**. Milk does not flow from the teat during this phase. When the pulsator opens, the space between the liner and the shell is exposed to system vacuum. This creates equal pressure on both sides of the liner, causing it to open. The cow's teat end is now exposed to the milking vacuum. This vacuum, in combination with the internal pressure of milk letdown within the cow's udder, causes milk to be drawn out through the teat streak canal. This component of pulsation is called the **milk phase**. The process of milking involves repeatedly opening (milk phase) and closing (rest phase) the teat cup liner.

The **pulsation cycle** is measured by the time, in seconds, for the completion of one milk phase and one rest phase. The **pulsation rate** refers to the number of cycles completed by a pulsator in 1 minute. Pulsation rates range from 45 to 60 cycles per minute. The **pulsation ratio** is the length of time in each cycle that the pulsator is in its milk phase compared with its rest phase. A common pulsation ratio is 60:40, indicating that in each pulsation cycle the teat cup chamber will be milking 60% of the time and massaging the teat 40% of the time. Wide pulsation ratios can speed up milking time but can put undue stress on the teats and teat ends from insufficient rest, predisposing to new intramammary infections.

**Pulsation phase** refers to the method of pulsation for the whole milking unit and is either simultaneous or alternating. In simultaneous pulsation all four teat cups milk at the same time and rest at the same time. With alternating pulsation, two teat cups milk while two teat cups rest, then alternate to complete the pulsation cycle. The alternating action may be from side to side or from front to rear. Alternating pulsation has several advantages. It allows a more uniform milk flow into and out of the claw, which helps to minimize flooding of the claw, resulting in fluctuations in the teat-end vacuum. In addition, front/rear alternating pulsation allows for a wider pulsation ratio on the rear quarters, which encourages a more uniform and timely milk out of all four quarters. For alternating pulsation systems with two different ratios, care must be taken to ensure that air hoses are not reversed when attached to the claw.

Electromagnetic pulsators are unaffected by environmental temperature and can function at a constant preset pulsation rate and ratio. Pneumatic pulsators can be greatly affected by changes in temperature and system vacuum. They require more maintenance and constant checking of the settings. Thus **electromagnetic pulsators using alternating pulsation are most recommended**, particularly for high-producing cows with fast milk letdown.

If a teat cup is not positioned properly on a teat, the liner may slip down the teat and produce a squawking sound. As this is happening, air is entering around the teat into the liner. The entrance of this air changes the system of stable milking vacuum within the claw and the other teat cups. These changes lead to droplets of milk being driven in a reverse direction back at the teat ends of the other teats. These are referred to as **milk impacts**. Repeated teat-end milk impacts, particularly with milk contaminated by mastitis pathogens, can result in new intramammary infections.

### Milk Transport System

Milking parlors and stanchion barn pipelines have similar systems for transporting milk from the cow to the bulk tank. The components of the transport system will be described in the direction of milk flow. The rubber or silicone insert in each teat cup is referred to as a **liner** or **inflation**. The liner should milk cows safely, with a minimal number of squawks from downward slippage, and without the teat cup crawl action of riding up on the teats to the base of the udder. Liner performance depends on many interrelated characteristics of the milking system. **Narrow bore liners are recommended**. Liners must be compatible with the teat cup shell. The most important management consideration with respect to teat cup liners is to **ensure regular replacement, as recommended by the manufacturer**. As a general guideline, natural rubber liners last 500 to 700 cow milkings, synthetic rubber liners 1000 to 1200 cow milkings, and silicone liners 5000 to 10,000 cow milkings. The desired milking inflation replacement interval (in days) can be calculated using the following formula:

$$\begin{aligned} \text{Number of days between changes} &= ((\text{number of cow milkings/set of liners}) \\ &\quad \times (\text{number of units})) / \\ &\quad ((\text{number of cows milking}) \\ &\quad \times (\text{number of milkings/day})) \end{aligned}$$

Other rubber parts of the unit, such as the short air tubes on the claw, should be constantly checked for cracks or signs of wear. These problems could seriously affect air flow and liner pulsation. Proper storage in dark, cool conditions, as well as the correct use of cleaners and sanitizers, can affect the life of rubber parts.

### Milk Claw

The **milk claw** is an important component of the milking unit. The claw is the collection point for milk from the four teat cups and should have adequate capacity to handle peak milk flow without flooding. Each claw should have a means of shutting off the vacuum to the teat end, so that the unit is not removed under vacuum. Most claws have an air vent in the upper half to allow a

predetermined quantity of air into the unit to facilitate milk flow away from the cow and into the pipeline. Claws should routinely be **inspected for cleanliness, plugged air vents, and dented liner connectors.**

A long milk hose is used to carry milk from the claw to the pipeline. The hoses can be made of plastic, rubber, or silicone. **They should be as short as possible,** with an appropriate hose hanger. If the milk hose is crimped or allowed to loop, milk flows will be interrupted, which leads to irregular fluctuations in teat-end vacuum. The milk hose should attach to an inlet located in the top third of the milk pipeline, at the 11 o'clock or 12 o'clock position. Inlets should be self-draining, self-closing, and should not cause milk flow restrictions that would result in irregular teat-end vacuum fluctuations.

### Milk Pipeline

The **milk pipeline** serves two important functions: transporting milk from the cow to the receiver jar and carrying air flow to provide milking vacuum to the teat end. Either glass or stainless steel can be used for milk pipeline construction. The milk line should form a complete circuit and must be rigidly supported from the floor to maintain the appropriate slope. It is generally recommended that **milk lines be installed as low as is practical.** In milking parlors, low pipelines are installed below udder level. In stall barns, high pipelines are used, but they should be no higher than 2 m above the cow platform. Milk moves by gravity through the pipeline to the receiver jar. The milk line must be self-draining and should have a continuous slope from the high point toward the milk receiver jar. The **correct slope** is important for the movement of milk and air during milking and for proper cleaning of the system. In the construction of new tie-stall barns, it is recommended that the foundation, floor, and gutter be sloped toward the milk house end. This will help to minimize pipeline height and to ensure that line slope will facilitate drainage during milking and washing.

Line diameter is another important feature of milk pipeline design. In addition to line slope and the level of herd production, pipeline diameter will determine the number of milking units that a system can handle. Too many units will lead to milk line flooding and a reduction in air flow rate. Slugs of milk moving through the line is an obvious sign of milk line flooding. This problem will have a negative impact on milking time, herd production, and udder health. The recommended minimum pipeline diameter is 51 mm (2.0 in.). At this pipeline size, high-producing herds should not use more than three milking units per pipeline slope. Thus larger pipeline sizes are often recommended for new installations. Pipeline couplers or welds must prevent air leakage into the system.

Milk should flow into the receiver jar in a continuous, unimpeded fashion. When sufficient milk has accumulated, an electronic probe triggers the milk pump to transfer milk from the receiver jar to the bulk tank. A milk filter is inserted into the transfer system to remove coarse impurities that may have entered the line. The receiver jar is connected to the main vacuum supply. A device called a sanitary trap is used to separate the "air-only" portion of the milking system from the "milk-handling" side of the system. The sanitary trap is designed to protect the vacuum supply from potential damage caused by the chemical cleaning and sanitizing solutions used to clean milk pipelines.

A milking system should have the capability of measuring the amount of milk from each cow. In older milking parlor systems, weight jars were often used for this purpose. They allowed for a quick visual means of monitoring individual cow production at each milking, as well as providing vacuum stability to the cow. However, they were expensive and represented a challenge to clean. More recently, milk metering systems have been developed that give an **electronic digital readout of the milk volume produced** at each parlor station. These systems can often be adapted to provide automatic data recording in an on-farm computer system. In stall barn pipeline installations, several types of mechanical milk meters are in use. It is important that any metering system should not be restrictive to the flow of air and milk. These restrictions can cause a drop in teat-end vacuum and the occurrence of irregular teat-end vacuum fluctuations. Increased milking time, incomplete milk out, and new intramammary infections can result.

### Bulk Milk Tank

The bulk milk tank is the vessel used to cool and store raw milk until it is picked up by the bulk milk transport truck. All tanks must be of an approved sanitary design and construction. They must be of sufficient capacity to cool and store up to 3 days of milk production. The cooling capabilities of bulk milk tanks are clearly specified. Appropriate cleaning and sanitizing procedures for bulk tanks are critical to prevent bacterial growth and contamination of raw milk.

### Relationship of Milking Equipment to Udder Health

The milking machine can influence new intramammary infection rates in several ways:

- It may be a carrier of mastitis pathogens from one cow to the next.
- It may serve as a pathway of cross-infection within cows.
- Malfunctioning or improperly used equipment may result in failure to relieve congestion in teat tissue. Eventually, teat-end damage and intramammary infection can occur.

- Abrupt loss of milking vacuum may create changes in air movement of sufficient force to move pathogens past the streak canal defenses. This phenomenon, known as the impact mechanism, was described earlier.

The pathogenesis of new infections related to machine milking probably involves all four of these factors. However, even though the milking system becomes the focus of many herd udder health investigations, there is little evidence that machine factors are of primary importance in most problem herds. It has been difficult to link milking machine factors and prevalence of herd infection, with the clear exceptions being **pulsation failure** and the **impact mechanism**. Mastitis has been difficult to produce experimentally by altering machine function.

Appropriate pulsation is important for sufficient teat-end massage. Although continuous vacuum will remove milk from cows' teats, eventually it will result in excessive congestion, edema, and teat-end damage. An adequate compressive load by the liner on the teat tissue is necessary to relieve the congestion. Mechanical failure of the pulsator, shortness of the liner barrel, and a too-short liner rest phase are the most common examples of pulsation problems. The impact mechanism results from an abrupt loss of milking vacuum. Poor liner design has been shown to increase the frequency of liner slips. During a liner slip, a reverse pressure gradient occurs across the streak canal of the other three teats. Liner design has been shown to be very important in reducing the amount of slippage. In combination with liner slips, the vacuum fluctuations that result from pulsation problems can lead to new intramammary infection.

Even with the myriad of potential machine problems, milking equipment is not usually the major risk factor for poor udder health.

### Maintenance and Evaluation of Milking Equipment

The most important aspect of udder health management related to milking equipment is the establishment of an appropriate evaluation, maintenance, and service schedule. Farm personnel should incorporate an inspection of the equipment into their regular milking process. Many of the problems discussed in conjunction with the description of milking system components can be discovered during this daily inspection. In addition, the producer should have milking equipment serviced on a regular basis. Items such as the vacuum pump, regulator, pulsators, and sanitary trap would be included in this check list. Also included in this inspection will be regular changing of the teat cup liners and other rubber parts. It is common for equipment dealers to schedule a regular visit to each farm client for the purpose of conducting this periodic maintenance schedule and for dispensing

chemical cleaners and disinfectants used in the udder health management program.

A complete milking system analysis should be conducted on a regularly scheduled basis. This regular analysis is perhaps just as important as the initial design and installation of the system. Many dairy cattle specialists believe that a regular independent analysis will ensure proper equipment function. Milking system analysis can be conducted by equipment dealers, government extension staff, veterinarians, or independent technicians. All these individuals need the appropriate knowledge and training. It is essential to use some type of systematic milking system analysis worksheet to record various performance measurements and to identify components requiring service or upgrading. A complete system analysis should be conducted at least once a year, and records should be kept for future reference.

### Robotic Milking

Mastitis control in robotic milking systems has specific challenges related to ensuring that clean dry teats are milked, diagnosing clinical mastitis, and the treatment of cows with clinical mastitis. Additional information is provided in a review article by Edmondson listed in additional reading.

## 3. DRY COW MANAGEMENT AND THERAPY

The proper management of dry cows and late-gestation heifers is an important component of a mastitis control program. The dry period offers a valuable opportunity to improve udder health while cows are not lactating. However, the beginning and the end of the dry period represent periods of increased risk of infection. **The objective of udder health management during the dry period is to minimize the number of infected quarters at calving.** Two of the three major principles of udder health management must be met to achieve this objective. **Infections present at the time of drying off should be eliminated, and the rate of new intramammary infections during the dry period must be minimized.** Thus dry cow therapy has a dual role in eliminating existing infections and preventing new infections during the dry period and has been widely adopted by dairy farmers. If these two principles are followed, udders will be free of infection at calving and can be expected to produce a maximum amount of low-cell-count milk in the subsequent lactation. Intramammary administration of long-acting antimicrobial agents to all cows at drying off remains a routine recommendation.

### Epidemiology of Intramammary Infection During the Dry Period

The development of effective udder health management strategies for the dry period requires an understanding of the epidemiology of intramammary infections in

dry cows. This in turn requires an understanding of the incidence of new infections during the dry period and the types of pathogen involved. Risk factors that affect the susceptibility of dry cows should also be understood.

### Incidence of New Infections

The rate of new intramammary infections is significantly higher in the dry period than during lactation. The greatest increase in susceptibility is during the first 3 weeks of the dry period. In this period, the new infection rate is many times higher than during the preceding lactation as a whole. A second period of heightened susceptibility occurs just before parturition. The reported rates of new intramammary infection in the dry period vary widely. Reasons for these differences include the diagnostic criteria used and the types of organism considered to be major pathogens. There are also important herd-level effects, such as the prevalence of existing infections at drying off and the method of dry off. The average rate of new infections in untreated dry cows is expected to be between 8% and 12% of quarters.

### Types of Pathogen Causing New Infections During the Dry Period

**Contagious pathogens** are transmitted among cows and quarters in association with the milking process. **Environmental pathogens** are primarily contracted from contamination with organisms in manure and bedding. **Teat skin opportunistic pathogens** are present on the teat, particularly the teat end. Contagious, environmental, and teat skin opportunistic pathogens need to be considered in designing mastitis control schemes for the dry period.

Exposure to environmental pathogens is likely to continue throughout the dry period; thus prevention of new dry period infection with environmental agents represents a considerably greater challenge. Herds that have implemented a basic mastitis control program still need to be aware of the importance of preventing environmental infections in the dry period. There are different rates of infection by the various environmental agents as the dry period progresses. For example, infections with environmental streptococcal species, *Klebsiella* spp., and *Enterobacter* spp. occur more frequently early in the dry period. On the other hand, *E. coli* infections tend to occur immediately before calving. Dry cow management strategies need to account for the risk of infection during the entire period from last milking until the next calving.

### Risk Factors That Affect Susceptibility in Dry Cows

Several factors contribute to the variation in susceptibility during the dry period. These factors are included in the following sections.

### Teat-End Protection

The cessation of routine milking-time hygienic practices such as teat dipping allows bacterial subpopulations on teat skin to increase in number and diversity. *S. aureus* numbers are high immediately after drying off, and environmental pathogens are more prevalent on teat skin late in the dry period and at calving time. Teat-end lesions increase the likelihood of intramammary infections during the dry period. A plausible mechanism to explain this association is that teat-end lesions increase the surface area available for bacterial colonization while presenting a variety of environmental niches. For instance, quarters with cracked teat ends were 1.7 times more likely to develop a new intramammary infection during the dry period than unaffected quarters.

The streak canal of the teat is more penetrable by bacteria during the early dry period. The **keratin plug** in the streak canal must form early and completely in the early dry period to prevent penetration and growth of bacteria and decrease the incidence of new intramammary infections. However, this natural internal teat sealant does not form in some cows, and delay in formation is common. For instance, in cows in New Zealand, 45% of teats are open on day 7 of the dry period, and 25% are still open on day 35 of the dry period. Similar results were obtained in North American dairy cows. Quarters that remain open during the dry period are 1.8 times more likely to develop a new intramammary infection than quarters that have developed an effective keratin plug. Internal and external teat sealants are discussed later in this chapter.

Swelling of the mammary gland, an increasing volume of secretion, and leaking colostrum contribute to the high risk of new infection during the prepartum period.

### Resistance Mechanisms Within the Mammary Gland

Throughout the dry period there are marked changes in the composition of mammary gland secretions and in the concentration of protective factors such as leukocytes, immunoglobulins, and lactoferrin. These changes probably influence the variation in susceptibility to both environmental and contagious pathogens.

Substantial evidence exists that innate and acquired defense mechanisms are lowest from 3 weeks precalving to 3 weeks postcalving. This lowered responsiveness includes aspects of systemic and mammary gland immunity that may account, in part, for the increased incidence of peripartum disease. Polymorphonuclear neutrophil function is impaired during the peripartum period and may contribute to the increased incidence of mastitis following calving. Diminished lymphocyte responsiveness around calving has also been observed. The role of the cow in effectively transferring antibodies and cells

to the mammary gland before parturition to ensure high-quality colostrum is also an important function, and this may be affected by prepartum vaccination schedules and the ability of the animal to respond effectively.

#### *Milk Production at Dry Off*

A high level of milk production at dry off increases the incidence of new intramammary infections at calving. It is reasonable to assume that high milk production at dry off will produce a higher intramammary pressure, increasing the likelihood of an open streak canal early in the dry period. High milk production at dry off will also decrease the concentration of protective fractions such as phagocytic cells, immunoglobulin, and lactoferrin, decreasing resistance within the mammary gland. The finding that cows leaking milk following dry off are four times more likely to develop clinical mastitis in the dry period supports the concept that **increased milk production at dry off increases the rate of new intramammary infections.**

#### *Method of Drying Off*

The industry standard method for cessation of lactation (drying off) is abrupt cessation of milking, in which milking stops on the day scheduled for dry off (all cows are usually scheduled to “go dry” on the same day each week) to facilitate administration of dry cow intramammary antibiotics, vaccinations, and vitamin E/selenium injections.

The large increase in milk production over the past 50 years has led to a new challenge; producers are forced to dry off dairy cattle at the end of lactation that have high milk production (>15–20 kg/day). Abrupt drying off of high-producing dairy cattle leads to rapid mammary distention and the leakage of milk that appears to be associated with an increased incidence of environmental intramammary infection. Abrupt drying off of high-producing dairy cattle also results in stress (based on increased fecal corticosteroid concentrations)<sup>4</sup> and behavioral changes, including bellowing, increased standing time looking at the milking parlor (indicating a preference to be milked), and reduced number of lying bouts.<sup>5</sup> Consequently, abrupt dry off of high-producing dairy cattle is increasingly viewed as an animal welfare and mastitis problem, and many producers are interested in effective and practical methods that alleviate stress at dry off.

For decades, the standard recommendation to decrease mammary distention and therefore stress when abruptly drying off high-producing dairy cattle has been to decrease energy intake over 1 to 2 weeks before dry off. In North America in component fed systems, this recommendation is implemented by decreasing the amount of grain fed. In total mixed ration systems, this recommendation is implemented by decreasing the total amount fed when cows are individually housed; however, this

recommendation is impractical in free-stall systems. Other approaches have been a gradual cessation of milking (such as once a day for the last 5 days).<sup>5</sup> Generally, gradual cessation of milking has not provided any significant production advantages, and as a result, abrupt cessation of milking remains the industry standard at dry off, coupled with an immediate change in diet.

A longstanding recommendation has been to decrease water intake at dry off, because this decreases milk production. This practice is rarely undertaken in northern Germany,<sup>6</sup> and it has been discouraged by the New Zealand dairy industry to comply with animal welfare codes. However, water intake is likely to be decreased at abrupt dry off because drinking behavior appears to be closely coupled with milking in dairy cattle and is also dependent on dry matter intake.<sup>7</sup>

#### *Parity*

Older cows are more likely to develop new intramammary infections during the dry period. This increased predilection may be caused by increased milk production at dry off, increased prevalence of abnormal teat placement (increasing exposure of the teat end to pathogens), or increased prevalence of open streak canals because older cows have higher milk production.

#### **Risk Factors That Affect Susceptibility in Heifers**

An increased risk for intramammary infection in the preparturient period in heifers is associated with the presence of *S. aureus* or *M. bovis* in the herd, calving in summer, high herd bulk tank milk SCCs, poor fly control, mastitic milk fed to calves, and contact with adult cows. Other risk factors are increased age at first calving, prepartum milk leakage, blood in milk, and udder edema.

#### **Udder Health Management Strategies for Dry Cows**

##### **Antimicrobial Therapy (Dry Cow Therapy)**

Antimicrobial therapy at the end of lactation (dry cow therapy) has been one of the key steps in mastitis control programs and has become the most effective and widely used control method for dry cows. The efficacy and advantages of antimicrobial therapy are well known. A meta-analysis concluded that the use of effective dry cow products resulted in a 78% increase in the elimination of existing infections,<sup>8</sup> with no detectable difference for pathogen type, including *S. aureus*. An accompanying meta-analysis indicated that dry cow therapy provided significant protection against new intramammary infections caused by *Streptococcus* spp. during the dry period and the first 21 days of lactation, but no protection was observed for new coliform or *Staphylococcus* spp. intramammary infection.<sup>9</sup>

Long-acting antimicrobial preparations have been formulated to **eliminate existing**

#### **infections and to prevent new infections.**

These preparations include benzathine cephalixin, benzathine cloxacillin, and sustained-release formulations of erythromycin, novobiocin, and penicillin. The withholding period for milk from animals treated with these dry cow formulations ranges from 30 to 42 days after treatment. It is important that the label directions are followed carefully for the recommended dosage level, required withdrawal period, storage guidelines, and expiry dates. A general recommendation is that dry cow treatment should never be administered within 1 month of the expected calving date. Single-dose syringe preparations of dry cow antibiotic treatment are recommended. The risk of contamination by environmental bacteria and yeast is much higher for multiple-dose bottles than for single-dose syringes. If bulk containers are used, great attention should be paid to maintaining sterility.

The use of long-acting and short-acting antimicrobial intramammary infusions at dry off have been compared. In some cases, short-acting antimicrobial agents were more effective than long-acting ones in eliminating infections caused by *S. aureus* or treating cows infected with major pathogens diagnosed twice before drying off. Intramammary infusion of cephalixin sodium 15 days prepartum in heifers was effective in reducing intramammary infections during late gestation and reduced the occurrence of residues in milk during early lactation. The milk of heifers that calve less than 15 days after treatment may contain antimicrobial residues.

Intramammary infusion is a widely used and highly recommended procedure for mastitis therapy; however, there is a potential for the introduction of pathogens during the infusion process. Insanitary infusion practices can introduce antibiotic-resistant environmental organisms into the udder. Infection with opportunistic microorganisms, such as yeast or *Nocardia* spp., may cause more extensive udder damage than the original organism for which treatment was being administered. Adequate teat-end preparation and careful dry cow treatment procedures can reduce this risk. Dry cow treatment procedures should be performed as follows:

- Milk out the udder completely.
- Immediately following teat cup removal, dip all teats in an effective teat dip.
- Allow the teat dip to dry. If necessary, remove excess dip from teat ends with a clean single-service paper towel.
- Disinfect each teat end by scrubbing for a few seconds with a separate alcohol-soaked cotton swab. Start with the teats on the far side of the udder and work to the near side.
- Infuse each quarter with a single-dose syringe of a recommended dry cow treatment. Start with the teats on the near side of the udder. Use the partial insertion method of administration into

the teat streak canal. Preferably, a modified infusion cannula should be provided with the treatment product.

- Dip all teats in an effective teat dip immediately following treatment.

The necessity of using appropriate dry cow treatment procedures cannot be overemphasized. An increased incidence of *Nocardia* spp. mastitis has been associated with blanket dry cow therapy, especially neomycin-containing products. However, *Nocardia* spp. were not found as a contaminant of the suspected products. Teat-end preparation by scrubbing with an alcohol-soaked cotton swab was protective against the occurrence of *Nocardia* spp. infection when teats were experimentally contaminated with organisms immediately before drying off. Most commercial dry cow treatment products provide individually wrapped alcohol-soaked cotton swabs for use with each syringe. The use of good teat-end preparation before intramammary infusion needs to be continually emphasized.

The method of intramammary infusion may be important. Partial insertion of the infusion cannula (up to 4 mm) results in fewer new intramammary infections and improved cure rates. The improvement with a short cannula is attributed to fewer organisms being delivered beyond the streak canal and decreased physical trauma to the streak canal. In addition, antimicrobial agents that are deposited within the streak canal should control local infections. Modified infusion cannulas for the convenient use of a partial insertion method of administration are now available for commercial dry cow products.

Another approach to preventing the problems associated with intramammary infusion would be the development of an effective systemically administered dry cow treatment. Preliminary results have indicated improved efficacy against *S. aureus* infections using a systemically administered fluoroquinolone antibiotic (norfloxacin nicotinate).

### Blanket Versus Selective Dry Cow Therapy

Three strategies for intramammary antimicrobial treatment of dry cows are available, although the current recommendation for all herds is blanket therapy:

- **Blanket therapy** (treat all quarters of all cows)
- **Selective cow therapy** (treat all quarters of any cow infected in one or more quarters)
- **Selective quarter therapy** (treat infected quarters only).

Although blanket dry cow therapy is a cornerstone of any mastitis control program, there is some controversy concerning the need to treat all quarters of all cows (**blanket therapy**) or only those quarters or cows requiring treatment. The controversy has gained momentum because the implementation of udder health management practices

has reduced the prevalence of infection and global interest in decreasing the use of antibiotics. As a result, Nordic countries have implemented selective dry cow therapy as part of their national mastitis control program.<sup>10</sup> The major reasons for selective therapy are to

- Avoid the elimination of minor pathogens, which may make cows more susceptible to environmental agents
- Reduce the expense of treatment
- Address increasing consumer concern regarding the routine administration of antibiotics to food-producing animals
- Avoid the possible emergence of antibiotic-resistant organisms

Each of these reasons should be carefully considered in making a decision between blanket and selective dry cow therapy. Selective dry cow therapy is preferable provided that an accurate, practical, and inexpensive method for selecting infected cows is available. This is the major problem with selective dry cow therapy because in most herds the sensitivity and specificity of the test used for selection is not adequate. The majority of economic analysis studies indicate that the optimum return on investment is provided by treating every quarter of every cow at drying off.

As general udder health improves and bulk tank milk SCC remains low, producers question the need to continue dry treatment on all cows and are attracted by a potential reduction in costs for the purchase of dry cow treatment. However, selective therapy requires a decision as to which cows or quarters are to be treated. The sensitivity and specificity of currently available screening tests are inadequate as a basis for decisions concerning selective therapy. The history of the number of episodes of clinical mastitis, lactation number, individual cow composite SCC during lactation and at dry off, CMT results during lactation or at dry off, and even bacteriologic culture toward the end of lactation all result in leaving some infected cows untreated; conversely these result in the treatment of many uninfected cows. An important requirement for large-scale implementation of selective dry cow therapy is the development of a cheap, practical, sensitive, and specific test to identify infected cows. The failure to prevent new intramammary infections during the dry period with the selective approach must also be considered. New infections in the dry period will become increasingly important as contagious pathogens are eliminated from herds. Finally, blanket dry cow therapy reduces new infection rates for quarters from approximately 14% to 7%. The increase in milk production alone resulting from prevention of these new infections provides enough return to offset the cost of treatment for all cows.

The most practical method currently available for implementing selective dry cow treatment appears to be a low SCC on a cow basis at the last milk recording before drying

off, with a low SCC defined as <150,000 cells/mL for primiparous and <250,000 cells/mL for multiparous cows.<sup>10</sup> In a split udder study of 1657 low-SCC cows in the Netherlands, the incidence of clinical mastitis in untreated quarters in the first 100 days of lactation was 70% higher than in quarters infused with a dry cow intramammary product containing 314 mg of potassium benzylpenicillin, 1000 mg of procaine benzylpenicillin, and 500 mg of neomycin sulfate. Clinical mastitis was most commonly caused by *S. uberis*. The SCC at calving and 14 days in milk were also higher in quarters dried off without antibiotics.<sup>10</sup> Despite increased antibiotic use for treating additional cases of clinical mastitis, total antibiotic use was decreased by 85% in low-SCC cows not administered an intramammary dry cow antibiotic.<sup>10</sup> This study highlights the balance the veterinarian must reach between increased incidence of clinical mastitis (and therefore more pain and discomfort) and overall reduction in antibiotic use when a selective dry cow therapy approach is applied using the most practical test.

Information presently available indicates that the general recommendation should be for **routine treatment of all quarters of all cows at the time of drying off (blanket dry cow therapy)**. There is a need to identify important management practices to limit new infections in untreated dry cows and to develop new screening tests to determine which cows should be treated. New environmental management methods and modern information processing capabilities may lead to the development of better selective dry cow treatment programs. These may include the administration of ancillary therapeutic agents. For instance, the intramammary infusion of recombinant bovine IL-2 along with cephapirin sodium at drying off marginally increased the cure rate of intramammary infections associated with *S. aureus*, but not other pathogens, during the dry period compared with the administration of cephapirin only. Interleukin did not affect the incidence of new intramammary infections for any pathogen group. However, the intramammary infusion of interleukin at drying off was associated with an increased incidence of abortion in dairy cows 3 to 7 days after the infusion.

### Factors Affecting the Success of Antimicrobial Treatment of Dry Cows

Despite blanket dry cow therapy, some cows calve with infected quarters and some with clinical mastitis. Several risk factors affecting the results of dry cow treatment have been evaluated. Some of these factors are

- **Number of quarters infected.** With *S. aureus* infections, there is a significant decrease in cure rate as the number of quarters infected per cow increases. Quarters from cows with either three or four of their quarters infected have a very poor cure rate.

- **Age of the cow.** As the age of the cow increases, the probability of *S. aureus* infections being cured by dry cow therapy decreases.
- **SCC before drying off.** The cure rate of *S. aureus*-infected quarters diminishes as the SCC before treatment increases. Controlling for age and number of quarters infected, there was a significantly lower cure rate in quarters with an SCC of more than 1,000,000 cells/mL.
- **Herd of origin.** There is a distinct herd effect on the success of dry cow therapy. The cure rate of *S. aureus* has been shown to be higher in herds with good hygiene and with a low prevalence of *S. aureus* infections at drying off.

There is considerable potential in using individual cow and herd-level information to predict the likelihood of a cure with dry cow therapy. For example, an older cow with three quarters infected with *S. aureus* and a persistently high SCC has a low probability of a cure. Continued development of information management systems to assist with therapy and culling decisions will clarify the expectations of dry cow treatment.

Persistent *S. aureus* infections represent only one of the shortcomings of antibiotic treatment for dry cows. Most dry cow products are formulated for efficacy against gram-positive cocci. These antibiotics are of limited usefulness against gram-negative bacteria. In other words, new coliform infections would not be prevented by this therapy.<sup>11</sup> Even though dry cow products are formulated for sustained activity, the provision of adequate protection during the critical prepartum period is questionable. The persistence of effective levels of antimicrobial agents has been evaluated for various dry cow treatments and depends on the formulation; very few products have persistent activity until the time of calving.

### Internal Teat Sealants

As discussed previously in risk factors for infection in the dry period, **the keratin plug is a natural internal teat sealant** that provides an effective barrier to new intramammary infections. High milk production at dry off increases the likelihood that the streak canal remains open and presumably compromises formation of the keratin plug, increasing the risk of intramammary infection.

A recent promising development in mastitis control has been **exogenous internal teat sealants** that are applied at dry off. The teat sealant product most extensively evaluated contains a heavy inorganic salt (**bismuth subnitrate**) in a paraffin wax base; this product does not have antibacterial properties but acts as a **physical barrier** to ascending intramammary infections. Because it is not an antibiotic use of the product may be permitted on organic dairies in some

countries. The formulation of bismuth subnitrate used has a higher density than milk causing it to sink to the bottom of the teat canal in which it creates a physical barrier. Administration of internal teat sealants alone requires meticulous attention to aseptic technique because it is easy to facilitate transfer of bacteria on the teat end into the gland during infusion.<sup>12</sup>

A meta-analysis of 18 publications concluded that internal teat sealants decreased new intramammary infections by 73% compared with untreated cows and decreased the risk of clinical mastitis after calving by 48% compared with untreated cows.<sup>13</sup> The same meta-analysis also concluded that internal teat sealants combined with antibiotic dry cow therapy decreased new intramammary infections by 25% compared with cows treated with antibiotic dry cow therapy alone and further decreased the risk of clinical mastitis after calving by 29%. The addition of an antimicrobial agent is a logical addition to the bismuth subnitrate internal teat sealant and has been a routine addition to the teat sealant for some years in Ireland. An experimental challenge study in New Zealand indicated that the addition of 0.5% chlorhexidine to the internal teat sealant at dry off increased the protection against intramammary infection after calving.<sup>14</sup>

Dry period length may be a factor to consider when deciding whether to use internal teat sealants, which persist for at least 100 days in treated cattle. As such, internal teat sealants are theoretically more likely to prevent new intramammary infections in cows with long dry periods than infusion of a long-acting intramammary antibiotic because an effective antibiotic concentration after infusion rarely persists longer than 70 days in glandular secretions.<sup>15</sup> However, study results have been mixed on this topic, with dry period length having no impact on the new infection rate or incidence of clinical mastitis in New Zealand dairy cattle administered an internal teat sealant. In contrast, a UK study found in cattle with a dry period length >70 days that the new infection rate was 11% in quarters treated with cephalonium compared with 4% in cows receiving combined cephalonium and internal teat sealant.<sup>16</sup>

Insertion of an internal teat sealant before calving shows promise as a control measure for heifer mastitis. In a New Zealand study of first-calf heifers, infusion of an internal teat sealant at approximately 30 days before calving decreased the incidence of *S. uberis* intramammary infection by 84% and the incidence of clinical mastitis by 68% in the first 14 days of lactation.<sup>17</sup>

Bismuth subnitrate internal teat sealants clearly show promise for the prevention of new intramammary infections during the dry period. However, because **bismuth subnitrate teat sealants do not eliminate existing intramammary infections**, and an

accurate method for determining the infection status of a quarter is unavailable (the exception being milk culture), the recommended application of internal teat sealants requires combined application with intramammary dry cow therapy, with the teat sealant infused immediately after infusion of the intramammary dry cow antibiotic. The teat sealant should not be massaged upward after infusion. This combined therapy is more effective than either treatment alone but may be uneconomical; however, a study conducted on grazing dairy cattle in Australia concluded that the use of combined therapy was likely to be of benefit in herds that had a clinical mastitis incidence of 6% or more in the first 3 weeks of lactation.<sup>18</sup> Widespread adoption of internal teat sealants will be facilitated by development of an accurate low-cost test for determining intramammary infection status at dry off.

It is important that the internal teat sealant does not reach the bulk milk tank. At the first milking after calving, each quarter should be stripped 10 to 12 times and colostrum should be withheld for a minimum of 4 days.

### External Teat Sealants

A longer-standing approach to providing a physical barrier to ascending infections is the use of external teat sealants, which were originally developed for use in lactating cows. The major problem with external teat sealants is the duration of adherence, which is too long for lactating cow use and too short for dry cows. Teat-end lesions and teat length influence the adherence of external teat sealants. Widespread adoption of external teat sealants will require a product that provides prolonged protection but is easily removed at calving.

### Teat Disinfection

Postmilking teat disinfection is a very effective means of reducing new infections in lactating cows. However, the efficacy of teat disinfection in decreasing the incidence of new intramammary infections in the dry period has been discouraging. Daily teat dipping for the first week of the dry period is not effective in reducing *S. uberis* infections. The lack of efficacy of teat disinfection needs to be contrasted to the efficacy of internal teat sealants.

### Intramammary Devices

Intramammary devices have been developed for use in preventing new infections in both lactating and dry cows. However, there is conflicting evidence as to the reduction in infection rate in quarters fitted with these devices, and such devices are no longer being investigated. The incidence of clinical mastitis may be less in cows fitted with these devices compared with control cows, but the prevalence of subclinical infection is unaffected. Intramammary

devices induce a significant increase in postmilking SCC compared with control cows, and test-day SCCs may be higher than in control cows.

### Vaccination of the Dry Cow

Immunization and immunotherapy for the control and prevention of mastitis have been active areas of research. Effective vaccines would have to eliminate chronic intramammary infections, prevent new intramammary infections, or decrease the incidence or severity of clinical mastitis. Currently available mastitis vaccines may reduce the incidence and severity of clinical mastitis but have not eliminated chronic intramammary infections or prevented new intramammary infections. The inability of vaccines to prevent infection may be caused by the wide variety of pathogens, inadequate specific antibodies, or the failure of antibodies to enter the mammary gland before infection. Currently available vaccines should be used as adjuncts to other more effective control strategies.

Vaccines have been developed to reduce the incidence and severity of clinical mastitis associated with gram-negative pathogens. R-mutant bacteria have an exposed inner wall structure (core lipopolysaccharide antigens) that is highly uniform, even among diverse and distantly related gram-negative bacteria. Vaccines containing killed R-mutant bacteria provide broad-spectrum immunity against a wide variety of unrelated gram-negative bacteria. The most commonly used coliform mastitis vaccines are the Rc-mutant *E. coli* O111:B4, known as the J5 vaccine, and the Remutant *S. typhimurium*, both of which are commercially available in the United States. R-mutant vaccines have been efficacious in reducing the incidence and severity of clinical mastitis caused by gram-negative bacteria. More than 50% of large (>200 cows) dairy herds and more than 25% of all dairy herds in the United States are using core lipopolysaccharide antigen vaccines. No protection is provided against environmental streptococci and staphylococci, or the contagious pathogens.

No effective vaccines are currently available for the control of mastitis caused by *S. aureus*, *S. agalactiae*, environmental streptococci, and *M. bovis*.

The use of recombinant bovine cytokines as adjuvants to enhance specific immunity in the mammary gland of cows after primary immunization indicate an enhancement of specific immunity in the mammary gland, which may be effective in mastitis immunization protocols.

### Management of the Environment for Dry Cows

Dry cows should be provided with an environment that is as clean and dry as possible. If this is not feasible in confinement housing, it is probably better to maintain dry cows on pasture. Variations in the load of

coliforms and environmental streptococci in the environment are important predictors of new infection rates. Minimizing the exposure to environmental bacteria will reduce the new infection rate. However, some pasture conditions promote the crowding of cows under shade trees. In hot, humid, and muddy conditions, heavy contamination of such a small area can result in a significant risk of new environmental infections in the dry period. In good weather, it is ideal to hold parturient cows in a clean, grassy area in which they can be observed and assisted if necessary.

In confinement housing systems for dry cows, it is important to provide adequate space, ventilation, bedding, and lighting to ensure cleanliness and comfort. Maternity (calving) stalls should be bedded with clean straw, sawdust, or shavings. Other important procedures for managing the environment for dry cows include adopting an effective fly control program. Clipping the hair on the udders, flanks, and inside the hind legs will help reduce contamination. **The words clean, dry, cold, and comfortable summarize the ideal environment for dry cows.** The words clean and dry also summarize the goal for the teat before attachment of the inflation during milking.

### Nutritional Management of Dry Cows

A nutritionally balanced dry cow feeding program is important to ensure udder health. A role has been suggested for specific nutritional factors in resistance to mastitis, especially over the dry period. Adequate levels of vitamin E and selenium in dry cow rations appear to be important for udder health at calving and in early lactation. This effect may be mediated through enhanced resistance mechanisms. Other vitamins and minerals may be important in udder health, but their role is less well substantiated.

Nutritional management of dry cows is also important for reducing the risk of milk fever, which is an important predisposing factor to mastitis in fresh cows. Appropriate body condition can be achieved by good nutritional management in late lactation. The association between body condition, energy metabolism, and udder health needs further clarification.

### 4. APPROPRIATE THERAPY OF MASTITIS DURING LACTATION

The early recognition and treatment of clinical cases remains an important part of a mastitis control program. Improvements in understanding of the epidemiology, pathophysiology, and response to therapy of various mastitis pathogens have clarified the role of intramammary and parenteral antimicrobial agents for the treatment of clinical and subclinical mastitis during lactation. This was covered extensively earlier in this chapter.

### 5. CULLING CHRONICALLY INFECTED COWS

The final step of the five-point mastitis control program is the selective removal of cows with chronic intramammary infection from the herd. Most producers have interpreted this recommendation to mean that cows with recurrent episodes of clinical mastitis should be eliminated. For example, some herds have established that cows having three or more clinical cases of mastitis in a lactation will be culled (**the popular three strikes and out approach**). However, very little research has been conducted to determine the effect of various culling strategies on herd udder health status and on the incidence of clinical cases.

Nevertheless, culling chronically infected cows meets one of the three guiding principles of mastitis control, namely the elimination of existing intramammary infections. Through the use of available monitoring techniques and the establishment of a defined culling program, a valuable opportunity exists to improve udder health by culling.

Generally, a record of chronic mastitis and severe fibrosis detected on deep udder palpation should be the basis of a recommendation to cull. Culling is an effective and documented mastitis control measure for some specific mastitis pathogens. For example, the removal of infected cows is a key element of the recommended mastitis control program for herds with a high prevalence of *S. aureus* infection. Removal of cows found to be infected with *S. aureus* accounted for more than 80% of the costs involved in the control program. Culling is also important in the control of other mastitis pathogens that respond poorly to antimicrobial therapy. Herds with mastitis cases associated with *M. bovis*, *Nocardia* spp., and *P. aeruginosa* should be aware of the benefits of culling infected cows.

A dairy herd culling program should be based on consideration of the net present value of each cow in the herd compared with the value of a replacement heifer. The net present value depends on the age of the cow, her potential for milk production, the stage of lactation, and her pregnancy status. Factors that determine the likelihood of treatment success, such as pathogen and duration of mastitis, as well as the cost of treatment, also need to be considered in calculating the net present value of the cow with mastitis. After consideration of the relative importance of udder health in the overall herd health management program, additional economic pressure may be applied to cows with a specific udder health status. For example, if an *S. aureus* control program is a major priority in the health management program, additional economic pressure should be applied in removal decisions of cows with known *S. aureus* infections. As health management data collection and

analysis improve in sophistication, decision analysis methods and expert computer models will be used to provide this information automatically.

### Biosecurity for Herd Replacements

Replacement animals may be purchased to increase herd size or to maintain cow numbers following culling. Biosecurity measures must be used to ensure that herd replacements are not infected with contagious mastitis pathogens (specifically *S. aureus*, *S. agalactiae*, and *M. bovis*). However, an economic analysis of the different components of a biosecurity program has not been performed, and it is likely that some components of currently used programs are not cost-effective.

An optimal biosecurity program includes knowing the herd of origin, knowing the cows, and protecting the home herd.

#### Know the Farm of Origin

- Request a bulk tank milk culture from the farm of origin
- Request the following data: 6 to 12 months of bulk tank milk SCC, bulk tank milk bacterial counts, and 6 to 12 months of records for clinical mastitis

#### Know the Cows

When purchasing single or small groups of animals the following prepurchase procedures are recommended:

- SCC and clinical mastitis records for each cow to be purchased
- Results of bacteriologic culturing of quarter milk samples from each cow on arrival (if lactating) or at calving (if late gestation) for *S. aureus*, *S. agalactiae*, and *M. bovis*. Generally, the sensitivity of a single milk culture to detect the presence of intramammary infections caused by *S. agalactiae* is approximately 95%, for *S. aureus* it ranges from 30% to 86%, and for *M. bovis* it is 24%.
- A physical examination of each cow, including udder, milk quality, and teat ends

#### Protect the Home Herd

Consider all purchased animals as potential health risks to the home herd by doing the following:

- Maintain all newly purchased animals in separate or isolated facilities until diagnostic tests for udder health have been completed and there is no evidence of infection that may spread to the rest of the herd (usually <14 day quarantine).
- Evaluate all herd replacements for evidence of antimicrobial residues in milk.
- Milk all purchased animals last or with separate milking equipment until it is

determined that they are free of infection.

- Obtain results of bacteriologic culturing of bulk tank milk samples or string samples for *S. aureus*, *S. agalactiae*, and *M. bovis*; culturing should be done on more than one occasion because the sensitivity of bulk tank milk culturing is not 100%, and is less than 50% for *M. bovis*.

### 6. MAINTENANCE OF AN APPROPRIATE ENVIRONMENT

The multifactorial nature of mastitis has been emphasized throughout this chapter. Intramammary infection results from a complex interaction between the cow, the mastitis pathogens, and the environment. Thus the control of unfavorable environmental influences is extremely important in dairy herd udder health management programs.

Intramammary infection involves exposure of the teat surface to potentially pathogenic microorganisms, entry of the pathogens into the gland via the teat duct, and establishment of the pathogens in the mammary tissue, producing an inflammatory response. Many environmental factors can influence this process of exposure, bacterial entry, and establishment of infection. For example, the type of bedding and manure management can have a great impact on the contamination of teat skin with microorganisms. Housing design can have an impact on the prevalence of teat injuries, which will influence intramammary invasion by mastitis pathogens. Extreme climatic conditions, poor nutritional management, and cow stocking densities will influence the immune system and the establishment of intramammary infection. A comprehensive udder health management program should involve steps to minimize the detrimental influences of the environment.

#### Global Environmental Influences

Worldwide, there are major differences in dairy herd health and production systems. For example, the type of animal used, economics of production, climatic conditions, housing structures, and management methods are widely variable. These differences greatly affect the interaction of cows with their environment, even though the predominant causative organisms are the same under different systems. Thus there are major variations in the relative incidences of different pathogens and in the importance of various approaches to mastitis control.

#### Classification of Environmental Influences

The influences of the total environment can be divided into the following:

- **External environment.** All aspects of the environment outside the housing facilities make up the external

environment. This includes the regional differences in climate, geography, and agricultural tradition. There are also local factors within a region that can have an important influence. These local factors include the topographic features of the land, natural shelters from the climate, and the availability of pasture.

- **Internal environment.** All environmental conditions inside the cow buildings make up the internal environment. The general internal environment includes the type of housing system, temperature, humidity, and air quality. There are also specific internal environmental influences such as stall design, type of bedding, nutritional management, and manure disposal. The milking environment has a major influence through the equipment, cow preparation methods, and approach to general hygiene.

#### External Environmental Influences on Mastitis Control

There is minimal evidence that external environmental factors directly influence the incidence of mastitis; however, the external environment determines the way in which cows are housed, fed, and milked. Through these associations, the external environment can be an important risk factor in problems with udder health in dairy herds.

#### Regional Environment

The climate and geographic features of a region have implications for the prevalence of mastitis. The ambient temperatures and amount of rainfall often determine the types of housing and nutritional program used. Extremely hot or cold conditions interact with other predisposing management factors. In areas prone to severe rainstorms, teats may be exposed to wet or muddy conditions. The soil type, cropping policy, and presence of other industries can also have an indirect impact on the prevalence of mastitis; for example, regions suitable for growing cereal grains will commonly use straw as a bedding material, which may favor the growth of environmental streptococcal organisms. In contrast, dairying areas close to the forestry industries may favor sawdust or shavings as bedding. The use of these materials may influence the incidence of coliform mastitis.

The socioeconomic structure and agricultural policy of a particular region can affect management factors known to influence udder health. These factors determine herd size and labor costs. Large herd sizes necessitated by economic conditions will dictate the housing, feeding, and milking management practices used. More recently, regional policy toward regulation of bulk tank milk SCC levels has had a profound impact on udder health status.

### Local Environment

The local environmental factors such as the topography of the land, the presence of natural shelters, and the type of pasture grown are thought to influence udder health status. However, direct scientific evidence is lacking. One important exception is summer mastitis, which affects nonlactating heifers and cows. This udder infection with *T. pyogenes* is greatly affected by the local environment, probably through the propagation of insects important in its transmission. Protected pastures increase insect populations and can result in a high incidence of infection.

### Internal Environmental Influences on Mastitis Control

The incidence of new intramammary infections can be greatly affected by the management and facilities used in confinement dairying systems. General aspects of the internal environment exert their influence on all cows in the herd, such as the type of housing and milking system. Tie-stall barns pose different environmental stresses from a free-stall system. The air quality and noise levels can have an impact on animal health. The nutrient content of component feed-stuffs can affect disease resistance.

Specific internal environmental factors exert their influence on an individual cow basis. For example, the stall design and tying system affect individual cows differently. Many epidemiologic studies have revealed interactions between udder disease and internal environmental conditions. Most of these studies relate to European tie-stall and seasonal grazing systems. However, the results are generally relevant to most housing and management systems. Some of the most important general and specific influences of the internal environment are as follows.

### Housing

Housing factors account for a great deal of the variation in udder health status between herds. In both tie-stall and free-stall barns, short and narrow stalls are associated with increased incidence of teat tramps and mastitis. An appropriate partition between stalls is beneficial. Stanchions or neck straps with chains can restrict the movement of the cow and increase the risk of teat injury. This occurs especially as cows are rising. In addition, the use of electrical cowtrainers has been associated with an increase in the rate of subclinical mastitis. The use of adequate amounts of a good bedding material will reduce mastitis incidence in both tie-stall and free-stall housing systems. Even though there are reports of specific bedding materials being associated with certain mastitis problems, the use of adequate amounts of properly maintained bedding is beneficial. Straw, shavings, sawdust, sand, shredded newspaper, and other cushion systems have all been used effectively.

The climate and air quality maintained within a building can have a major influence on udder health. Draughty conditions, high relative humidity, and marked changes in indoor temperature over a 24-hour period are factors that contribute to higher mastitis rates. Adaptation to adverse internal environmental conditions may cause stress, which can reduce the cow's defense mechanisms. Indoor climate, especially temperature and humidity, can also account for differences in the concentration of pathogenic organisms to which cows are exposed.

### Nutritional Management

A complex relationship exists between the quantity and quality of feed and udder health status. Improper nutritional management can result in an increase of new intramammary infections, the exacerbation of preexisting chronic infections, and an increase in clinical mastitis. Several mechanisms have been suggested for this association. An improper anion to cation balance in the dry cow ration is a predisposing factor for periparturient hypocalcemia, which in turn increases the risk of new intramammary infections. Feeding programs that result in excessively fat or abnormally thin cows may affect resistance to disease. Also, there is some evidence that feeds high in estrogenic substances may be detrimental to udder health status.

The dietary concentration of some vitamins and minerals may have an important relationship to udder health. Studies have shown that intramammary infection is related to plasma concentrations of vitamin E and blood concentrations of selenium. Dietary supplementation of vitamin E and selenium improved the natural resistance of the mammary gland to infection. Associations between udder health and the levels of vitamin A,  $\beta$ -carotene, zinc, and other nutrients have been proposed but are not well documented.

### Management Approach

Cow supervision, decision making, and general animal care by dairy herd managers may be important epidemiologic factors in the relationship between environment and udder health. For example, lack of consistency in the performance and timing of various herd activities results in decreased udder health status. Irregular intervals between milkings should be avoided.

### General Hygiene

Even outside the milking environment, general hygiene can greatly influence the exposure of the udder and teats to pathogenic bacteria. The degree of hygiene achieved is directly related to the type of housing, the amount of bedding, and the efficiency of manure removal. Worldwide trends toward increasing herd sizes and decreasing labor force necessitate more emphasis on the importance of cow hygiene.

### Udder Singeing

Hair on the udder facilitates the accumulation of fecal material and other organic material that, when wet, can contaminate the teat orifice and result in new intramammary infections, or enter the bulk tank milk vat. Udder hair can be removed by clipping or more quickly by "udder singeing" every 2 to 3 months, which has become popular in parts of North America. A soft yellow flame from a handheld propane torch is held about 15 to 20 cm below the udder to singe the udder hair and the ash brushed away using a gloved hand. Studies have demonstrated that udder singeing results in cleaner udders, but a beneficial effect on decreasing herd SCC, milk bacterial count, or the incidence of clinical mastitis does not appear to have been reported. Appropriate clinical studies documenting the pain and discomfort associated with the procedure do not appear to have been conducted.

### Use of Recombinant Bovine Somatotropin

It has been suggested that the use of bST may increase the incidence of clinical mastitis by an indirect mechanism that acts through increased milk production. Controlled field studies have shown that the use of bST is not associated with an increase in the incidence of clinical mastitis, milk discarded because of therapy for clinical mastitis, or culling for mastitis.

### Environmental Control in an Udder Health Management Program

There is a strong association between herd udder health status and the number of stress factors operating within the herd. It has been proposed that mastitis occurs when stress factors exceed the cow's ability to adapt. It follows that a major objective of an udder health management program should be to limit the number and severity of environmental stress factors.

Veterinarians responsible for udder health management programs should have a good understanding of the importance of environmental management. The three major objectives of environmental control for improvement of udder health are to prevent

- Contamination of the teat end
- Invasion of mastitis pathogens
- Pathogens from establishing in the mammary gland

The important steps in achieving these three objectives have been discussed. For example, an adequate housing system and manure handling are important to limit bacterial contamination of the teats. The prevention of environmentally induced teat injuries will aid in preventing invasion of pathogens into the gland. The producer's approach to cow management, control of the nutritional program, and ensuring that the internal environment is appropriate will all greatly

improve host defense mechanisms and prevent intramammary pathogens from establishing within the gland.

## 7. GOOD RECORD KEEPING

Good record keeping involves the collection of useful data to monitor performance, calculation of appropriate indices, and decision making based on comparison to target levels. For acceptable performance the monitoring process is repeated and the cycle continues. If performance is not acceptable, further evaluation and analysis is performed, and a plan of action is instituted. Once again, the monitoring process carries on and the cycle continues. For many of the health management programs in food animal practice, a limiting factor is the availability of accurate and objective data. With respect to udder health, data have been readily available. Bulk tank milk SCC, individual cow composite SCC, and bacteriologic culture results are all accessible and useful. These data provide the information necessary to monitor udder health status and to make specific health management decisions. However, problems can still exist. Herds with a low prevalence of infection and very low bulk tank milk SCC can still have a high incidence of environmental infections and clinical mastitis cases. Thus an important step in an effective udder health management program is the maintenance and use of mastitis records. The increasing adoption of computerized dairy health management record systems provides an opportunity to make effective use of a clinical mastitis episode and therapy data. Even without a computerized system, manual records for clinical mastitis are easy to implement and use.

### Objectives and Uses of Clinical Mastitis Records

The objective of maintaining computerized or manual records of clinical mastitis episodes is to complete the decision-making capabilities of a mastitis control program. The availability of this information will allow completion of the health management cycle over the entire spectrum of herd udder health situations.

There are several important uses of clinical mastitis records:

- To assess the risk factors associated with clinical mastitis episodes
- To evaluate lactational and dry cow therapy programs

To provide information useful in the evaluation of net present value of individual cows for the purposes of culling decisions. Without the ready availability of accurate data surrounding mastitis events, decisions associated with therapy, culling, and the removal of risk factors are difficult to make.

### Recording Clinical Mastitis Data

There is a limited amount of specific data necessary to make effective use of mastitis

records as a health management tool. The cow identification, date of the clinical episode occurrence, type of therapy used, and the date that milk withholding will be complete are the essential pieces of information. If a manual record system is used, it will be important to add the lactation number, the date of calving, and the most recent test date production. A standard form that calculates the distribution of clinical episodes by lactation number and by stage of lactation is desirable. These are the same distributions often provided with an individual cow SCC report.

### Using Clinical Mastitis Monitoring Systems

Because clinical mastitis is a common event in dairy production, it is ironic that these records have not traditionally been kept. The key to overcoming this hurdle is the regular use of this information for health management decisions. Some of these uses and decisions are as follows.

#### *Cow Versus Herd Clinical Mastitis Problems*

Calculation of the percentage of cows affected in the herd and the average number of clinical episodes per affected cow will aid in determining whether the clinical mastitis is more of an individual cow problem or a herd-level issue.

#### *Probability of Recurrence of Clinical Mastitis in the Same Lactation*

The number of animals with repeat cases of mastitis divided by the total number of clinical cases gives an estimate of the likelihood of recurrence. The same calculation can be made for specific parity groups. This information can be useful to characterize the problem, and for culling decisions.

#### *Stage of Lactation and Seasonal Profile*

If clinical mastitis data are collected consistently over a considerable period of time, potentially useful problem-solving information can be derived. For example, calculating days in lactation at first occurrence can help to identify specific risk factors for new intramammary infections. There is a higher proportion of clinical occurrences during the first few weeks after calving. However, analysis of clinical mastitis records might yield a different stage-of-lactation profile. In these cases, the evaluation of potential nutritional, environmental, or other stress factors would be indicated. There may be different immediate and long-term solutions that should be implemented.

Analysis of clinical mastitis records over several years may identify a significant seasonal pattern, such as the documented seasonal pattern for bulk tank milk SCC data and antibiotic residue violations. Action may be necessary to deal with seasonal

environment and housing problems that impact new infection rates.

### *Days of Discarded Milk*

It is very common for producers to have an aggressive attitude toward the treatment of clinical mastitis. This approach may result in huge economic losses if waste milk is not fed to calves. These losses are largely the result of discarded milk during the clearance of antibiotic residues from treated cows. Calculating the days of discarded milk may suggest that the mastitis therapy program during lactation should be evaluated. Establishment of an appropriate treatment program and careful selection of cows for therapy might significantly decrease the need for discarding milk. In addition, cows that are responsible for a large percentage of the discarded milk should be identified for selective removal. The calculations from mastitis records that can help to clarify these issues include:

- Total days of discarded milk for the herd
- Days of discarded milk per episode
- Days of discarded milk by lactation number
- Accrued days of discarded milk for individual cows

## 8. MONITORING UDDER HEALTH STATUS

An important step missing from early mastitis control programs was the monitoring of udder health status. Although intuitively it appears necessary to chart the progress of any program, it is only quite recently that monitoring has been included as an integral component of udder health management. **Monitoring is now recognized as the third key principle of mastitis control.** The development of objective, inexpensive, and efficient methods of monitoring udder health has made it much easier to complete the health management cycle for this component of herd programs.

The implementation of SCC measurement on bulk tank milk and on individual cow samples has been widespread throughout the major dairy regions of the world. Because SCC is objective and standardized, it can be used to evaluate the progress of regional control programs. This has allowed rapid improvement in udder health compared with most of the other components of dairy health management programs. Regional authorities have established new regulatory limits and targets for milk quality performance.

Implementing an effective system of monitoring udder health involves:

- Monitoring udder health at the herd level
- Monitoring udder health of individual cows
- Use of cowside diagnostic tests

This discussion will emphasize the use of monitoring methods for decision making and problem solving in udder health management programs. Monitoring of udder health should be done at the **herd level** and **individual cow level**.

### Monitoring Udder Health at the Herd Level

The monitoring of bulk tank milk provides the best method to evaluate the overall udder health status of dairy herds and the effectiveness of mastitis control programs. **Herd-level monitors of udder health include bulk tank milk SCC, bulk tank milk bacteriologic culture, and herd summaries of individual cow SCC data.** Analysis of clinical mastitis records is also useful for monitoring udder health at the herd level.

#### Bulk Tank Milk Somatic Cell Counts

Most milk marketing organizations and regional authorities regularly measure SCC on bulk tank milk as a monitor of the milk quality and udder health status of each herd. Many of these agencies use bulk tank milk SCC for penalty deductions or incentive payments. Improvement in bulk tank milk SCC is associated with improvement in other measures of milk quality such as bacterial counts, inhibitor test violations, and milk freezing point. Countries and regions set milk quality targets using this SCC data, with milk being rejected from processing plants when the bulk tank milk SCC exceeds 400,000 to 1,000,000 cells/mL, depending on the country.

Several management practices are associated with low, medium, and high SCC in bulk tank milk. Postmilking teat disinfection and dry cow therapy are most frequently associated with herds with a low bulk tank milk SCC. In herds with a low bulk milk SCC, more attention is given to hygiene than in herds with a medium or high bulk tank milk SCC. Cubicles, drinking buckets, and cows are cleaner in herds with a low bulk tank milk SCC. Cleaner calving pens and cubicles for herds with low bulk tank milk SCC coincide with the observations that bedding for lactating cows and in maternity pens is drier for herds with a low bulk tank milk SCC. In herds with a high bulk tank milk SCC, a higher percentage of cows are culled because of a high SCC.

The incidence of clinical mastitis in dairy herds may not be different among those with low, medium, and high bulk tank milk SCC. However, clinical mastitis associated with gram-negative pathogens such as *E. coli*, *Klebsiella* spp., or *Pseudomonas* spp. occurs more commonly in herds with a low bulk tank milk SCC. Clinical mastitis associated with *S. aureus*, *S. dysgalactiae*, and *S. agalactiae* occurs more often in herds with a high bulk tank milk SCC. Systemic signs of illness associated with clinical mastitis occur more

often in herds with a low bulk tank milk SCC. In herds with a high bulk tank milk SCC, more cows with a high milk SCC were culled. In herds with a low bulk tank milk SCC, more cows were culled for teat lesions, milkability, udder shape, fertility, and character than in herds with a high bulk tank milk SCC. In herds with a low bulk tank milk SCC, cows were culled more for export and production reasons.

#### Herd Average of Weighted Individual Cow Somatic Cell Count

The arithmetic mean of individual cow SCC values, weighted by the cow's milk production, is also a good measure of the general udder health status of the herd. It should be noted that the high degree of variability of SCC measurements makes it inappropriate to compare this mean directly with the bulk tank milk SCC.

#### Other Herd-Level Somatic Cell Count Monitors

There are several other calculations using individual cow SCC data that are useful for monitoring herd udder health. Generally, these indices attempt to use mathematical calculations to reduce the impact of individual cows and to measure the change over time. These summaries are used to assist producers in the use of individual cow SCC information at the herd level. These indices include the following.

##### Herd Average Somatic Cell Score

The use of the somatic cell score (SCS, linear score; Tables 20.4 and 20.5) can simplify SCC interpretation and buffer the effects of individual cows with very high values. Thus the herd average of SCS is a very useful monitor of herd udder health status. A realistic goal for most dairy herds is an average SCS of less than 3.0, equivalent to fewer than 100,000 cells/mL. It is not correct to estimate herd production loss from the average linear score using the individual cow linear score–production loss relationship developed for bulk tank milk SCC.

##### Percentage of Herd Over Somatic Cell Count Threshold

Interpretation of SCC and SCS requires the choice of a threshold value for classification of cows as positive and negative. The threshold value used ranges from 200,000–400,000 cells/mL (SCS, 4 to 5). A useful herd goal for subclinical mastitis is to have less than 15% of cows with SCC values greater than 200,000–250,000 cells/mL (prevalence). A second goal is to have fewer than 5% of cows developing new subclinical infections each month (incidence).

##### Percentage of Herd Changing Somatic Cell Count to Over Threshold

Most uses of SCC data focus on the determination of current udder health status. In

other words, SCC is used as an estimate of the prevalence of existing infections in the herd; however, an important objective of a mastitis control program is to minimize the number of new intramammary infections. The change in the SCC of individual cows from month to month can be used as an estimate of the rate of new infections, and the use of SCC data in this way has been evaluated. Using SCC changes from month to month as a test for the rate of new infections has low sensitivity and high specificity. More research is needed on the usefulness of SCC to monitor the occurrence of new infections.

A popular way to represent these data graphically is to plot the SCC value (or linear score) for the current month on the y-axis and the SCC value (or linear score) for the preceding month on the x-axis. This graphing arrangement is preferred because the current SCC value is dependent, in part, on the previous SCC value. Using this graphical approach, individual SCC values in the upper left quadrant are new infections, values in the upper right quadrant are persistent infections, and values in the lower right quadrant are resolved infections.

#### Bacteriologic Culture of Bulk Milk

Although SCC is widely used for monitoring udder health status in dairy herds, decision making often requires information about the prevalence of specific pathogens. With the regular collection of bulk tank milk samples for the purposes of quality monitoring programs, culturing of the bulk tank milk is an attractive alternative to culturing milk from individual cows. Bulk tank milk culture has been formally evaluated as a mastitis screening test. For the major mastitis pathogens, bulk milk culture had a low sensitivity. Even in herds infected with *S. agalactiae*, repeated bulk milk cultures were necessary to detect positive herds. Mastitis pathogens of greatest interest are contagious pathogens, such as *S. agalactiae*, *S. aureus*, *M. bovis*, and *C. bovis*.

The **standard plate count** (plate loop count) provides an estimate of the total numbers of aerobic bacteria in bulk tank milk and is an important measure of milk quality and udder health. It is most commonly used to evaluate the efficiency of cleaning the milking system. **A standard plate count of less than 10,000 CFU/mL can be achieved on most farms, and less than 5,000 CFU/mL should be the goal.** Standard plate counts higher than 10,000 CFU/mL indicate milking of cows with dirty teats or mastitis, poorly sanitized milking equipment, or delayed cooling of milk in the bulk tank. Many herds routinely have bacteria counts of 1,000 CFU/mL or less. Total bacterial counts have some value as an early warning system because up to 50% of violations of the standard are associated with mastitis-related bacteria. For example, bacterial counts in the milk of acute clinical cases

may be as high as 10,000,000 CFU/mL. Milk from subclinically infected quarters may contain 1,000 to 10,000 CFU/mL, and normal quarters yield less than 1000 CFU/mL. In nonmastitic cows, higher counts (up to six times higher) are seen in housed cows than in pastured cows.

The **preliminary incubation count** is an estimate of the total number of cold-loving bacteria. As such, the preliminary incubation count provides an index of milk production on the farm. A preliminary incubation count below 50,000 CFU/mL can be achieved on most farms, with less than 10,000 CFU/mL being the goal. The preliminary incubation count should be less than 3 to 6 times the standard plate count.

### Herd-Level Measures of Clinical Mastitis

The incidence of clinical mastitis, calculated as cases per 100 cows per year, can provide a rough assessment of new intramammary infections. The goal is less than 2 new cases per 100 cows each month (equivalent to <24% of cows affected each year). Calculation of the total treatment days can provide a herd-level assessment of the approach to therapy of clinical mastitis, as well as an estimate of the economic losses.

In a random sample of dairy herds in the Netherlands, the following risk factors were associated with a higher incidence of clinical mastitis: one or more cows leaking milk, one or more cows with trampled teats, no disinfection of the maternity area after calving, consistent use of postmilking teat disinfection, Red and White cattle as the predominant breed, and an annual bulk tank milk SCC of less than 150,000 cells/mL. Factors associated with a higher rate of clinical mastitis caused by *E. coli* included cows with trampled teats, no disinfection of the maternity area after calving, consistent use of postmilking teat disinfection, use of a thick layer of bedding in the stall, and the stripping of foremilk before cluster attachment. Factors associated with a higher rate of clinical mastitis caused by *S. aureus* included Red and White cattle as the predominant breed, cows with trampled teats, stripping of foremilk before cluster attachment, no regular disinfection of the stall, no regular replacement of stall bedding, and an annual bulk tank milk SCC of less than 150,000 cells/mL. Teat disinfection appeared to increase the incidence of clinical mastitis associated with *E. coli*, which may be explained by the higher incidence around calving and during early lactation, when the resistance of cows is low combined with an increase in the numbers of environmental bacteria associated with maternity pens.

### Monitoring Udder Health of Individual Cows

Earlier in this chapter, one direct test (culture) and several indirect tests for

intramammary infection were described. Currently, four methods are widely used to detect subclinical mastitis: culture of composite or quarter samples, SCC values of composite or quarter samples, and CMT and electrical conductivity of quarter samples. Currently, cow-level data (culture or SCC) are the most commonly used of these four monitoring tools, but the usefulness of these tests varies depending on their cost, sensitivity, specificity, convenience, and availability.

### Bacteriologic Culture of Milk

Culture of aseptically collected milk samples has been a cornerstone of mastitis control programs. Extensive diagnostic laboratory systems have been developed for the culture of milk. For many years, milk bacteriology has been recognized as the gold standard of mastitis diagnostic tests. The sensitivity and specificity of milk bacteriology are now being examined and, as the costs of laboratory procedures have risen, there is an increasing need to justify diagnostic expenses. However, there is still an important need for information concerning the predominant types of mastitis organism active in a herd.

Several schemes have been proposed for obtaining a pathogen profile of the mastitis pathogens in a herd. The following suggestions are offered as the most appropriate times to collect samples for milk bacteriology:

- **Pretreatment milk samples from clinical cases.** Samples should be frozen, collected at a herd visit, and submitted for culture.
- **Cows that have an increased SCC.** At each scheduled herd visit, each cow that has an increase in SCC over a preset threshold is sampled, and the sample is submitted for culture.
- **A composite milk sample from each lactating cow in the herd.** This whole-herd culture would be conducted annually, or more frequently, depending on the herd situation. This method is most appropriate for herds having problems with contagious pathogens, but the economics of this approach have not been evaluated.
- **Culture of cows at a specific management event.** One example is milk culture at drying off and at the first milking after calving. This can be useful for assessment of the dry cow management program.

The cost-effectiveness of any one or a combination of these methods of obtaining a bacteriologic profile of a herd's milk will depend on the current situation in the herd. For the vast majority of dairy herds, the routine culture of cows for subclinical mastitis diagnosis is not cost-effective. Herds with a low bulk tank milk SCC and a low incidence of clinical mastitis episodes can conduct an efficient udder health

management program without culturing milk. It is very wise, however, to collect pretreatment milk samples from clinical mastitis cases. These samples can be frozen without significant alterations of the culture results for most pathogens. The samples are collected at a scheduled herd visit and submitted to the laboratory. In most herds, this approach will give a meaningful bacteriologic profile of the herd and assist in assessment of the treatment protocol.

*C. bovis* is not a common cause of clinical mastitis on most farms but is frequently found in random milk samples. Because *C. bovis* is highly infectious and susceptible to teat disinfection, it has been suggested that its prevalence could be used as an indicator of teat-dipping efficiency in a herd, either of the intensity of the dipping or of the efficacy of the dip. Because *C. bovis* is limited in its colonization to the streak canal, it is valuable as a monitor of teat disinfection.

### Somatic Cell Counts

Several management decisions can be based on individual cow composite SCCs. Before any decisions can be made using SCC, criteria must be established to categorize cows based on their SCC results. This involves establishing threshold values or other criteria. The **recommended threshold is 250,000 cells/mL in herds with a low prevalence (<5%) of subclinical mastitis**, providing a sensitivity of 0.55 and specificity of 0.96. In comparison, the **recommended threshold is 200,000 cells/mL in herds with a high prevalence (40%) of subclinical mastitis**, providing an apparent sensitivity of 0.73 to 0.89 and a specificity of 0.86. A clinically more appropriate approach is to calculate likelihood ratios using test sensitivity and specificity, estimated herd prevalence, and a spreadsheet. Cows are identified for further investigation based on their SCC, using three different methods:

- **Change in SCC to over the threshold.** A cow with a marked increase in SCC from one month to the next would be identified as potentially being infected.
- **Persistently elevated SCC.** Cows with a persistently elevated SCC month after month would be identified for management intervention. The lactation average linear score and the lifetime linear score are also useful in this respect. This information is especially useful if dry period therapy has already been unsuccessful for the cow in question.
- **Percentage contribution to herd average.** An estimate of the percentage of the SCC in bulk tank milk contributed by each problem cow can be calculated using individual cow test-day milk weights and SCC data. It should be noted that cows with high milk production and intermediate SCC levels can make a significantly higher

contribution to SCC than some cows with a very high SCC but low production. It is not uncommon for a few problem cows to be responsible for more than 50% of the cells in the bulk tank, particularly in small herds. In most circumstances, the cows with the highest percentage contribution merit immediate action.

With these methods of identifying individual cows based on SCC results, several udder health management decisions can be made, including:

- **Selection of cows for milk bacteriologic culture.** The importance of having a good bacteriologic profile of the intramammary infections in the herd has been emphasized. Several lactation events are suggested as useful times to collect milk for bacteriology. One such event is a clinical mastitis episode. Selection of cows for culture can also be based on an elevated SCC.
- **Selection of cows for dry cow treatment.** Blanket dry cow therapy is currently recommended for most herds. However, herds that use selective dry cow therapy need a suitable screening test to make therapy decisions; such a test is currently unavailable, although individual cow SCCs may be of some help in this decision-making process. Cows with a very high SCC have significantly lower cure rates after dry cow treatment than cows that are infected but have a lower SCC. The SCC can be used as a general indicator of the expected success of dry cow treatment.
- **Treatment during lactation.** The development of a treatment protocol and the criteria for selecting cows to treat during lactation were presented earlier. Treatment on the basis of a change in individual cow SCC from month to month is not economically justifiable. Many other factors need to be considered for a cost-effective treatment decision, and SCC could be one of these criteria.
- **Evaluation of the response to treatment.** Individual cow SCC data can be used as a preliminary evaluation of the mastitis therapy program. With good records on clinical cases and the treatment administered, individual cow SCC data in the months following treatment can be used as a general indicator of the response to therapy. Spontaneous cures and new infections will confound this evaluation, but with data from multiple farms and over a considerable time period a low-cost preliminary evaluation can be achieved.
- **Culling decision.** The lifetime average SCC or linear score of an individual cow is useful additional information in making specific culling decisions. In conjunction with milk culture results,

the SCC data are useful to help establish a cow's net present value. An elevated SCC month after month serves to emphasize that culling is the only method of elimination of some chronic cases of mastitis. Removal of these cows eliminates a source of infection for the rest of the herd, as well as assisting in general improvement in the quality of the bulk tank milk.

- **Alter the milking order.** It is generally recommended that infected cows be milked last, although this is often impractical for free-stall and pasture-based dairy enterprises. Individual cow SCC can be used to establish a milking order in tie-stall barns. Alternatively, some large herds establish a special milking string for infected cows. These milking order and segregation programs can be based on SCC results, but cows with an elevated SCC but no intramammary infection may be incorrectly classified. In segregation programs these false-positive cows may be at increased risk.
- **Management procedures to limit the effect of individual cows.** There is some evidence that machine disinfection after milking infected cows may limit the spread of contagious pathogens. In an intensively managed tie-stall herd, it is possible to manually disinfect the milking unit between cows. To maximize the efficiency of this labor-intensive step, individual cow SCC can be used to identify the cows after which machine disinfection would be useful. Another management method involves using the milk from specific cows for feeding calves. In situations in which there are significant financial incentives for low SCC bulk milk, removal of the milk from one or two cows can have an impact on the amount of premium received. Individual cow SCC values can be used to identify specific cows that should be eliminated from the bulk tank. Precautions need to be taken to prevent intersucking between calves receiving this high-SCC milk.
- **Use of individual cow SCC in economic decision analysis.** The relationship between individual cow SCC and milk production losses has been well established. SCC values can be used to estimate the economic losses from subclinical mastitis. This information may be extremely useful in calculating the potential economic benefit of implementing a new udder health management strategy.

#### Problem Solving Using Individual Cow Somatic Cell Counts

A simple approach to problem solving involves defining the problem by **answering the questions: who, when, where, and what**

**is involved** in the situation. Individual cow SCCs provide an inexpensive consistent source of information to answer these questions. This process is completed by dividing the herd into subgroups and calculating the percentage of cows with SCCs over a threshold (250,000 cells/mL) in each group.

- **Who is affected?** The herd can be subdivided based on several defining characteristics. These include production level, genetic factors (sire), and other characteristics such as having a previous clinical mastitis episode. A gradual increase in the proportion of elevated SCC would normally occur as lactation number increases. Thus a higher percentage of older cows are expected to have elevated SCCs than first-lactation and second-lactation animals. A high proportion of elevated SCC values in heifers would suggest a problem in the replacement program or a breakdown of hygiene in the immediate periparturient period for first-calf heifers. A markedly elevated percentage of high-SCC cows in older animals suggests that infections have become chronic and that the culling strategy should be reevaluated.
- **When does high SCC occur?** It is appropriate to examine SCC distributions according to stage of lactation and season of the year. Normally there is a gradual increase in the prevalence of elevated counts as the lactation progresses. If the prevalence of cows with elevated SCCs is high in early lactation, it suggests a problem with dry cow management or with new infections occurring around the time of calving. If the distribution of cows over threshold shows a dramatic increase during lactation, cow-to-cow transmission of contagious organisms is suspected. Measures of new infection rate are also helpful in solving these problems. The percentage of cows over threshold in the herd can be charted over time. It is expected that this indicator will indicate the same seasonal trends as found in bulk tank milk SCC in the population. For example, the percentage of the herd over threshold should be highest in the fall and lowest in the spring. An increase in this index in the spring would contradict the population trend and should be investigated.
- **Where are the affected cows located?** The distribution of cows with elevated SCC according to their location in the tie-stall barn, in milking strings, or according to milking order may provide evidence for some risk factors for new infections. A mastitis problem caused by environmental pathogens in a free-stall operation can be difficult to solve. Calculating the percentage of cows with

an SCC greater than 250,000 cells/mL for each milking group can help to determine where the problem is most severe. If a specific milking order is followed, as is the case in most tie-stall systems, the distribution of cows with elevated counts according to milking order can demonstrate weaknesses in milking hygiene.

- **What is the problem and why has it occurred?** The information obtained by answering the questions **who**, **when**, and **where** in the problem-solving process can go a long way toward defining **what** the problem is. Prevalence distributions can be combined with the incidence of clinical mastitis, information from milk cultures, and an estimate of the financial losses to complete the picture. Subsequently, specific solutions will be aimed at **why** this problem might exist.

With the development of computerized dairy health management records systems, the epidemiologic analysis of udder health information can be greatly simplified. Ultimately, specific risk factors would be automatically tested for statistical significance. In addition, the relative importance of many potential risk factors would be evaluated.

## 9. PERIODIC REVIEW OF THE UDDER HEALTH MANAGEMENT PROGRAM

Many aspects of mastitis control, such as milking management and therapy of clinical cases, become routine practices. However, changes continue to occur in the udder health status of the herd, environmental conditions, and available technology. With these changes, the current udder health management program may no longer be appropriate. New employees may be introduced, and it is possible that various steps are not being appropriately implemented. In some dairy herds, management practices are passed on from previous generations without critical examination. Mastitis results from a continually evolving relationship between microorganisms, the cow, and the environment. Any program intended to limit problems from these relationships needs to be reevaluated on a regular basis.

An effective udder health management program should undergo regular periodic review. The review process should involve the producer and the herd veterinarian, although input may be sought from various farm management advisors. The review should be objective and thorough, but simple and easy to conduct. The use of a standard investigation form structured on the 10 steps of the mastitis control program is recommended. The same standard form can be used for the investigation of problem herds.

## 10. SETTING GOALS FOR UDDER HEALTH STATUS

The establishment of realistic targets of performance for various udder health parameters is the final component in an udder health management program. These goals are important to determine whether there have been shortfalls in the milk quality and udder health performance. The goals should be realistic and achievable, as well as having economic significance. In addition, the targets must be easily measured and should be accepted by all members of the farm management and labor team.

The setting of appropriate goals for mastitis control efforts is crucial for completion of the health management cycle. In some cases, the target will be the industry reference value; however, in most situations it will be a farm-specific level of performance.

### Relationship of Udder Health to Productivity and Profitability

Mastitis is generally considered to be the most costly disease facing the dairy industry. The reduced profitability is caused by two major factors:

- Reduced milk production associated with subclinical mastitis accounts for approximately 70% of the economic loss.
- The treatment costs, culling, and reduced productivity associated with clinical mastitis are responsible for the remaining losses.

### Production Losses From Increased Somatic Cell Count

It is well accepted that milk production decreases as SCC increases, but the relationship between SCC and milk production is curvilinear for individual cattle but approximates a straight line when a logarithmic transformation (such as somatic cell score) is used. Estimates of the milk production losses range from 3% to 6% with each one unit increase of somatic cell score (SCS) above 3. The loss in first-lactation heifers is greater than that in older cows. A general rule of thumb would suggest that there is 5% loss for each unit of SCS increase above a linear score of 3.

There is also a relationship between bulk tank milk SCC and milk production because there is a linear decrease in herd milk production with an increase in bulk tank milk SCC. Estimates of the production loss range from 1.5% to 3.0% for each increase of 100,000 cells/mL over a baseline of 150,000 cells/mL. Using an average of these estimates, daily milk and dollar losses can be calculated from bulk tank milk SCC and herd production levels.

### Clinical Mastitis and Lost Productivity

Economic losses associated with the treatment of clinical mastitis arise from the cost of drugs, veterinary services, and milk discarded. In addition, decreased milk

production, premature culling, and replacement heifer costs are also significant. However, more than 80% of the loss attributed to a clinical episode involves the discarding of nonsaleable milk and decreased milk production.

## ASSESSMENT OF THE COST-EFFECTIVENESS OF MASTITIS CONTROL

Dairy producers look to their veterinarian for information and services related to mastitis and its control. With this motivation, veterinarians should be able to implement comprehensive udder health management programs on the majority of dairy farms. To achieve a high rate of implementation of mastitis control strategies, it may be necessary to demonstrate the cost:benefit ratio of the suggested practices before they are adopted. A reassessment of their impact over time may also be useful. A 2008 study in the Netherlands estimated that a single episode of clinical mastitis cost €210, with subclinical and clinical mastitis costing an estimated €140 per cow per year, and found that the majority of farmers underestimated the cost of mastitis.<sup>19</sup>

Mastitis control is feasible, practical, and cost-effective. The economics of the efforts of a mastitis control program in a herd can be estimated. There are several steps necessary to complete this assessment.

1. Programs for monitoring udder health and for establishing achievable goals must be in place for an economic assessment.
2. The losses resulting from mastitis must be quantified. The amount of reduced milk production resulting from increased SCC is calculated. In addition, costs associated with the discarded milk and treatment of clinical cases must be estimated.
3. The udder health management program to be implemented must be described. An accounting system should be established to calculate the costs associated with this program.
4. Using an estimate of the potential loss for a hypothetical herd with no mastitis control efforts, the profitability of the herd's current udder health management program is determined.
5. By estimating the costs of implementing new udder health management measures, the remaining potential profits from mastitis control can be calculated.

This economic assessment is done using a computer spreadsheet program. With such a computer program, veterinarians can simply and rapidly input actual values for a particular farm and assess the economic circumstances. The impact of each element of control can be considered from the point of view of a cost:benefit ratio. The results of

economic assessment will vary widely from farm to farm, but usually the following conclusions are made:

- Mastitis will remain a costly disease, even with implementation of properly applied, effective control programs.
- Loss of milk production attributable to subclinical infection will remain a major cause of economic loss because of mastitis in most herds.
- Proper application of simple, inexpensive mastitis control procedures will have a significant impact on profitability and will bring higher returns on investment.

## Miscellaneous Abnormalities of the Teats and Udder

Several diseases are characterized clinically by lesions of the skin of the teats and udder. These diseases are most common in dairy cattle and are of economic importance because teat lesions cause pain and discomfort during milking, and udder edema and udder cleft dermatitis are very common in heifers at calving.

The skin of the wall of the teat and the skin surrounding the teat canal orifice must be inspected closely to observe lesions and

palpated to detect lesions covered by scabs. It may be necessary to superficially irrigate and gently wash teat lesions with warm 0.9% NaCl solution to see the morphology and spatial arrangement of the lesions. The entire skin of the cranial, lateral, and posterior aspects of the udder should be examined by inspection and palpation. Lesions may be restricted to the lateral aspects of the udder and teats, as in photosensitization, or completely surround the teats, as in pseudocowpox.

In North America, the most common viral diseases of the teats of cattle, which result in vesicles or erosion of the teats, include pseudocowpox and bovine herpes mammillitis, with vesicular stomatitis occurring occasionally. The vesicular diseases of the teats are particularly important because they require differentiation from the exotic vesicular diseases such as foot-and-mouth disease. The appearances of the lesions of each of these diseases are similar, which makes clinical diagnosis difficult. However, in most cases, the morphologic and epidemiologic differences in the lesions in groups of animals aid in the diagnosis.

In pigs, **necrosis of the skin of the teats of newborn piglets** may occur in outbreak form. Abrasion of the nipples of baby pigs raised on rough nonslip concrete may be observed as acute lesions or be apparent only when the piglets mature and are found to have deficient teat numbers, as described under agalactia.

The skin of the mammary gland and teats of lactating ewes may be affected by the lesions of **contagious ecthyma**, which are transmitted from the lips of suckling lambs. **Ulcerative dermatosis** of the teats in lactating ewes has lesions similar to those of herpes mammillitis in cows. It is a disease of housed ewes and may be initiated by bedding on infected straw. Mastitis and teat deformity are common sequels. The etiology varies from *S. aureus* to CNS or *Pasteurella* spp.

## LESIONS OF THE BOVINE TEAT

**Traumatic injuries to teats** are very common and range from superficial lacerations to deep lacerations into the teat cistern with the release of milk through the wound. Accidental trampling of a teat by a cow may cause amputation of the teat.

**Chapping and cracking of the skin of the teats** is common in dairy and beef cattle. The cracks in the skin are often linear and multiple and are painful when palpated or when the milking machine teat cups are applied to the affected teats. Cracks of the skin of the teats initiated by milking machine action can be aggravated by environmental factors to create chapping of the teats. The condition is common when adverse weather conditions follow turn out in spring. Linear lesions appear on the teat wall near the teat-udder junction and extend transversely

around the teat. The addition of **10% glycerin** to the teat dip provides an excellent method of improving teat skin condition.

**Frostbite of teats** occurs in dairy cows housed outdoors during severely cold weather without adequate bedding. The skin of the teats is cold, necrotic, and oozes serum. Usually the front teats are more severely affected than the rear teats because the latter are less exposed to adverse ambient temperatures.

**Teat-end lesions** are common in dairy cattle. Lesions include teat canal eversion, teat canal prolapse, prolapse of the meatus, eversion of the meatus, and teat orifice erosion. Limited information is presently available about the mechanism of development for these lesions and their clinical significance; one study found no association between the presence or absence of a teat-end lesion and intramammary infection.

It is normal to see a 2-mm wide white ring around each teat orifice of machine milked cows. The first stage of a teat orifice abnormality occurs when this ring undergoes hypertrophy, keratinization, and radial cracking. Progression leads to increased hypertrophy, secondary bacterial infection, scab formation, eversion of the distal teat canal, and eventually teat orifice erosion. Improper milking machine function can produce teat orifice abnormalities. Excessive or fluctuating vacuum levels, faulty teat cup liners, incorrect pulsation ratios, and other faults attributed to inadequate maintenance and careless use of milking machines have been shown to cause teat injury. A high milking vacuum combined with a relatively low pulsation chamber vacuum can result in bruising and hemorrhage of the teat-end teat wall by the slapping action of the liner.

**Black spot (black pox)** is a sporadic lesion of the teat tip characterized by a **deep, crater-shaped ulcer** with a **black spot** in the center. Black spot lesions occurring at the ends of the teats commonly involve the teat sphincter and are responsible for a great deal of mastitis. This abnormality is caused in most cases by excessive vacuum pressure or overmilking in teats that are naturally firm and have pointed ends. There is no specific bacteriology, although *F. necrophorum* is commonly present, and *S. aureus* is frequently isolated from the lesions. Lesser lesions of teat sphincters are listed under vacuum pressure in bovine mastitis control. The lesions are painful, leading to kicking by the cows, sometimes to repeated kicking off of the teat cups, and to blockage of the sphincter. *T. pyogenes* mastitis is a common sequel. Black spot lesions are poorly responsive to treatment, even if the machine error is corrected.

Treatment of black spot is usually by topical application of ointments: Whitfield's, 10% salicylic acid, 5% sulfathiazole and 5% salicylic acid, and 5% copper sulfate are all recommended. An iodophor ointment, or iodophor teat dip with 35% added glycerol,

is also effective, but treatment needs to be thorough and repeated and milking machine errors need to be corrected.

**Thelitis** or inflammation of the tissues of the teat wall leading to gangrene is a common complication of gangrenous mastitis, and is most commonly associated with peracute *S. aureus* mastitis. The skin of the teats is cold, edematous, and oozes serum. The subcutaneous aspects are commonly distended with gas. The skin is commonly dark-red to purple-black. Sloughing of the skin may be evident.

Inflammation of the wall of the teat (thelitis) is a nonspecific lesion usually associated with traumatic injury to the lining of the teat cistern. The wall of the cistern is thickened, hardened, painful, and, in chronic lesions, irregular in its internal lining. The lesion can be felt as a dense, vertical cord in the center of the teat tip. The lesions have historically been intractable to treatment, which usually consists of intramammary antibiotics and refraining from milking. The recent application of teat endoscopy has assisted in identifying cattle that are most likely to respond to medical or surgical treatment.

**Bovine nodular thelitis** was first described in France in 1963, with subsequent reports in Japan and Switzerland. The disease is characterized by nodular lesions in the teat wall and ventral portion of the udder. The lesions are multicentric nodules containing atypical acid-fast mycobacteria, including *M. terrae* and undescribed *Mycobacterium* species that are related to *M. leprae* and *M. lepromatosis*.<sup>1</sup> Some nodules evolve to ulcers, demonstrating cicatrization and fibrosis.

**Photosensitization of the teats (photosensitive thelitis)** is a local manifestation of generalized photosensitization, but occasionally photosensitive thelitis is the first clinical abnormality detected by the producer. There is a characteristic erythema and hardness of the unpigmented or white parts of the lateral aspects of each teat. The medial aspect is soft and cool. The teats are also painful and in the early stages apparently irritable, because affected cows will also stand in ponds or waterholes in such a way that the teats are immersed, and then rock backward and forward. They will also brush the sides of the udder with the hind feet in a way that could suggest the stamping movements of abdominal pain. In cases in which the photosensitization is related to the induction of parturition by the administration of corticosteroids, the skin lesions are usually restricted to the teats. In cases due to other causes there are usually obvious lesions of photosensitive dermatitis on the dorsal aspects of the body but confined to the white parts.

**Corpora amylacea** are inert concretions of amyloid that may become calcified and detached from the mammary tissue so that they cause blockage of the teat canal and cessation of milk flow. They are formed as the result of stasis caused by blocked mammary tissue ducts and resorption of the milk fluids.

**Papillomatosis of the teats** is caused by bovine papillomavirus and is characterized clinically by small, white, and slightly elevated nodules with a 0.3-cm diameter or elongated tags 1 cm long that are removable by traction. This is covered more extensively in Chapter 16.

**Pseudocowpox** is characterized clinically by painful localized edema and erythema with a thin film of exudate over the edematous area. Vesicle formation is uncommon. Within 48 hours of onset of signs, a small orange papule develops, shortly followed by the formation of an elevated, small, and dark-red scab. The edges of the lesion then extend and the center becomes umbilicated; at 1 week the lesion measures approximately 1 cm in diameter. By 10 days the central scab tends to desquamate, leaving a slightly raised circinate scab commonly termed a “ring” or “horseshoe” scab. One teat may have several such lesions, which coalesce to form linear scabs. The majority of lesions desquamate by 6 weeks without leaving scars, although occasionally animals develop chronic infection.

## LESIONS OF THE BOVINE TEAT AND UDDER

**Thermal burns of the skin of the udder and teats** may occur in mature cattle exposed to grass fires. The hairs of the udder and base of the teats are singed black. Thermal injury to the skin varies from marked erythema of the teats to blistering and necrosis and weeping of serum.

## BOVINE HERPES MAMMILLITIS

### SYNOPSIS

**Etiology** Bovine herpesvirus-2, rarely bovine herpesvirus-4

**Epidemiology** Occurs as an outbreak in cows, particularly heifers, usually within 2 weeks after calving. Commonly followed by persistent infection in the herd

**Clinical findings** Lesions confined to teats and udder. Vesicles leading to sloughing of skin and necrotic ulceration. Prolonged clinical course

**Clinical pathology** Virus isolation and electron microscopy on fresh lesions and serology

**Treatment** Antiseptic and emollient ointments

**Control** Isolation and milking hygiene, but not effective. Control of periparturient udder edema

## ETIOLOGY

The causative virus, **bovine herpesvirus-2** (BHV-2), is an  $\alpha$ -herpesvirus. Infection with BHV-2 can produce two distinct syndromes

in cattle, **bovine herpes mammillitis**, in which there are vesicular and erosive lesions with necrotic ulceration on the skin of the udder and teats, and **pseudolumpy skin disease** (Allerton virus), which manifests with generalized superficial skin lesions over the body. Pseudolumpy skin disease is uncommon. The difference in clinical manifestations between the two diseases may be caused by the strain of the virus or the method of infection. **BHV-4** (DN599 strain), which is usually associated with respiratory disease in cattle, is also capable of causing mammary pustular dermatitis.

## EPIDEMIOLOGY

### Occurrence

Herpes mammillitis is recorded in North America, Australia, Europe, and Africa, but probably has **widespread occurrence**. Herds infected for the first time have a high morbidity rate; subsequently, the incidence is low and is limited to fresh heifers. The **morbidity** rate varies between 18% and 96%, with susceptible herds recording more than 30% affected. The **mortality** rate is negligible.

## ORIGIN OF INFECTION AND TRANSMISSION

Introduction of bovine ulcerative mammillitis into a herd may occur with the introduction of infected animals, but outbreaks have been observed in self-contained herds. Spread within a herd is consistent with the presence of carrier animals, which may shed virus during times of stress, particularly in the periparturient period. Latent infection is an intrinsic trait of herpesvirus infections, and BHV-2 has been isolated from the trigeminal ganglion of healthy cattle.<sup>1</sup> It is presumed that the virus also remains latent in inguinal nerves but this has not been verified in cattle. However, BHV-2 has been demonstrated in lumbar ganglia of ewes experimentally inoculated with BHV-2; these ganglia are sensory to the ovine udder.<sup>2</sup> There is a seasonal incidence of clinical disease that has been related to the activity and presence of insect vectors. Experimental studies indicate that transmission requires virus inoculation at or below the level of the stratum germinativum of the teat or udder skin; therefore trauma associated with milking, teat cracks, or biting flies is a requirement for infection to be transferred. Milking machine liners, hands, and udder cloths may act as carriers of virus when a large amount of it is being released.

Seasonal and circumstantial evidence in the **UK** and **Australia** suggest an insect vector, but this has not been confirmed by attempts at transmission with the stable fly (*Stomoxys calcitrans*), and in the Midwest of the **United States**, the disease is more common in the winter months between November and April.

Survival of the virus for long periods in carrier animals occurs, and it is thought that

this may be the means of survival of the virus within a herd that has become immune. Infection in some cows is suspected to result in chronic infection at the teat end with the cows becoming **hard milkers** and **carriers** of the disease.

### Animal and Pathogen Risk Factors

Lesions are most common in animals within the **first 2 weeks after calving**, particularly in **heifers**, and the disease is more severe in heifers. Heifers that have **udder edema** at calving are particularly prone to develop severe lesions. Occasionally, lesions may be seen on the teats of replacement heifers, and calves suckling infected dams often develop mouth lesions.

The disease is **usually self-limiting**, persisting in a herd for 6 to 15 weeks, and the severity of the lesions decrease as the outbreak progresses. Immunity appears to last about a year; herds infected naturally can suffer recurrences a year later. **Large herds** may have **persisting** disease, particularly in heifers.

The virus is relatively resistant to environmental influences and can survive freezing. It is susceptible to **iodophor disinfectants** and less so to hypochlorites.

### Economic Importance

Forms of loss include a much higher incidence of mastitis, reduction in milk in affected herds by up to 20%, the **culling** of some cows because of severe mastitis and of heifers because of intractable ulcers, and a great deal of interference with normal milking procedure.

### Zoonotic Implications

There are anecdotal reports of herpetic lesions in farmers exposed to infected cattle.

### PATHOGENESIS

Typical clinical lesions and histopathological changes can be produced locally by introduction of the virus into scarifications of the skin of the teat and the oral mucosa and by intradermal and intravenous injection. There is no viremia, and spread is by local extension. In contrast to the poxes, the characteristic lesion in mammillitis is destructive. The higher incidence of the disease and the greater severity of the lesions close to calving are thought to be from the immunosuppression caused by parturition and to a greater predisposition from periparturient udder edema.

### CLINICAL FINDINGS

There is an **incubation period** of 5 to 10 days. There is no systemic illness, and lesions are confined to the teats and udder. When the disease occurs in a herd for the first time the first case is usually in a cow that has calved during the previous 2 to 3 days. Rapid lateral spread then occurs to other cows.

**Bovine herpes mammillitis** is characterized by the formation of variable-sized vesicles, severe edema, and erythema of the teat with subsequent erosion of the teat epithelium. The vesicles rupture within 24 hours, and copious serous fluid often exudes from the dermis. Scabs form over the lesions by the fourth day, and the epithelium is reestablished under the scab by the third week, although the trauma of milking may delay healing, especially when secondary infection occurs. Scar formation on recovery is uncommon. Lesions may be present on several teats and the base of the udder.

In cows calved more than a few weeks previously, the characteristic lesions are almost entirely confined to the skin of the teats; in recently calved cows they are restricted to the skin of the teats and the udder. The severity of the disease in recently calved cattle appears to be directly proportional to the degree of postparturient edema which is present. **Vesicles** occur but are not commonly seen. They are characteristically thin walled, 1 to 2 cm in diameter, variable in outline, and often commence at the base of the teat and spread over much of the udder surface (Fig. 20-8). Rupture and confluence of vesicles leads to weeping and extensive **sloughing** of the skin.

In the most **severe cases**, the entire teat is swollen and painful, the skin is bluish in color, and it exudes serum and sloughs, leaving a raw ulcer covering most of the teat. In less severe cases, there are raised, deep red to blue, circular plaques, 0.5 to 2 cm in diameter, which develop shallow ulcers. In most cases, scab formation follows, but machine milking causes frequent disruption of them, resulting in frequent bleeding. The least severe lesions are in the form of lines of erythema, often in circles and enclosing dry skin or slightly elevated papules, which occasionally show ulceration. Mild lesions tend to heal in about 10 days, but severe ulcers may persist for 2 or 3 months. The severity of lesions on the teats on longer-calved cows varies, but in all cases the lesions are

**Fig. 20-8** Vesicles on the left foreteat of a Holstein heifer with acute herpes mammillitis infection. The vesicles are fragile and appear as the first sign of infection.

sufficiently painful to make milking difficult. Lesions on the skin of the udder heal more rapidly because of the absence of trauma.

Ulcers in the mouth of affected cows have been observed rarely, and calves suckling affected cows develop lesions on their oral mucosae and muzzles. Ulcerative lesions on the vaginal mucosa have been recorded rarely. During the recovery phase there is obvious scar formation and depigmentation. Infrequently, secondary infections are severe and animals are euthanatized.<sup>3</sup>

### CLINICAL PATHOLOGY AND NECROPSY FINDINGS

Material for tissue culture, electron microscopy, or cutaneous transmission tests is best obtained by syringe from early vesicles, or as swabs from early ulcers or oral lesions. The virus may be difficult to demonstrate if the lesions are as old as 7 days and if there has been intensive application of teat disinfectants such as iodophors.

**Serology** is more commonly used for diagnosis. The presence of high virus-neutralizing antibody titers in serum taken during the acute phase of the disease, and a fourfold increase or decrease in titer in paired samples, are all supportive for diagnosis. Titers of 1:16 or higher for BHV-2 and 1:20 for BHV-4 indicate exposure. Antibody to both viruses should be tested for diagnostic purposes.

Necropsy is not commonly performed, and no necropsy reports of cases of bovine ulcerative mammillitis are available.

### DIAGNOSIS

#### DIFFERENTIAL DIAGNOSIS

Diagnosis is made on the basis of clinical signs in multiple animals. Virus may be isolated from aspirating the fluid from vesicles before they rupture. Serology has been performed to identify a threefold to fourfold rising titer but it is not widely available, and many animals seroconvert early in the disease process.

Differentiation of other diseases of the skin of the teat and udder is dealt with in the section on cowpox.

### TREATMENT

There is no specific treatment, and the aim should be to develop scabs that can withstand machine milking. This is most easily effected by the application of a water-miscible, antiseptic ointment just before putting the cups on, followed by an astringent lotion, such as triple dye, immediately after milking. Crystal violet dyes have an excellent reputation as treatments. Cattle that develop a thickened teat caused by secondary bacterial infections are likely to develop clinical mastitis, and treatment success of affected quarters is poor.

## CONTROL

Isolation of affected animals and strict hygiene in the milking parlor are practiced but have little effect on the spread of the disease. Milking heifers first also has minimal impact on disease spread. An **iodophor** disinfectant is recommended for use in the dairy to prevent spread because it has good virucidal activity. Reducing the incidence and severity of **periparturient edema** in heifers may reduce the severity of herpes mammillitis. Inoculation of the natural virus away from the teats produces a local lesion and good immunity, but the method has not been tested as a control procedure.

## LESIONS OF THE BOVINE UDDER OTHER THAN MASTITIS

### Udder Impetigo

**Udder impetigo** associated with *S. aureus* is characterized by small, 2- to 4-mm diameter pustules at the base of the teats that may spread to involve the entire teat and the skin of the udder. This disease is important because of the discomfort it causes, its common association with staphylococcal mastitis, the occasional spread to milkers' hands, and the frequency with which it is mistaken for cowpox. The lesions are usually small pustules (2- to 40-mm diameter), but in occasional animals they extend to the subcutaneous tissue and appear as furuncles or boils. The most common site is the hairless skin at the base of the teats, but the lesions may spread from here on to the teats and over the udder generally. Spread in the herd appears to occur during milking, and a large proportion of a herd may become affected over a relatively long period. The institution of suitable sanitation procedures, such as dipping teats after milking, washing of udders before milking, and treatment of individual lesions with a suitable antiseptic ointment, as described earlier, usually stops further spread. An ancillary measure is to vaccinate all cows in the herd with an autogenous bacterin produced from the *S. aureus* that is always present. Good immunity is produced for about 6 months, but the disease recurs unless satisfactory sanitation measures are introduced.

Sores of bovine teat skin in Norway, characterized by the presence of *S. aureus* and referred to as "**bovine teat skin summer sore**" are thought to be caused by cutaneous invasion by *Stephanofilaria* spp. nematodes. The differential diagnosis of discrete lesions on bovine teat skin is dealt with in the subject of cowpox.

### Udder Cleft Dermatitis

Severe clinical disease caused by **udder cleft dermatitis (udder rot, flexural seborrhea)**

**Fig. 20-9** Healing udder cleft dermatitis in the caudodorsolateral aspect of the udder of a Holstein Friesian heifer. The heifer is in dorsal recumbency. Smooth beds of granulation tissue are developing 1 week after aggressive debridement of the focal areas of dermatitis.

of cattle is most common in dairy heifers that have calved recently. Lesions are present in three locations on the udder: between the halves of the udder (udder cleft dermatitis), on the ventral midline immediately cranial to the udder, and on the caudodorsolateral aspect of the udder in which it comes into contact with the medial aspect of the thigh. Lesions are usually detected during foot trimming or milking and are clearly underdiagnosed—cross-sectional studies in Sweden and the Netherlands identified a prevalence of lesions in the cranial udder of 18% in 1084 cows in 30 dairy herds, and 5% in 948 cows in 20 dairy herds, respectively.<sup>1,2</sup> Udder cleft dermatitis occurs is most common in older dairy cattle; higher producing dairy cattle; and cows with a deep udder relative to the hock, large front quarters, and a small angle between the udder and the abdominal wall.<sup>1,2</sup> Although the etiology remains uncertain, there is speculation that bacteria associated with digital dermatitis may be associated with the development of udder cleft dermatitis.<sup>3</sup>

Udder edema is thought to play an important role in development of lesions on the caudodorsolateral aspect of the udder, because these are most common in periparturient dairy heifers and typically are more severe. The etiology of caudodorsolateral lesions in heifers may be different to that of cranial lesions in older cows.

In lesions of all three anatomic sites, there is variable inflammation and outpouring of sebum. Extensive skin necrosis may develop in a small number of cases, characterized by a prominent odor of decay. The irritation and pain of the caudodorsolateral lesion may cause the animal to appear lame when walking, and the animal may attempt to lick

the affected part. Shedding of the oily, malodorous skin leaves a raw surface beneath, which heals in 3 to 4 weeks. Anecdotal reports exist of extension of infection into the subcutaneous veins resulting in severe hemorrhage and death.<sup>2</sup>

Freshly calved heifers with lesions on the caudodorsolateral aspect of the udder benefit from resolution of udder edema and mechanical debridement using a towel drawn repeatedly across the inguinal area. In advanced cases, a soft tissue curette is used to facilitate debridement of necrotic material after casting the cow in dorsal recumbency, or in lateral recumbency and elevating the upper hindlimb, so that the inguinal area can be adequately visualized (Fig. 20-9).

The efficacy of topical treatment is unknown. Lesions in the other two sites are usually asymptomatic and treatment efficacy is unknown.

### Blood in the Milk (Mammary Gland Hematoma)

Blood in the milk is usually an indication of a rupture of a blood vessel in the gland by direct trauma (such as getting caught on top of a wooden fence or the result of a kick) or more commonly by capillary bleeding in heifers with udder edema. Although in the latter circumstance the bleeding usually ceases in 2 to 3 days, it may persist beyond this period and render the milk unfit for human consumption. The discoloration varies from a pale pink to a dark chocolate brown and may still be present 7 to 8 days after parturition. Rarely, the blood loss may be sufficiently severe to require treatment for hemorrhagic shock (see Chapter 4). Cases of blood in the milk are usually sporadic in occurrence, but there are records of herds

with over 50% of cows affected; clotting defects were not detected in these herds.

Treatment is often requested, although the cow is clinically normal in all other respects. Intravenous administration of calcium borogluconate or parenteral coagulants such as intravenous formaldehyde (see Chapter 5) is widely practiced, but efficacy studies are lacking and it is difficult to believe that either treatment has therapeutic value. Difficulty may be experienced in milking the clots out of the teats, but they will usually pass easily if they are broken up by compressing them inside the teat. The presence of bloodstained milk in all four quarters at times other than immediately postpartum should arouse suspicion of leptospirosis or diseases in which extensive capillary damage occurs.

### UDDER EDEMA

Edema of the udder at parturition is physiologic, but it may be sufficiently severe to cause edema of the belly, udder, and teats in dairy cows and occasionally in mares. In most cases the edema disappears within a day or two of calving, but if it is extensive and persistent it may interfere with suckling and milking. Udder edema is symmetric and extends cranially to the udder along the ventral abdomen (Fig. 20-10). The presence of an asymmetric ventral edema should alert the veterinarian to a mammary vein hematoma or thrombophlebitis of the mammary vein secondary to intravenous injection. The tissue feels colder to the touch than surrounding skin and pits on finger pressure. In severe cases, it extends caudodorsally in the perineal region. A 10-level scale of severity

has been devised for dairy cattle and could be applied in assessing the effects of treatment (Table 20-7). Edema is a prominent sign in inherited rectovaginal constriction of Jersey cows, and is described under that heading.

**Table 20-7** Scale used in rating udder edema

Score	Definition
0	No edema apparent
1	Edema in the base of the udder around one or two quarters
2	Edema in the base of the udder around two or three quarters
3	Edema covering the lower half of the udder
4	Edema beginning to show in the midline and umbilicus
5	Extensive fluid accumulation along the midline and umbilicus
6	Edema covering entire udder. Median suspensory ligament crease has disappeared.
7	Midline fluid accumulation extended to the brisket
8	Midline fluid accumulation extended dorsally; the subcutaneous abdominal vein is indistinguishable.
9	Fluid accumulation extended to the thighs
10	Severe edema; marked fluid accumulation in the vulva; edema extensive in all of the areas mentioned earlier

Source: From Tucker WB et al. *J Dairy Sci* 1992; 75:2382.

**Udder edema is most severe in periparturient dairy heifers**, and the mechanism for its development is not well understood. Hypoproteinemia is not a precursor of udder edema. One epidemiologic study identified an increased risk of udder edema in dairy heifers if calving was in winter, the heifer was taller at the withers, and a bull calf was born.<sup>4</sup>

It is a common recommendation that the amount of grain fed in the last few weeks of pregnancy be limited, and there is evidence that heavy grain feeding predisposes to the condition, at least in heifers. High sodium or potassium intakes increase the incidence and severity of udder edema, especially in housed cattle; the disease often disappears when cows are turned out to pasture. The tendency for udder edema may be heritable in some herds and selection against bulls that sire edematous daughters is thought to be worthwhile. Such a tendency could be mediated through a complex interaction between sex steroids, which are thought to play a role in the etiology. There is also a reduction in blood flow through, and an increase in blood pressure in, the superficial epigastric or milk veins of cows with chronic edema, through an unidentified mechanism.

A mild form of udder edema is the presence of a hard localized plaque along the ventral abdomen immediately cranial to the udder after parturition in heifers. This is common and relatively innocuous but may interfere with milking or ventral abdominal surgical repair of a left displaced abomasum. If the mild udder edema occurs repeatedly over a number of lactations it may result in permanent thickening of the skin (scleroderma) of the lateral aspect of the udder. Hot fomentations, massage, and the application of liniments are of value in reducing the hardness and swelling. A chronic form of the disease is recorded from New Zealand, but no credible etiologic agent has been proposed.

If udder edema is severe, one or more of the following empirical treatments is recommended. Milking should be started some days before parturition, but colostrum from heifers should be discarded because it is likely to be of poor quality. After parturition, frequent milking and the use of diuretic agents is recommended. Corticosteroids appear to exert no beneficial effect. Acetazolamide (1–2 g twice daily orally or parenterally for 1–6 days) gives excellent results in a high proportion of cases, with the edema often disappearing within 24 hours. Chlorthiazide (2 g twice daily orally or 0.5 g twice daily by intravenous or intramuscular injection, each for 3–4 days) is also effective. Furosemide is the most potent diuretic agent and should be administered parenterally (1 mg/kg BW, intramuscularly or intravenously; 5 mg/kg BW orally) in severe cases of udder edema, but prolonged use can result in hypokalemia, hyponatremia,

**Fig. 20-10** Udder edema in a 2-year-old Holstein Friesian heifer that calved a few days previously. Note the extension of edema cranial to the udder. This is a grade 5/10 udder edema score.

and metabolic alkalosis. The use of diuretics before calving may be dangerous if considerable fluid is lost. When there is a herd problem, detection of the cause is often difficult.

An outbreak of udder edema in ewes has been recorded. Affected animals were afebrile, bright, and clinically normal except for the udder, which within 24 hours of lambing was white, cool, and firm, with edema. The milk was normal grossly and laboratory tests detected no abnormalities. Most ewes recovered within 5 to 10 days of lambing.

Hard udder or indurative mastitis in goats is described under the heading of caprine arthritis-encephalitis, and that in ewes under maedi.

### RUPTURE OF THE SUSPENSORY LIGAMENTS OF THE UDDER

Rupture of the suspensory ligaments is most common in adult cows and develops gradually over a number of years. The cause is thought to be severe udder edema at calving, with excessive weight on the udder causing breakdown of the udder attachments, particularly the median suspensory ligament. The result is that the teats on affected cows are not vertically aligned but point more laterally. When rupture of the suspensory ligament occurs acutely, just before or after parturition, the udder drops markedly and is swollen and hard, the teats point laterally, and serum oozes through the skin. Severe edema occurs at the base of the udder. The condition may be confused with gangrenous mastitis or abdominal rupture caused by hydrops allantois on cursory examination. Partial relief may be obtained with a suspensory apparatus, but complete recovery does not occur.

### AGALACTIA

The most important cause of agalactia in farm animals is postpartum dysgalactia syndrome (PPDS) in sows, formerly named mastitis-metritis-agalactia (MMA) syndrome, which is addressed later in this chapter. The general principles that apply to PPDS also apply to the less common cases of agalactia that occur in all species. There is partial or complete absence of milk flow, which may affect one or more mammary glands. The condition is of major importance in gilts and sows, although it occurs occasionally in cattle. The importance of the disease in gilts and sows derives from the fact that piglets are very susceptible to hypoglycemia. The condition may be caused by failure of letdown or absence of milk secretion.

The causes of **failure of letdown** include painful conditions of the teat; sharp teeth in the piglets; inverted nipples that interfere with suckling; primary failure of milk ejection, especially in gilts; and excessive

engorgement and edema of the udder. In many sows the major disturbance seems to be hysteria, which is readily cured by the use of tranquilizing drugs. Treatment of the primary condition and the parenteral administration of oxytocin, repeated if necessary, is usually adequate.

**Ergotism** may be a specific cause of agalactia in sows and has been recorded in animals fed on bullrush millet infested with ergot.

Apparent **hormonal defects** do occur, particularly in cattle. Sporadic cases occur in which cows calve normally and have a normal udder full of milk but fail to let it down when stimulated in the normal way. A single injection of oxytocin is often sufficient to start the lactation. In rare cases repeated injections at successive milkings are required. There is one report of a number of cows in a herd being affected. The cows were under severe stress for a number of reasons and had depressed serum cortisol levels. In heifers and gilts there may be complete absence of mammary development and, in such cases, no treatment is likely to be of value. In animals that have lactated normally after previous parturitions, the parenteral administration of chorionic gonadotrophin has been recommended but often produces no apparent improvement.

Mares grazing fescue may fail to lactate after parturition because of inhibition of prolactin release.

### Milk Drop Syndrome

This is a herd syndrome in which the milk yield falls precipitately without there being any clinical evidence of disease, especially mastitis, or obvious deprivation of food or water. Heat stress (particularly the combination of heat and humidity), summer fescue toxicosis, and leptospirosis caused *Leptospira hardjo* are among the more common causes.

### Low Milk Fat Syndrome

In this syndrome the concentration of fat in milk is reduced, often to less than 50% of normal, although milk volume is maintained. This syndrome is a significant cause of wastage in high-producing cows. Low concentration of fat in milk occurs with ruminal acidosis in cattle.<sup>5</sup> The cause appears to be an increase in concentrations of conjugated linoleic acid in the diet, with subsequent reduction in lipogenesis in the udder.<sup>6</sup> A supply of polyunsaturated fatty acids in the cows' ration and alteration in fermentation in the rumen results in biohydrogenation of linoleic acid (abundant in oils and seeds) and formation of intermediate fatty acids in the rumen. These incompletely hydrogenated fatty acids are absorbed into the blood and have an inhibitory effect on lipogenesis.<sup>7</sup> It is most common in cows on low-fiber diets, for example, lush, irrigated pasture, or grain rations that are ground very finely or fed as pellets. Treatment is achieved by

administration of sodium bicarbonate or magnesium oxide, which increase fiber digestibility and hence the propionate:acetate ratio. Magnesium oxide also increases the activity of lipoprotein lipase in the mammary gland and increases uptake of triglycerides by the mammary gland from the plasma.<sup>8</sup>

### "FREE" OR "STRAY" ELECTRICITY AS A CAUSE OF FAILURE OF LETDOWN

Free electrical current is common in dairies, especially recently built ones. The problem is most common when a herd moves into a new shed, but it also occurs with alterations to electrical equipment and wiring or with ordinary wear and tear. The stray current is present in the metallic part of the building construction, much of which is interconnected. Cows are very sensitive to even small amperages and are highly susceptible because they make good, often wet contact with the metal and with wet concrete on the floor. People working in the dairy are not likely to notice the electrical contact because they are usually wearing rubber boots. The voltage present would be too low to be of much interest to the local power authority, and an independent technician may be necessary to perform the examination, which should be performed while the milking machine is working. The effects of free electricity in the milking shed may be as follows:

- Fatal electrocution, stunning causing unconsciousness, frantic kicking, and bellowing, which are all manifested when the animal contacts the electrified metal, as set down under the heading of electrocution
- Restlessness, frequent urination, defecation, failure to let milk down, and in tie-stalls frequent lapping at the water bowl but refusing to drink; the abnormal behavior may be apparent only when the cow is in a particular position or posture.
- Startled, alert appearance with anxiety, baulking, and refusal to enter the milking parlor
- Failure of letdown leads to lower milk production and recrudescence of existing subclinical mastitis leading to appearance of clinical signs.

**Table 20-8** Diagnosis of free electricity problems based on voltage difference between two points that can be accessed by an animal with resultant current flow

Normal	0–0.5 V
Suspicious as possible cause for abnormal behavior	1.0–2.0 V
Moderate behavioral reactions possible	1.5–3.0 V
Behavioral reactions likely	>3.0 V

*The estimates are guidelines and there is marked individual animal variability.*

In spite of the many field observations of these abnormalities experimental application of AC current up to 8 mA causes changes in behavior but not in milk yield or letdown. Additional information on stray voltage is provided in Chapter 4.

Recommended guidelines for a diagnosis of free electricity problems are set out in Table 20-8. For simplicity it can be assumed that cows will behave abnormally if the free voltage exceeds 1 V AC, although 2 V and a current of 3.6 to 4.9 mA does not reduce milk production. A safer threshold is 0.35 V AC as a maximum. A proper voltmeter is necessary to make a diagnosis, and in most circumstances a qualified electrician is necessary for the exercise.

The development of voltages in the metalwork of the milking shed can arise from many factors. Obvious short circuits from faulty wiring are the least common cause. Most cases are caused by accumulation of relatively low voltages because of increased resistance in the earth or ground system, thus neutral to earth voltages. Reasons for the accumulation include a poor earthing or grounding system, grounding rods that are too short to reach the water table, insufficient grounding rods, or dry seasons lowering the water table. The problem may be intermittent and even seasonal, depending on climatic conditions that facilitate the passage of current through the cow as an alternative grounding system.

## NEOPLASMS OF THE UDDER

The most common neoplasm of cows' teats is viral papillomatosis. It is esthetically unattractive and may play a part in harboring mastitis organisms on the teat skin. It is dealt with in detail under the heading of papillomatosis. Similar papillomata occur on the teat and udder skin of lactating Saanen goats. Rarely, these lesions may develop a squamous cell carcinoma lesion of low malignancy.

Neoplasms of the bovine udder are extraordinarily rare. In a report by the United States Department of Agriculture in 1945, 13 million bovine udders were inspected and none were found to have gross evidence of

cancer. There are a handful of isolated reports of fibrosarcoma, carcinoma, and fibroadenoma of the mammary gland in cattle.<sup>1</sup> Carcinomas are rarely reported in goats, and adenoma and carcinoma are very rare in sheep.<sup>1,2</sup> Malignant mammary carcinoma occurs occasionally in mares. The extremely low rate of mammary gland neoplasia in female ruminants is primarily attributed to their herbivore diet and because many ruminants are slaughtered before reaching middle age.<sup>1</sup> An additional reason for the low rate is that female ruminants that are retained in the herd or flock have an extremely low lifetime exposure to estrogen as they spend most of their reproductive life being pregnant or not cycling.

## TEAT AND UDDER CONGENITAL DEFECTS

The common sporadic defects in cows are supernumerary teats, fused teats with two teat canals opening into one teat sinus, hypomastia, absence of a teat canal and sinus, and absence of a connection between the teat sinus and the udder sinus; in sows insufficient and inverted teats are the common errors. Supernumerary teats are common (up to 33%) in Simmental and Brown Swiss heifers and are removed surgically. A high prevalence of defects is recorded in Murrah buffaloes and inheritance of hypomastia, rudimentary teats, and angulation of teats is suspected in cows.

Traditionally sows are required to have at least 12 functional teats and sows deficient in this regard are likely to be culled. Reasons for the deficit include inherited shortage (teat number is highly heritable), misplaced teats (usually too far posteriorly to be accessible to the piglets), or unevenly placed, inverted teats, either congenital or acquired as a result of injury; vestigial nipples that do not acquire a lumen, cistern, or gland; and normal-sized teats that are occluded. Inverted teats in sows may be this way because they lack a teat upturn, which is the teat duct opening directly into the mammary gland cistern.

## MILK ALLERGY

Signs of allergy, principally urticaria, are often manifested by cows during periods of milk retention. Most of these occur as the cow is being dried off. The Channel Island breeds of cattle are most susceptible, and the disease is likely to recur in the same cow at

subsequent drying off periods; it is almost certainly inherited as a familial trait.

The important clinical signs relate to the skin. There is urticaria, which may be visible only on the eyelids or be distributed generally. Local or general erection of the hair may also be seen. A marked muscle tremor, respiratory distress, frequent coughing, restlessness to the point of kicking at the abdomen and violent licking of themselves, and even maniacal charging with bellowing may occur. Other cows may show dullness, recumbency, shuffling gait, ataxia, and later inability to rise. The temperature and pulse rates are usually normal or slightly elevated, but the respiratory rate may be as high as 100 beats/min.

Diagnosis of milk allergy can be made by the intradermal injection of an extract of the cow's own milk. A positive reaction occurs with milk diluted as much as 1 in 10,000, and edematous thickening is present within minutes of the injection. Other clinicopathologic observations include the development of eosinopenia, neutrophilia, and hyperphosphatemia during an attack.

Spontaneous recovery is the rule, but antihistamines are effective, especially if administered early and repeated at short intervals for 24 hours. Prevention is usually a matter of avoiding milk retention in susceptible cows, but in many cases it is preferable to cull them.

## Mastitis of Sheep

### ETIOLOGY

Most cases of clinical mastitis are caused by *S. aureus* or *Mannheimia* spp. (predominantly *M. haemolytica* and *M. glucosida*, but also *M. ruminalis*). Each is responsible for around 40% of cases in ewes suckling lambs for meat or wool production, whereas in dairy sheep *S. aureus* has a higher prevalence, and is responsible for around 80% of clinical cases.<sup>1,2</sup> *S. agalactiae* is also important, with other agents including CNS (often associated with persistent subclinical infections and elevated SCCs), *E. coli*, *H. somni* (formerly *H. ovis*), *Clostridium perfringens* type A, *Pseudomonas* spp., *C. pseudotuberculosis*, or *E. faecalis*. *Acholeplasma oculi* is predominantly isolated from cases of contagious ophthalmia but can cause mastitis and agalactia.

Another important cause is *M. agalactiae*, the agent of contagious agalactia, which is described under that syndrome.

### EPIDEMIOLOGY

#### Occurrence

Most cases of clinical mastitis in ewes occur up to 4 to 8 weeks after parturition or immediately after weaning. Compared with housed ewes, those grazing pasture have a lower prevalence with cases predominantly caused by *M. haemolytica* or *Staphylococcus* spp.

Many cases are associated with teat injury from any cause, such as when ewes are housed on abrasive floors.

Clinical mastitis in grazing ewes averages only about 2% per year, but mastitis can be responsible for up to 10% of all ewe deaths. More than 30% of dairy ewes can have subclinical mastitis.

The forms of loss in milk sheep are the same as those for dairy cattle: reduced milk production, reduced milk quality, which can negatively affect cheese production, and the culling of affected ewes. In meat and fiber sheep the most obvious losses are deaths, usually from gangrenous mastitis, and decreased growth and deaths in lambs. Where suckling lambs have access to supplemental feed the effect of subclinical mastitis on lamb performance is negligible.

The sheep dairy industry in many countries is developing, so anything that adversely affects the quantity and quality of ovine milk, especially for the production of cheese, will cause financial loss. In Greece, where ewe milk is used to produce feta cheese, the prevalence of subclinical mastitis in flocks varies from 29% to 43%, with CNS and *S. aureus* isolated from 44% and 33% of the positive milk samples, respectively.

### Staphylococcal Mastitis

The most prevalent mastitis pathogen of the ewe is *S. aureus*. The incidence of clinical mastitis may be as high as 20%, with ewe mortality rates of from 25% to 50%. The affected halves in surviving ewes are usually necrotic and destroyed. Chronic mastitis can cause a 25% to 30% reduction in milk yield from the affected udder halves. Consequently, this disease is very important in countries, such as Greece, in which ewes' milk is an important component of the human diet. The disease is probably spread from infected bedding grounds, with the infection gaining entry through teat injuries caused by suckling lambs. Intensive housing can be associated with an increased prevalence of lesions, probably caused by cross-suckling by lambs with oral or nasal infections.<sup>3</sup>

Other staphylococcal mastitides in ewes include *S. epidermidis*; many clinically normal quarters show a high rate of infection with coagulase-negative staphylococcus. Experimental infection with *S. chromogenes* causes clinical mastitis, *S. simulans* causes subclinical mastitis, and *S. xylosus* causes a transient increase in the SCC.

### Mannheimia Mastitis

Peracute, gangrenous mastitis associated with *Mannheimia* spp. is a common mastitis. *M. haemolytica* and *M. glucosida* can be isolated from affected halves, and the disease can be reproduced experimentally by the intramammary infusion of cultures of the organism. *S. aureus*, *T. pyogenes*, and streptococci are often present as secondary invaders.

*Mannheimia* mastitis occurs sporadically in the western United States, Australia, and Europe in ewes kept under systems of husbandry varying from open pasture to enclosed barns. Mastitis is most common in ewes suckling large lambs up to 3 months old. Infection is thought to occur through injuries to teats, perhaps caused by over vigorous suckling. Occurrence is not related to hygiene, and many outbreaks occur in grazing sheep. However, because of sheep's behavior (using "sheep camps" at night), it is possible that these areas become contaminated and facilitate transmission by contact with infected soil or bedding. There is a high diversity among *Mannheimia* isolates, and horizontal transmission by lamb suckling probably occurs.<sup>4</sup>

### Streptococcal Mastitis

Streptococcal mastitis can be reproduced by the introduction of *S. agalactiae* into the mammary glands and occurs naturally in dairy ewes. The infection originates from an infected udder and is transmitted to the teat skin of other ewes by milking machine liners, milkers' hands, washcloths, and any other material that can act as an inert carrier. *S. dysgalactiae* and *S. uberis* are also occasionally isolated.

### PATHOGENESIS

The mechanisms of pathogenesis are similar to those for bovine mastitis.

### CLINICAL FINDINGS

In milking ewes clinical mastitis is similar to that in cows, with acute and subacute forms manifested by swelling of the gland and wateriness and clots in the milk. Most clinical cases occur with 2 to 3 weeks of parturition or at weaning, and take the form of gangrenous mastitis, affecting one or both halves.

### Staphylococcal Mastitis

In sheep there is a strong similarity between this form of mastitis and that associated with *M. haemolytica*. They are both peracute, gangrenous infections. The ewe is usually recumbent and profoundly toxic, and the affected gland and the surrounding area of belly wall are blue-green in color and cold to the touch. A few drops of clear, bloodstained liquid is all that can be expressed from the udder. A fatal clinical course of 1 to 2 days is usual.

### Mannheimia Mastitis

*Mannheimia* mastitis is an acute systemic disturbance, with a high fever (40°C–42°C; 105°F–107°F), anorexia, dyspnea, and profound toxemia, with acute swelling of the gland and severe lameness on the affected side. This lameness is an important early sign and is useful in locating affected animals in a group. The udder is at first hot, swollen, and painful and the milk watery, but within

24 hours the half is discolored blue-black and cold, with a sharp line of demarcation from normal tissue. The secretion is watery and red and contains clots. The temperature subsides in 2 to 4 days, the secretion dries up entirely, and the animal either dies of toxemia in 3 to 7 days or survives with sloughing of a gangrenous portion of the udder. This is followed by the development of abscesses and the continual draining of pus. Usually only one side is affected. Cases of pneumonia caused by the same organism may occur in lambs in flocks in which ewes are affected.

### Clostridial Mastitis

*C. perfringens* A is a rare and highly fatal cause of acute mastitis in ewes. Clinical signs of infection are principally hemolytic and are characterized by hemoglobinuria, jaundice, and anemia, plus fever, anorexia, and recumbency. The affected half is swollen, painful, and hot and contains watery, brown, flocculent secretion.

### Caseous Lymphadenitis and Mastitis

Suppurative lesions associated with *C. pseudotuberculosis* are common in ovine mammary glands, but they usually involve only the supramammary lymph nodes and are not true mastitis. However, the function of the mammary gland may be lost when the infection spreads from the lymph node to mammary tissue.

### Pseudomonas Mastitis

Naturally occurring pseudomonas mastitis in ewes is likely to be gangrenous and lethal, as well as accompanied by severe lameness in the hindlimb on the affected side. Infected intramammary infusions or milking machine malfunction are the usual means of introducing the infection.

### CLINICAL PATHOLOGY

The SCC is a useful predictor of mammary gland infection of individual dairy ewes, although thresholds are not as uniform or as widely accepted as for dairy cows.<sup>5,6</sup> The SCC in normal ewe milk ranges from 0.5 to  $1.0 \times 10^6$  cells/mL, with 95% of samples having counts  $<0.5 \times 10^6$  cells/mL. Ewe milk SCC tends to increase more in later lactation compared with the cow, but consecutive testing when counts range from 0.5 to  $1.0 \times 10^6$  cells/mL will improve its diagnostic accuracy. In bulk milk samples, counts of  $0.65 \times 10^6$  cells/mL indicate that from 10% to 15% of ewes in a flock have subclinical mastitis.<sup>5</sup>

Other tests include the California Milk Test, a reliable indicator of SCC, and staining milk films with Giemsa or May-Grunwald stains to detect what type and proportion of cells are present. Early mammary gland infections change the proportion of ions in milk; thus measuring electrical conductivity can indicate mastitis. However, there are

large interanimal and intraanimal variations, so specific algorithms that account for this daily variation are required.<sup>7</sup> Ultrasound examination of the udder and supramammary lymph nodes and infrared thermography of the udder are potentially rapid and sensitive tests for subclinical mastitis in specialist dairy flocks.<sup>8,9</sup> Infection of ewes with maedi-visna virus does not alter their SCC.

### NECROPSY FINDINGS

The gross appearance of the affected glands varies with the agent involved and the duration of the process. Generally, the swollen, hemorrhagic, and/or gangrenous nature of fatal acute ovine mastitis is obvious. A purulent exudate is sometimes present, especially in the case of chronic *C. pseudotuberculosis* infection.

### Samples for Confirmation of Diagnosis

- Bacteriology: chilled mammary gland for aerobic culture; anaerobic culture if *Clostridium* sp. is suspected.

### DIFFERENTIAL DIAGNOSIS

*Mannheimia* mastitis is peracute and resembles mastitis associated with *Staphylococcus aureus*. A similar disease in ewes has been ascribed to *Actinobacillus lignieresii*. Suppurative mastitis associated with *Corynebacterium pseudotuberculosis* is chronic, and no systemic signs occur.

### TREATMENT

Broad-spectrum parenteral and intramammary antimicrobial agents are effective. Although ewes probably require smaller doses of intramammary infusions than cows, it is customary to use ordinary cow-type mammary infusion treatments. However, this results in a much longer period during which the milk in the half has a level of antibiotic greater than acceptable limits for human consumption (the "withhold period"). The treatment of ewes with peracute gangrenous mastitis requires systemic treatment, but this is often not successful and the affected half sloughs after several weeks.

### CONTROL

Control programs for milking sheep flocks are less well defined, but principles similar to those outlined for dairy cows apply. This requires early detection and prompt treatment of affected ewes with an effective antimicrobial. Results of culture and sensitivity testing will not be immediately available, but milk samples should be collected aseptically from affected and nonaffected ewes to inform future treatment options, with the aim of testing up to 10 isolates of each species present.<sup>2</sup> Dry treatment with intramammary infusions into both halves of dairy ewes has been shown to reduce subclinical infections

and/or SCC during the next lactation.<sup>10</sup> Selective treatment of ewes with a consistently high SCC, rather than treatment of all ewes, will be a more cost-effective strategy, but this information will only be available within well-developed dairy operations. For flocks of suckling ewes with a high prevalence of mastitis the use of dry period treatment at weaning may be useful, but care and aseptic technique is required to prevent iatrogenic infections.

Phenotypic culling of affected dairy or suckling ewes is often undertaken, although this will not reliably prevent further clinical or subclinical infections in the flock. Genetic selection of dairy ewes with a reduced SCC is an indirect way of reducing susceptibility to mastitis infections and may offer a longer-term option for the control of subclinical mastitis. However, to have the most chance of success this needs reliable pedigree information, performance recording, and estimates of breeding values.<sup>6</sup>

### Staphylococcal Mastitis

Two multivalent bacterins have been released for use against staphylococcal mastitis in dairy cattle, Lysigin (United States) and Startvac (Europe and Canada), but as yet they have not been systematically evaluated in sheep. The former, a multivalent whole-cell lysed bacterin, did not prevent infections but reduced the severity of mastitis after experimental challenge of heifers with *S. aureus*. Vaccination did not lower SCC, increase milk yields, or reduce the staphylococcal infection rate.<sup>10</sup> The second product includes an inactivated *E. coli* strain. It does not eliminate new staphylococci infections, but field studies in dairy cattle show a reduced time and transmissibility of infections.<sup>11</sup>

For dairy ewes, frequent changing of pasture areas and culling of affected ewes may help reduce environmental contamination and control the spread of infection.

### Mannheimia Mastitis

In older studies polyvalent hyperimmune serum and an autogenous vaccine of killed *M. haemolytica* were shown to prevent intramammary infections with *Mannheimia* spp. More recently, *M. haemolytica* serotype 1 has been used in vaccines in an attempt to control respiratory disease in cattle and pasteurellosis in sheep. However, a primary virulence factor of *Mannheimia* spp. isolates is leukotoxin A (LktA), and this may have an important role in immunity to disease caused by *Mannheimia* spp. A comparison of the similarity of the LktA of *Mannheimia* spp. isolated from clinical cases of mastitis found that the LktA from *M. glucosida* may be more suitable for a monovalent vaccine than the LktA from *M. haemolytica*.<sup>12</sup>

## Mastitis of Goats

*S. aureus* and *E. coli* are the most common causes of clinical mastitis. Other infectious agents include *Pseudomonas* spp., *S. hyicus* (much less pathogenic than *S. aureus*), *S. dysgalactiae* spp., *Streptococcus* spp., *Actinobacillus* spp., *C. pseudotuberculosis*, *M. haemolytica*, and *Actinobacillus equuli* causes a systemic reaction and granulomatous lesions in the udder and lungs. The gland prevalence of subclinical mastitis *N. asteroides* in goats, caused predominantly by infection with CNS, can range from 9% to 65%, although these organisms are often present in clinically normal halves.<sup>1</sup>

Goats have intrinsically higher SCCs than cows or sheep, which increase with age and stage of lactation, so goat milk can often exceed legal thresholds for human consumption mandated in some jurisdictions in the absence of a high prevalence of clinical or subclinical mastitis.<sup>2</sup>

Mastitis is also an important sign in the infectious diseases associated with *M. agalactiae* and *M. mycoides* var. *mycoides*.

### Staphylococcal Mastitis

This is the most common cause of mastitis in goats and the same CNS can persist in subclinical infections for up to 7 months.<sup>1</sup> A New Zealand study of over 600 does from 18 herds found bacteria in 23.3% of glands, and CNS (13.4%) and *Corynebacterium* spp. (7.3%) were the most common isolates.<sup>3</sup> The incidence of new infections was highest in early lactation, and prevalence of infections increased with age.

*S. aureus* is commonly isolated from clinical mastitis but at a much lower prevalence than CNS. Experimentally produced *S. aureus* mastitis in goats has a similar pathogenesis to that in the cow except for a marked tendency for the staphylococci to invade and persist in foci in the interacinar tissue. As in cattle, some staphylococci in goats' milk produce enterotoxins and the toxic shock syndrome toxin, so these can cause food poisoning in humans. Latex agglutination tests

are available for the identification of the enterotoxins.

### Streptococcal Mastitis

Goats are susceptible to *S. agalactiae* and *S. uberis*, and sporadic cases or outbreaks of mastitis associated with these and other streptococci do occur. In flocks of milking goats the infection is passed from infected quarters to others by means of the milkers' hands, the teat cups of milking machines, and washcloths used to disinfect the udder before milking. *S. zooepidemicus* causes chronic suppurative mastitis in does, and artificially induced infections with *S. dysgalactiae* are indistinguishable from mastitis associated with *S. agalactiae*. The pathogenesis is probably similar in all streptococcal mastitides.

### Pseudomonas Mastitis

Experimental pseudomonas mastitis in goats is acute, with extensive necrosis and fatal septicemia. As for dairy cattle, infection is often introduced through contaminated water.<sup>1</sup>

### Summer Mastitis

Summer mastitis associated with *T. pyogenes* has been produced experimentally in goats with udder lesions typical of acute suppurative mastitis. Nonlactating goats developed a severe mastitis, whereas lactating animals were less severely affected.

### Other Infections

Mastitis in goats is associated with an organism tentatively identified as *M. haemolytica*. *Yersinia pseudotuberculosis* has caused mastitis in an aborting goat doe that probably experienced a bout of systemic yersiniosis. This infection would be a potential zoonosis. Granulomatous lesions in the mammary glands and in internal organs have been observed in goats experimentally infected with *Cryptococcus neoformans*.

### CLINICAL FINDINGS

Clinical mastitis in goats is similar to that in cattle, with subclinical, chronic, acute, and peracute gangrenous forms occurring. Particular care is needed in the clinical examination of goat's milk because of its apparent normality when there are severe inflammatory changes in the udder.

SCCs in milk of goats are higher than in cattle or sheep but vary widely because of the apocrine nature of milk secretion.<sup>2</sup> The counts increase with stage of lactation, lower milk production, and increased parity, and goats without intramammary infection may have an SCC of more than  $1 \times 10^6$  cells/mL, which is the mandated limit of goat milk for human consumption in some jurisdictions.<sup>4</sup> These variations make the value of SCC as a guide to diagnosis in goats controversial.

In staphylococcal mastitis, infected halves have higher NAGase and CMT than normal

halves. However, they and the LDH and antitrypsin tests give variable results, thus they are still not considered to be as reliable as in dairy cows.<sup>5</sup>

### Treatment and Control

Treatment and control of mastitis techniques to be used in goat does have been adapted from those used for cattle, with the details of dry period and lactational treatments informed by laboratory culture. If cow dose rates are used, retention of the antibiotic in the udder of goats will be prolonged, even for short-acting products such as ampicillin, so withholding periods need to be increased.<sup>6</sup>

For treatment of acute cases, intravenous flunixin meglumine is an effective antipyretic and leads to clinical improvement in the mammary gland when combined with intravenous dextrose and electrolytes. The preferred antimicrobials to achieve therapeutic tissue concentrations in the mammary gland include macrolides, trimethoprim, tetracyclines, and fluoroquinolones.<sup>7</sup>

Vaccination using killed bacterins has been investigated for a number of years, and two multivalent bacterins are available for use against staphylococcal mastitis in dairy cattle, Lysigin (United States) and Startvac (Europe and Canada). The effect of the former on the prevalence of staphylococcal mastitis and SCC in a 30-doe U.S. dairy goat herd was evaluated over 18 months.<sup>8</sup> The average SCC of vaccinates was lower ( $1.3$  versus  $1.5 \times 10^6$  cells/mL for controls), which reduced the milk below the mandated level for human consumption, and they had more spontaneous cures (1.28 versus 0.6 per doe for controls).

## Contagious Agalactia in Goats and Sheep

### SYNOPSIS

**Etiology** Classic disease caused by *Mycoplasma agalactiae* in sheep and goats; also *M. agalactiae*, *M. mycoides* subsp. *capri* (formerly *M. mycoides* large colony type), and *M. capricolum* subsp. *capricolum* in goats

**Epidemiology** Outbreaks and severe disease are especially problematic in the Mediterranean area of Europe and Africa.

Introduction of infected animals. Direct spread by infected milk and ocular discharge to suckling young and to adults by contamination of bedding, feed, and milking equipment

**Clinical findings** Triad of mastitis, arthritis, and ocular disease. Sometimes accompanied with respiratory disease, abortion, and diarrhea

**Lesions** Indurative mastitis with abscessation, polyarthritis

**Diagnostic confirmation** Culture, polymerase chain reaction, serology

**Treatment** Antimicrobials may mitigate disease severity but not achieve a bacteriologic cure.

**Control** Flock/herd biosecurity, milking-time hygiene. Test and slaughter eradication. Vaccines have poor efficacy.

### ETIOLOGY

Contagious agalactia is a disease of sheep and goats, particularly those used for milk production. *M. agalactiae* is the main causal agent in sheep and goats, but *M. mycoides* subsp. *capri* and *M. capricolum* subsp. *capricolum* produce a similar if not identical clinical presentation. There is apparent variation in virulence between isolates from different regions and countries. The situation in goats is quite complex, and frequently more than one of these agents can be isolated from the same outbreak.

*M. putrefaciens*, first isolated from the joints of arthritic goats in California, has been isolated and implicated in some outbreaks of contagious agalactia, but experimental challenge with this organism does not produce classical contagious agalactia. *M. putrefaciens* can cause septicemia, pneumonia, and mastitis in small ruminants that are predisposed by other diseases.

### EPIDEMIOLOGY

#### Occurrence

Contagious agalactia is endemic in most European countries and Africa and occurs in many other areas of the world including Asia and the Indian subcontinent, the Middle East, and North and South America. The disease is common in Mediterranean countries, and is particularly widespread and problematic in Spain.

#### Prevalence

In endemic areas the disease is cyclic in occurrence with periods of outbreaks of severe disease interspersed with periods of chronic or mild disease.

Peak rates of clinical disease occur after parturition in both the dams and their young with another peak occurring in association with the onset of machine milking after the young are removed from suckling. The mortality rate can be high (10%–30%), and many

adult females are culled because the udder is permanently damaged.

### Transmission

The organisms are present in the milk and ocular secretions of infected animals and in respiratory secretions in which the pulmonary form of the disease is present. Transmission is by direct contact, aerosol transmission, ingestion, and by contact with infected fomites. The young are infected through the ingestion of infection present in colostrum and milk. Infected milk can also contaminate bedding, feed and dairy equipment, and spread occurs with machine milking. The organisms reside in the ear canal of asymptomatic carrier sheep and goats, and are thought to be transmitted by ear mites. Venereal transmission is also thought to occur.

The common practice of transhumance and communal grazing in endemic areas promotes transmission between herds and flocks, either from direct contact or grazing over infected pastures. The organisms have been isolated from outbreaks of disease in a range of wild ruminants, but the role of these in the epidemiology of contagious agalactia in domestic small ruminants is unclear.<sup>1</sup> Illegal importation of animals from an endemically infected area can introduce the disease to disease-free areas.

### Experimental Reproduction

Contagious agalactia can be reproduced experimentally and reflects the natural disease with acute and chronic multifocal necrotizing mastitis, acute arthritis, conjunctivitis, and subacute enteritis. Shedding of the organism precedes the onset of clinical disease by 1 to 10 days. The experimentally produced disease is much more severe in pregnant animals.

### Host Risk Factors

The relative severity of clinical disease in sheep versus goats depends on the infecting mycoplasma and varies with region. There are also breed and age differences in susceptibility. Septicemia and acute disease is more common in young lambs and kids and lactating females, with less severe disease in adult males and nonlactating nonpregnant females. Asymptomatic carriers are important in transmission of the organisms.

### Pathogen Risk Factors

There is regional variation in the virulence of isolates; *M. agalactiae*, *M. mycoides* subsp. *mycoides* subsp. *capri*, *M. capricolum* subsp. *capricolum*, and *M. putrefaciens* have all been isolated from goats in Australia and the United States over several decades, but clinical disease in these countries associated with these organisms is extremely rare.

Molecular studies show a high genetic diversity of *M. agalactiae* isolates from goats in Spain compared with relatively

low diversity from sheep isolates in France and Spain.<sup>2,3</sup> This has implications for vaccines developed to control the disease in goats.

### CLINICAL FINDINGS

The classical signs of contagious agalactia include septicemia, arthritis, mastitis, conjunctivitis, and localization in abscesses, but these are not all consistently present in outbreaks.

In acute cases the onset is sudden with pyrexia, abrupt and complete agalactia, and unilateral or bilateral swelling of the udder with enlargement of the mammary lymph nodes and the development of multiple abscesses in the mammary gland. Induration of the udder may result in culling. In animals that survive, mycoplasma are excreted in the milk for several months and will persist in the udder to subsequent lactations.

Arthritis may be manifested by lameness or recumbency and its presence detected in the carpal and tarsal joints by the occurrence of heat and palpable joint fluid and confirmed by aspiration and examination of joint fluid. Conjunctivitis progresses to keratitis with corneal revascularization in one or both eyes. Some cases have diarrhea.

In less acute cases, there is a long period of illness of from one to several months. Abortion may also occur and genital disease with vulvovaginitis and metritis occurs in some outbreaks.

### CLINICAL PATHOLOGY

Herd diagnosis is possible by the isolation of the organism *M. agalactiae* from the bloodstream, joint fluid, and mammary tissue. A multiplex real-time PCR on a range of samples, including bulk milk, can be used to identify the disease if the causative *Mycoplasma* spp. are present.<sup>4</sup>

Herd diagnosis can also be made serologically. The complement fixation (CFT) test becomes positive soon after clinical signs, although commercial ELISA kits can have variable sensitivity and specificity depending on the strain of *M. agalactiae* and cross-reactions with nonpathogenic *Mycoplasma* spp.<sup>5</sup>

### NECROPSY FINDINGS

Lesions are indicative of indurative mastitis with abscessation, lymphadenopathy, arthritis, and ocular disease.

### Samples for Confirmation of Diagnosis

- **Bacteriology (aerobic culture) and PCR:** milk, ocular fluid, joint fluid aspirate, nasal swabs, ear swabs, lung lesions, brain
- **Serology:** CFT, ELISA

### TREATMENT

Antimicrobial therapy can reduce the severity of disease and mortalities and is an

alternative to culling, especially for animals of high genetic merit. The preferred antibiotics are fluoroquinolones, tetracyclines, and macrolides. Antibiotic resistance to tetracyclines, or an intrinsic lack of efficacy, is a problem as is the cost and practicality of therapy in many endemic areas. In vitro sensitivity testing of field isolates of *M. agalactiae* found enrofloxacin most effective, followed by tylosin, tetracycline, lincomycin, and spectinomycin, with high cure rates reported with lincomycin, spectinomycin, and tylosin. However, treatment of bucks with marbofloxacin did not eliminate *Mycoplasma* from the ear canal of goat bucks, so it would have little impact on eliminating carriers in chronically affected herds.<sup>6</sup>

### CONTROL

The majority of infections in healthy flocks come from introduction of carriers or contact with infected animals. Thus isolation from infected flocks and herds and a closed herd policy are important control measures. Where disease is restricted to a small number of flocks in a geographically isolated area, slaughter of serologically or culturally positive flocks can be an effective control method. In endemic areas disease is common, so eradication by slaughter is not an option and control relies on biosecurity, hygiene, antibacterial therapy, and the use of killed monovalent and polyvalent vaccines.

The efficacy and duration of immunity to vaccines is relatively poor, but they do reduce excretion of mycoplasma and clinical disease. Vaccination of sheep and goats with either an attenuated live vaccine or a killed adjuvant vaccine of *M. agalactiae* gives mixed results; in late pregnant ewes the former is too virulent, and the latter insufficiently so unless it is used in ewes before mating, when efficiency is good. Early vaccination is recommended because of the susceptibility of young animals but should not be performed before 10 weeks of age. Extensive use of both vaccines over a period of 13 years resulted in almost complete disappearance of the disease from Romania, but live attenuated vaccines are not permitted in many countries.

Comparison between commercial vaccines shows that a saponified vaccine gives better results than a live, egg-cultured vaccine, and saponin and phenol inactivated vaccines show better efficacy against experimental disease than do vaccines killed by heat or formalin. An *M. agalactiae* bacterin combined with a mineral oil adjuvant has given good results when three doses are given before, and one dose after, each parturition, and the herd is kept isolated. Intramammary vaccination provides the highest level of antibody.

Autogenous vaccines prepared from milk, brain, and mammary gland homogenates from infected sheep have been used for many years in parts of Europe but have been linked to outbreaks of scrapie.

In infected herds, hygiene at milking time is important in limiting the spread of disease. Pasteurization of colostrum (60 minutes at 60°C; 140°F) eliminates *M. mycoides* subsp. *capri*, but *M. agalactiae* can survive for 120 minutes at 60°C (140°F).<sup>7</sup>

## Mastitis of Mares

Mastitis in mares is generally regarded as rare, but it might be more common in breeding animals than has previously been recognized. The percentage of mastitis in breeding mares is about 5% and is most common during udder involution, but lactating and juvenile mares as well as suckling foals are also affected.<sup>1</sup> *C. pseudotuberculosis*, *P. aeruginosa*, *S. zooepidemicus*, *S. equi*, *S. pyogenes*, *S. aureus*, *E. coli*, *Klebsiella* spp., and *Neisseria* spp. can cause the disease.  $\beta$ -Hemolytic streptococci have been found in the milk of many normal, just-foaled mares. Mastitis in non-lactating mares can be caused by *S. aureus* and evident as chronic, draining abscessation (botryomycosis).<sup>2</sup> Predisposing factors, other than lactation, are not identified. Mastitis can be traumatic (as a result of a kick), extension of an abdominal incision into the mammary gland, secondary to teat suckling of nonlactating mares, and in filly foals.<sup>3</sup>

Other causes of mammary gland enlargement in mares include fungal infection, neoplasia (lymphoma, adenocarcinoma), and idiopathic causes.<sup>4,5</sup>

Clinical cases occur at any time during the lactation and many occur in nonlactating mares. Many mares with typical signs of severe swelling and soreness of the udder, but without abnormal milk, are first observed when a sick foal has not suckled for 24 hours. In streptococcal mastitis there may be severe local pain and moderate systemic signs. In most cases both halves are affected.

The milk, or udder secretions, are usually abnormal. Cell counts exceeding 100,000 cells/mL during lactation and 400,000 cells/mL during involution are regarded as abnormal.<sup>1</sup>

Severe cases, sometimes accompanied by fever, depression, and anorexia, show swelling, pain, and heat in the affected half, and ventral edema and clots in the milk; the mare is lame in the leg on the affected side. Gangrene and sloughing of the ventral floor of a gland can occur.

Because of the high frequency of gram-negative bacteria as causative agents in mares, treatment should include a broad-spectrum antibiotic in an intramammary infusion plus parenteral antibacterial treatment such as with gentamicin-penicillin or trimethoprim-sulfonamide combinations. Hot packs and frequent milking are also recommended.

## Postpartum Dysgalactia Syndrome of Sows

PPDS is a failure to provide sufficient colostrum and milk to piglets during the early stages of lactation. It is usually not accompanied by inflammatory lesions. A whole variety of names have previously been given to this complex syndrome including the mastitis-metritis-agalactia (MMA) syndrome. (The term mastitis-metritis-galactia was originally developed to describe sows with agalactia that had swollen udders, assumed to be caused by mastitis, and the appearance of a vulval discharge, assumed to be caused by metritis.) Progress in this field has only been made possible by the efforts of Guy-Pierre Martineau and Chantal Farmer and their colleagues. Most practicing veterinarians might now recognize MMA as the most serious version of PPDS in which there is clinical mastitis or metritis or recognizable toxemia, but there are many more cases of PPDS than there are MMA.

### ETIOLOGY

The etiology is unclear and complex. Lactation is a very complex physiologic process. Many factors are involved, but they all result in a disturbed gilt or sow that is unable to deliver a proper colostrum/milk supply through adverse hormonal, biochemical, (collectively been called dys-homeorhesis), farrowing, and nursing responses (collectively called behavioral responses). There are four main areas that are involved in the PPDS syndrome:

- Toxemia: The sow may contribute toxins from the gut following constipation, from the bladder following cystitis, from the mammary gland following mastitis, and from the uterus following endometritis postfarrowing.<sup>1</sup> The levels of toxins may also be affected by low

feed intake, low water intake, stress, lack of exercise, overfeeding in late gestation, and inadequate vitamin E levels.

- Bad management of the gilt in preparation for farrowing by incorrect feeding: This happens by moving at the wrong time and because of new social groupings. This may be complicated by the effects of moving sows into crates from loose housing, etc., and poor environment (too hot for sows, rarely too cold). These factors distress the sow, cause stress, and affect lactation through neurophysiologic mechanisms.
  - The sow may be too fat, over muscled, or undergoing inflammation as a result of disease or toxemia or be in pain or suffering from anorexia as a result of a multitude of factors. She may not have developed the normal mammary development to sustain the required level of lactation, which may in part be from genetics.
  - Colostrum and milk production may be faulty for a whole variety of reasons that lead to the individual piglet not receiving sufficient colostrum and/or milk. A major problem in the determination of the etiology is the difficulty of being precise in the description of the clinical findings of the abnormal mammary glands of affected sows. The common clinical findings are swelling of the glands, agalactia, toxemia, and fever. There is a very considerable farm effect in the appearance of the condition because sow care and management are so individual and important. There is considerable overlap in the clinical findings from one affected sow to another, but the lesion present in the mammary glands may vary from uncomplicated physiologic congestion and edema to severe necrotizing mastitis.
- Ringarp published the classic work on this disease based on 1180 cases of postparturient illness in sows in which agalactia was present. At least five causes of agalactia or hypogalactia were recognized, which are as follows (the incidence of each group as a percentage of the total cases is given in parentheses):
- Eclampsia (0.6%), usually of older sows, responding to calcium and magnesium therapy
  - Failure of milk ejection reflex (3.3%), affecting primarily first-litter gilts and usually treated satisfactorily with oxytocin
  - Mammary hypoplasia (1.5%) in gilts, resulting in deficient milk secretion
  - Primary agalactia (6%), in which reduced milk supply is the only abnormality
  - Toxic agalactia (88.6%), the most important numerically and economically. It is characterized by

anorexia, depression, fever, swelling of the mammary glands, and a course of 2 to 4 days. Mastitis was commonly present, but there was no evidence of metritis.

### Mastitis

Postweaning mastitis is not uncommon after drying off. Chronic mastitis as a result of traumatic contact between udders and dirty infected floors or traumatic piglets' teeth resulting in abscesses, granulomas, and fibrous udders at weaning or after are also common. Where there are damaged glands sows are not usually agalactic but they may be producing less.

In many instances, traumatic injury from unclipped piglets' teeth and infected sawdust bedding are factors in mastitis in sows. Quite often, the condition occurs in the first 3 days postpartum and in many cases, if severe and untreated, will lead to the death of sows. Infectious mastitis is suggested as a major cause in many clinicopathologic investigations, and there is a greater incidence of intramammary infection in PPDS-affected sows compared with normal sows. Peracute mastitis in sows is readily recognized as a clinical entity, but less severe infections may result in small foci of inflammation within the gland that cannot be detected on clinical examination. Single gland mastitis is uncommon except when there are particularly vindictive piglets causing severe teat trauma. Glands may then become unusable, and this may cause more piglet pressure on available teats and functional glands, which may in turn increase the trauma to the remaining glands and accelerate the process. Mastitis is recognizable clinically by inflammation, edema, skin congestion, pyrexia, and inappetence in the sow and failing piglets. Gram-negative organisms predominate (*E. coli*, *Enterobacter*, and *Klebsiella* spp.), but there are also gram-positive organisms (streptococci and staphylococci).<sup>2</sup> *E. coli* and *K. pneumoniae* have been recovered from the mammary glands of naturally affected cases, and both bacterial species are associated with histopathological changes of mastitis. Experimental intramammary inoculation of sows with field isolates of *E. coli* and *K. pneumoniae* has resulted in cases of lactation failure and mastitis that closely resemble naturally occurring cases. Unfortunately, they cannot always be demonstrated. *Streptococcus* spp. and *Staphylococcus* spp. have also been isolated, but these are frequently isolated from healthy glands not associated with pathologic changes. It is unlikely that *Mycoplasma* spp. are important.

Coliforms are the most significant pathogens isolated from sows with mastitis. Coliform mastitis is often the most visible of the disorders involved in this syndrome.<sup>3,4</sup> In the second study, there were no differences in virulence genes demonstrated in the *E. coli* from healthy sows and sows with mastitis.

Pathologic examination of affected sows that were euthanized within 3 days after parturition revealed the presence of varying degrees of mastitis, and *E. coli* and *Klebsiella* spp. were the most common organisms recovered. A recent study has shown that *E. coli* strains from mastitis in sows are highly variable in serotype, biochemical profile, virulence factors, and random amplified polymorphic DNA (RAPD) type. No relationship between serotypes, virulence factors, and RAPD types was found. Toxic agalactia can be produced experimentally by the introduction of *E. coli* endotoxin into the mammary gland of sows at parturition. The clinical, hematologic, and serum biochemical changes are similar to those that occur in naturally occurring cases of toxic agalactia. *E. coli* endotoxin acting at the level of the hypothalamus can suppress prolactin release, which results in a pronounced decline in milk production. Experimental *Klebsiella* mastitis in sows is an excellent model for the study of toxic agalactia because of infectious mastitis.

Agalactia may also be the result of a deficiency of prolactin. Prolactin levels may be dramatically reduced by even the smallest amounts of endotoxin. Any factor that interferes with the release of prostaglandin from the uterus may affect the increase in prolactin that must occur to stimulate lactogenesis immediately before parturition.

In summary, field observations have suggested many different causes and predisposing factors, including infectious mastitis, nutritional disturbances, metabolic disorders, and the stress of farrowing in total confinement in a crate. Based on the examination of spontaneously occurring cases, infectious mastitis appears to be a major cause. Both prolactin and oxytocin release can be stopped by stressors and toxins from bacteria such as *E. coli*.

### EPIDEMIOLOGY

#### Occurrence

PPDS is most common in sows at farrowing or within the first 48 hours after parturition, and in sows that farrow in crates indoors. A peak incidence during the summer months has also been observed. The disease will often occur in one batch and then disappear again for months.

#### Morbidity and Case Fatality

Morbidity and mortality data are not readily available or precise because of the difficulty of making a reliable clinical diagnosis. Epidemiologic observations indicate that the risk of sows developing toxic mastitis increases with increasing age up to the third or fourth litter. The population incidence of toxic agalactia ranges from 4% to 10% of all farrowings, whereas the herd incidence may vary from 0% to 100%. A recent study in Denmark<sup>5</sup> suggested that 32.5% of sows on the first day of farrowing, 31.5% on the second day, and 10.1% on the third

day after farrowing were affected (using the criteria of inappetence, reddened or swollen mammary glands, and temperature over 39.4°C; 102.9°F).

The fatality rate in sows is usually less than 2%, but piglet losses caused by starvation and crushing may be as high as 80%. The disease does not usually recur in the same animal, and this suggests that immunity develops and sows should not necessarily be culled.

### RISK FACTORS

#### Feed

The risk factors that have been proposed based on field observations include overfeeding during pregnancy and a drastic change of feed at farrowing.

Reduced feeding on the day of farrowing followed by an increase over the first week of lactation reduces PPDS,<sup>6</sup> and a fish diet before farrowing improves feed intake after farrowing.<sup>7</sup> It is best to switch diets 7 days before farrowing.

Constipation of the sow at farrowing<sup>8</sup> has been suggested as a cause of PPDS. Higher rates of PPDS do occur in constipated sows, which may be associated with pain.<sup>9</sup> However, clinical and pathologic examinations of both spontaneously occurring cases of agalactia and experimental agalactia induced by the introduction of *E. coli* endotoxin into the mammary gland have been unable to support the observation of constipation. Both sick and normal sows defecate less frequently from 1 day before farrowing until 2 days later. There is no difference in the weight of feces in the terminal colon and rectum between sick and normal sows.

Digestive disturbances and certain feeding practices have been associated with the disease. Sows that have been on high-level feeding during pregnancy appear to be susceptible to the disease, especially if they are subjected to a change of feed immediately before parturition. Also, any management practice that results in a marked change in feed intake at or near farrowing may appear to precipitate the disease. A sudden change of feed severe enough to result in gastrointestinal stasis has been used to reproduce the condition experimentally.

The effects of different feed allowances during late pregnancy may affect the incidence rate of the disease. Feeding sows during the last 15 days of gestation a diet at a level of 3.4 kg daily compared with 1.0 kg daily resulted in an incidence rate of 26.6% and 14.0%, respectively. The explanation for the effects of feeding is unknown. It has been proposed that intense feeding may promote toxin production in the alimentary tract, but how this is related to mastitis is unknown. Another hypothesis suggests that increased feeding in late gestation may intensify the initiation of lactation and result in udder engorgement and increased susceptibility to intramammary infection. A further

suggestion is that moldy food may play a part, but this has never been proven.

The clinical status of the mammary glands, the bacteriologic findings, and the total cell count and its percentage of polymorphonuclear leukocytes and pH in colostrum and milk secretion during the first 3 weeks of lactation of sows on high- or low-feeding regimes during late pregnancy have been examined. *E. coli* infection was present in 80% of the sows affected with toxic agalactia and 30% of the healthy sows. The *E. coli* were eliminated at between 3 and 8 days of lactation and were not isolated from sows examined at the time of weaning. The different feeding regimes did not influence the total cell count, the polymorphonuclear cells, or the pH in milk from bacteriologically negative glands or glands with *E. coli* mastitis. The two feeding regimes had no influence on total cell count, the percentage of polymorphonuclear cells, or the pH of colostrum and milk of healthy sows.

The only mycotoxin found to be important in PPDS was shown to be ergot,<sup>10</sup> which probably affects prolactin production. Insufficient water may also be a factor. Omega 3 reduces inflammation and omega 6 increases inflammation.

A variety of ingredients may influence PPDS; probiotics reduce PPDS, as do formic acid, lactulose, and fermented potato protein.

### Housing

Moving sows only 4 days before farrowing has been associated with more PPDS than moving them at 7 days.<sup>6</sup> Housing sows so that they can in fact nest rather than placement in crates may reduce PPDS.<sup>8</sup> Houses that are too hot encourage sows not to eat.

### Management

Insufficient time for the sow to adjust to the farrowing crate after being transferred from the gestation unit is thought to be an important factor, as is the induction of farrowing.<sup>7</sup> Frequent supervision of farrowing sows may reduce the problems of PPDS. Cross-fostering may also help.<sup>11</sup>

The disease occurs under management, environmental, and sanitation conditions ranging from very poor to excellent; however, the possible relationship between the level of bacterial contamination in the farrowing barn and on the skin of the sow and the incidence of the disease has apparently not been examined. Dirty conditions greatly increase the bacterial contamination of the udder. Environmental or other animal noises and disturbances and uncomfortable farrowing crates are potential PPDS factors.

### Animal Factors

The initiating factors have not been identified. The incidence of the disease may be higher in sows with larger litters than sows in the same herd that remain healthy and in those with a higher number of stillbirths and

pigs found dead after birth. Long gestation and long farrowing times increase the incidence of PPDS. It is more common in young sows and relatively rare in older sows. Low exercise has also been suggested as a cause, and this also contributes to constipation. The role of water intake or lack of it and stress or disturbance during parturition has also not been investigated. This may also contribute to the fat sow and the over muscled sow syndrome,<sup>12,13</sup> which may also contribute to PPDS.

The nursing behavior of the sow and the suckling behavior of the piglets may provide an explanation for the pathogenesis and clinical findings of some cases of agalactia in sows. Successful ejection of milk by the sow is dependent on proper stimulation of the sow's udder by the piglets followed by a complex response by the sow. A period of time ranging from 15 to 45 minutes must elapse from the last successful milk ejection to the next. Failure of milk ejection may occur in up to 27% of sows that attempt to suckle their piglets within 40 minutes after the previous milk ejection. The failure of milk ejection in sows within the first few crucial adjustment days after farrowing might possibly contribute to the cause of mastitis and engorgement of the mammary glands.

The over fat sow has a lower glucose tolerance postpartum with a lower appetite, and drinks less and lies down more. The sow may have already switched to a catabolic state at or before farrowing using body reserves to produce milk.<sup>14</sup> Just before farrowing the circulating levels of nonesterified fatty acids also rise,<sup>8</sup> which indicates a catabolic state. There may also be a resistance to insulin at farrowing if there have been high levels of energy fed in late pregnancy.<sup>15</sup>

### Microorganisms

Each section of the mammary gland of the sow is divided into a separate rostral and caudal section, each with its own teat cistern and teat canal. In a sow with 14 teats there are 28 potential portals of entry, so mastitis is common immediately after parturition when the teat canals have become patent. Bacteria in the gut and in endometritis have been proposed as a source of endotoxin, particularly as  $\beta$ -hemolytic streptococci and coliforms have been associated with the condition.

Some clinicopathologic examinations of affected sows have revealed the presence of a slightly enlarged, flaccid uterus from which coliform and streptococcal organisms can be recovered. However, pathologic evidence of metritis in affected sows is uncommon; the organisms that can be recovered are common in the reproductive tract of normal sows after parturition, and their recovery from vaginal mucus is difficult to interpret.

### PATHOGENESIS

The pathogenesis of infectious mastitis caused by *E. coli* or *Klebsiella* spp. is probably

similar to that of bovine mastitis in which the infection gains entry through the teat canal and invades the mammary tissue causing mastitis. Endotoxemia accounts for the fever initially as well as for the depression, anorexia, and agalactia, even in glands that are unaffected. The lipopolysaccharide endotoxins acting at the level of the hypothalamus and hypophysis suppress the release of prolactin, which results in a marked decline in milk production. The endotoxin may also have a direct inhibitory effect on the mammary gland. There is a higher prevalence of bacterial endotoxin in the blood of affected sows compared with control animals. The endotoxin can be detected in the blood of about 33% of sows affected with coliform mastitis. However, the oral administration of endotoxin daily to prepubertal gilts did not result in any clinical abnormalities. Experimentally, mastitis can be produced in sows by contamination of the skin of the teats with *K. pneumoniae* either shortly before or after parturition. The clinical signs are similar to those described for MMA; mastitis is present in more than 50% of the mammary gland subsections, and a marked leukopenia and degenerative left shift occurs. A total of 120 organisms is sufficient to produce the mastitis when the organisms are inoculated into the teats. In recent experimental infections with *E. coli* it was shown that the time of infection of the mammary gland relative to parturition and the number of circulating neutrophils at the time of infection influenced the development of clinical coliform mastitis in the sow. Similarly, parturition allows the penetration of vaginal organisms into the reproductive tract, and the absorption of endotoxin reduces F2 $\alpha$  in the uterus. This stimulates prolactin, which may contribute to the hypogalactia and agalactia.

### CLINICAL FINDINGS

At one extreme is the sow that has no signs but has poor growth in piglets,<sup>16</sup> and this may have meant that colostrum provision has failed and not been noticed until the piglets begin to fade away. At the other extreme is a severely affected sow with high mortality in piglets.

PPDS occurs in sows between 12 and 48 hours (sometimes 72 hours) after farrowing and is characterized clinically by anorexia, lethargy, restlessness, lack of interest in the piglets, fever, swelling of the mammary glands (udder edema), and agalactia. Most affected animals respond to therapy within 12 to 24 hours. Pathologically, there are varying degrees of mastitis. In some sows the level of oxytocin may be half the level in unaffected sows. The disease is of major economic importance when outbreaks occur because the inadequate milk production leads to high piglet mortality from starvation and secondary infectious diseases. In cases of subclinical MMA there is often a failure to achieve weaning weights (<4 kg at 24 days).

Necropsy of spontaneously occurring cases has frequently confirmed the presence of mastitis, but the incidence of metritis has been insignificant.

The prevalence of the condition appears to have reduced recently with the increased attention to hygiene in the farrowing house and the use of more porous and less traumatic floorings. When it does occur it can be quite common, with up to 11% to 58% of the sows affected. A recent case definition suggests that the pathognomonic signs are poor piglet growth and sow rectal temperatures greater than 39.5°C (103.1°F).

Sometimes there may be a delay in parturition of more than 5 hours. The sow is usually normal, with a normal milk flow, for the first 12 to 18 hours after farrowing. Normally, the sow will suckle her piglets for about 20 seconds once an hour. One of the first indications of the disease is the failure of the sow to suckle her piglets. She is uninterested in the piglets, generally lies in sternal recumbency, and is unresponsive to their squealing and suckling demands. Litters of affected sows are noisier and are generally scattered around the pen searching for an alternative food supply. Such piglets may drink surface water or urine in the pen and infectious diarrhea may occur. If suckling is permitted, it does not progress from the vigorous nosing phase to the quiet letdown stage, and it is accompanied by much teat-to-teat movement by the piglets. Many piglets may die of starvation and hypoglycemia. A failure to grow at more than 105 g per day is a sure sign of piglet problems. Some sows are initially restless and stand up and lie down frequently, which contributes to a high mortality from crushing and trampling.

Affected sows do not eat, drink very little, and are generally lethargic. The body temperature is usually elevated and ranges from 39.5°C to 41°C (103.1°F to 105°F), especially if there is mastitis. However, there is a wide range of "normal temperatures" in newly lactating sows from 38.4°C to 40.5°C (101.1°F to 104.9°F),<sup>17</sup> but this may be lactational hyperthermia. Mild elevations in body temperatures of sows in the first 2 days after parturition are difficult to interpret because a slight elevation occurs in normal healthy sows. This is known as uncomplicated farrowing fever. However, temperatures above 40°C (104°F) are usually associated with acute mastitis that requires treatment. One detailed investigation of the disease in Sweden concluded that 78% of sows with a temperature exceeding 39.5°C (103.1°F) had clinical evidence of mastitis. It is suggested that a temperature of 39.4°C (102.9°F) at 12 to 18 hours after farrowing is an appropriate threshold at which to give preventive treatment for the disease. The heart and respiratory rates are usually increased.

Initial temperatures greater than 40.5°C (104.9°F) are usually followed by severe

illness and toxemia. Normally, the sows get better within 3 days, but not always if the temperature is very high.

Characteristic findings are present in the mammary glands including varying degrees of swelling and inflammation. In most cases, several glands are affected, which may appear as diffuse involvement of the entire udder. Individual sections (half glands) are enlarged, warm, and painful, and may feel "meaty" and lack the resilience of normal mammary tissue. There may be extensive subcutaneous edema around and between each section, which results in a ridge of edema on the lateral aspects of the udder extending for its entire length. The skin overlying the sections is usually reddened and is easily blanched by finger pressure. The teats are usually empty and may be slightly edematous. A few drops of milk may be expressed out of some teats after gentle massage of the section or the administration of oxytocin but rarely can a normal stream of milk be obtained. In severe cases of mastitis the milk contains flakes and pus or is watery.

The feces are usually scant and drier than normal, but whether or not constipation is present in most cases is uncertain. The inappetence and anorexia and failure to drink normally could account for the reduced volume of feces. Constipation with impaction of the rectum with large quantities of feces is uncommon in sows, and when it does occur as the only abnormality it has little effect on appetite and milk production.

A vaginal discharge is normal following parturition, and normal sows frequently expel up to 50 ml of a viscid, nonodorous, and clear mucus that contains variable amounts of white material within the first 3 days following farrowing. Tenacious strands of this discharge may also be observed within the vagina. The presence of this discharge has been misleading and has been interpreted as evidence of the presence of metritis. Necropsy examination after euthanasia of affected sows has failed to reveal evidence of significant metritis. The clinical diagnosis of metritis in sows is difficult, but generally large quantities of dark-brown, foul-smelling fluid are expelled several times daily, accompanied by severe toxemia. This is uncommon in sows. Diagnosis is usually made on clinical signs.

## CLINICAL PATHOLOGY

### Examination of Milk

The number of somatic cells in the milk from sows with mastitis will range from 2 to 20 × 10<sup>9</sup> cells/mL compared with the normal of less than 2 × 10<sup>9</sup> cells/mL. Significant numbers of bacteria are present in the milk of more than 80% of sows with toxic agalactia. Milk obtained for laboratory examination and culture should be taken after thorough cleaning and disinfection of the teats to minimize contamination by skin flora. However, because mastitis may be

present in only one or a few of the mammary gland subsections in the sow and because it is often impossible to clinically identify affected subsections and distinguish them from unaffected adjacent glands, which may be swollen and agalactic because of continuous swelling, a valid assessment of intramammary infection is not possible unless milk samples are obtained from each subsection. Subclinical mastitis may not be easy to detect with cells not reaching 2 × 10<sup>9</sup> cells/mL but 75% may be polymorphs. Normally, milk is around 1 × 10<sup>9</sup> cells/mL.

## Hematology and Serum Biochemistry

Some hematologic and biochemical changes are present in affected sows but may not be marked enough to be a routine reliable diagnostic aid. In severe cases of infectious mastitis, a marked leukopenia with a degenerative left shift is common. In moderate cases there is a leukocytosis and a regenerative left shift. The serum biochemical changes that occur in naturally occurring cases and in the experimental disease are recorded. The plasma cortisol levels are commonly elevated, which may be caused by a combination of the stress of parturition and infectious mastitis. The plasma protein-to-fibrinogen ratio is lower than normal, and the plasma fibrinogen levels are commonly increased in severe cases that occur 8 to 16 hours after parturition.

## NECROPSY FINDINGS

Lesions in the udder and the reproductive tract are not consistent. If they are found, the most important lesions are in the mammary gland. There may be extensive edema and some slight hemorrhage of the subcutaneous tissue. Grossly, on cross-section of the mammary tissue there is focal to diffuse reddening and often only one subsection of a mammary gland may be affected. Histologically, the mastitis may be focal or diffuse in distribution, and the intensity of the lesion varies from a mild catarrhal inflammation to a severe purulent and necrotizing mastitis usually involving more than 50% of all the mammary glands. There are no significant lesions of the uterus compared with the state of the uterus in normal healthy sows immediately after parturition. The adrenal gland is enlarged and heavier than normal, presumably caused by adrenocortical hyperactivity. In a series of spontaneous cases, *E. coli* and *Klebsiella* spp. were most commonly isolated from the mammary tissues. The abscesses of the mammary glands of sows examined at slaughter are not sequelae to coliform mastitis but rather probably caused by injuries and secondary infection.

## Samples for Confirmation of Diagnosis

- Bacteriology: mammary gland, regional lymph node
- Histology: formalin-fixed mammary gland

## DIFFERENTIAL DIAGNOSIS

The characteristic clinical findings in toxic mastitis and agalactia are a sudden onset of anorexia and lack of interest in the piglets, acute swelling of the mammary gland, hypogalactia or agalactia, a moderate fever, and a course of about 2 days. The mammary secretion from mastitic glands may be watery or thickened and contain pus, and the cell count will be increased up to  $20 \times 10^9$  cells/mL. The acute swelling and agalactia of infectious mastitis must be differentiated from other noninfectious causes of acute swelling or “caking” of the mammary glands, which also results in agalactia as follows:

- Agalactia caused by a failure in milk letdown is most common in first-litter gilts and is characterized by a fullness of the mammary glands but an inability of the gilt to suckle her piglets in spite of her grunting at them. The gilt is usually bright and alert and systemically normal. The response to oxytocin is dramatic, and repeat treatment is rarely necessary.
- Farrowing fever is characterized clinically by loss of appetite, inactivity, and a body temperature of  $39.3^\circ\text{C}$ – $39.9^\circ\text{C}$  ( $102.7^\circ\text{F}$ – $103.8^\circ\text{F}$ ) with minimal detectable changes of the mammary gland.
- Parturient psychosis of sows is characterized by aggressive and nervous behavior of the sow after the piglets are born. The sow does not call the piglets, and does not allow them to suck. When the piglets approach the sow's head, she will back away, snap, and make noisy staccato nasal expirations. Some sows will bite and kill their piglets. The mammary gland is usually full of milk, but the sow will not let it down. Ataractic drugs and/or short-term general anesthesia are indicated, and the response is usually excellent. Some sows need repeated tranquilization or sedation for the first few days until the maternal–neonatal bond is established.
- Other causes of agalactia accompanied by enlargement of the mammary gland include inherited inverted teats and blind teats caused by necrosis of the teats occurring when the gilt was a piglet. These are readily obvious on clinical examination. The sharp needle teeth of piglets may cause the sow to refuse to suckle her piglets. The sow attempts to suckle but leaps up suddenly, grunting and snapping at the piglets. The piglets squeal and fight to retain a teat, thus causing more damage to the teats, which is obvious on clinical examination. Other causes of agalactia accompanied by systemic illness include retained piglets and infectious disease such as outbreaks of transmissible gastroenteritis and erysipelas. The common causes of agalactia in pigs in which there is lack of mammary development include ergotism, immature gilts, and inherited lack of mammary development.

## TREATMENT

Most affected sows will recover within 24 to 48 hours if treated with a combination of antimicrobials, oxytocin, and antiinflammatory agents. The treatment should begin when the temperature reaches  $39.4^\circ\text{C}$  ( $102.9^\circ\text{F}$ ).

Antimicrobials are indicated in most cases because infectious mastitis and metritis are two common causes of the disease. The choice is generally determined by previous experience in the herd or region, but broad-spectrum antimicrobials are indicated because *E. coli* and *Klebsiella* spp. are the most common pathogens involved. They should be given daily for at least 3 days. Usually ampicillin, tetracyclines, trimethoprim-sulfonamide, or enrofloxacin is used.

As soon as possible after the disease is recognized every effort must be made to restore normal mammary function through the use of oxytocin and warm water massaging of the affected mammary glands.

Oxytocin 30 to 40 U intramuscularly or 20 to 30 U intravenously is given, frequently, to promote the letdown of milk. If there is a beneficial response the piglets should be placed on the sow if she is willing to allow them to suck. This will assist in promoting milk flow. Massage of the mammary glands with towels soaked in warm water and hand milking for 10 to 15 minutes every few hours may assist in reducing the swelling and inflammation and promote the flow of milk. It will also relieve the pain and encourage the sow to suckle her piglets. Intramuscular injections of oxytocin may be repeated every hour, along with massaging of the glands with warm water. Failure of milk letdown or a low response following the use of oxytocin may be caused by a reduced sensitivity of the sow to oxytocin during the first week of lactation. In the normal, healthy sow the peak response to oxytocin occurs in the second week of lactation and gradually decreases to a low response by the eighth week.

Oxytocin has an effect for about 14 minutes, whereas the long-acting analog has an effect for about 6 hours. Preliminary results of its use in agalactic sows indicate superior results compared with oxytocin.

Antiinflammatory agents are commonly used for their antiinflammatory effect but are rarely used on their own; flunixin meglumine has been shown to be beneficial as well as ketoprofen<sup>18</sup> to alleviate pyrexia and endotoxemia. Recently meloxicam and oxytocin were shown to reduce mortality compared with flunixin. Plasma cortisol levels are increased in the experimental disease and for this reason may be contraindicated. However, field reports suggest that their use along with antimicrobials and oxytocin provides a better response than when they are not used. Corticosteroids used alone do not appear to prevent the disease or enhance recovery. To be effective they must be used in combination with antimicrobials and oxytocin.

Dexamethasone at the rate of 20 mg intramuscularly daily for 3 days for sows weighing 150 to 200 kg has been recommended.

Sows with toxemia almost invariably dehydrate, so fluid therapy is essential.<sup>19</sup>

## Supplementation of Piglets

The hypoglycemic piglets must be given a supply of milk and/or balanced electrolytes and dextrose until the milk flow of the sow is resumed, which may take 2 to 4 days, and most importantly they must be kept warm until body reserves are reestablished. Piglets should receive 300 to 500 mL of milk per day divided into hourly doses of 40 to 50 mL given through a 12- to 14-French plastic tube passed orally into the stomach. A solution of balanced electrolytes containing 5% glucose can also be given for 1 to 2 days if a supply of cows' milk is not available. Intraperitoneal injection of 15 mL of 5% glucose will prevent starvation. Condensed canned milk diluted with water 1:1 is a satisfactory and readily available supply of milk. In severe cases in which the return to milk production and flow are unlikely, the piglets should be fostered onto other sows. If these are unavailable, the use of milk substitute fortified with porcine gamma globulin is recommended to prevent the common enteric diseases. This is discussed under colibacillosis. Many more piglets are treated for diarrhea when the sows are treated for MMA, perhaps up to 19% compared with up to 9% normally.

## CONTROL

It is necessary for modern pig farms to develop control measures<sup>6,20</sup> and to assess the six major areas outlined previously.<sup>21</sup> It has been difficult to develop a rational approach to control because the disease has been considered to be a complex syndrome caused by several different factors. However, the control of infectious mastitis would seem to be of major importance. The routine use of antibiotics and oxytocin without indication does not appear to be helpful. Farrowing crates should be vacated, cleaned, disinfected, and left vacant for a few days before pregnant sows are transferred from the dry sow barn and placed in the crates. Pregnant sows should be washed with soap and water before being placed in the crate. Farrowing crates must be kept clean and hosed down if necessary, particularly a few days before and after farrowing to minimize the level of intramammary infection. In problem herds, it may be necessary to wash and disinfect the skin over the mammary glands immediately after farrowing. All-in/all-out in the farrowing area with proper cleaning and disinfection facilitated by batch farrowing will reduce the disease. An opportunity for exercise will help, because under outdoor conditions (sows in paddocks) the condition is rare.

To minimize the stress to the sow of adjusting to the farrowing crate and the farrowing facilities, the sow should be placed in

the crate at least 1 week before the expected date of farrowing.

The nature and composition of the diet fed to the sow while in the farrowing crate should not be changed. To minimize the risk of toxic agalactia, it is recommended that the daily feed allowance be related to body condition score. It may be necessary to reduce the feed to 1 kg/day (from 100 days' gestation) before farrowing. The daily intake (compared with the intake during the dry period) may be increased on the day after the sow has farrowed and in increments thereafter as the stage of lactation proceeds. The inclusion of bran at the rate of one-third to one-half of the total diet for 2 days before and after farrowing has been recommended to prevent constipation. In some herds the use of lucerne meal or other vegetable protein at the rate of 15% of the diet may help control the disease. However, under intensified conditions it may be impractical to prepare and provide these special diets on a regular basis. Although field observations suggest that a bulky diet at the time of farrowing will minimize the incidence of toxic agalactia, there is little scientific evidence to support the practice.

Antimicrobial agents used prophylactically have apparently been successful in controlling some outbreaks. A trimethoprim-sulfadiazine and sulfathiazole combination at 15 mg/kg in feed from day 112 of gestation to day 1 after farrowing may reduce the prevalence. Using oxytocin early may also help. In a recent study where *E. coli*, streptococci, and staphylococci were the most cultured pathogens, marbofloxacin (10% solution) was found to be superior to amoxicillin. All *E. coli* were susceptible to the former, but 32% were resistant to the latter antibiotic.

The use of prostaglandins for the induction of parturition in sows has not been associated with a marked consistent change in the incidence of the disease. Some field trials have shown a reduction, whereas others have had no effect.

## Diseases of Complex or Undetermined Etiology

### COLD COW SYNDROME

Cold cow syndrome is a herd disease problem reported only from the United Kingdom in the early 1980s in cows freshly turned out onto lush pasture with a high (27% to 43%) soluble carbohydrate content. There is a high morbidity (up to 80%) and a large number of outbreaks in an area. The syndrome includes hypothermia, dullness, inappetence, agalactia, and profuse diarrhea. Affected cows feel cold to the touch. Some have perineal edema; some collapse. The herd milk yield falls disastrously, but there is a quick return to normal if the cows are moved to a different field. The problem may occur on the same pasture each year and recur if the cows are returned to the same pasture. There is no obvious clinicopathologic abnormality. It is postulated that the syndrome might be a result of zearalenone or related metabolites produced by microfungi in the pasture.

### RECUMBENCY IN HORSES OF UNDETERMINED ETIOLOGY

Diagnosis and management of adult horses that are recumbent can be challenging. The large size of adult horses, the variety of conditions that can cause recumbency, the difficulty in performing a thorough clinical examination, and the need for prolonged and intensive care all present formidable obstacles to management of recumbent horses. Causes of prolonged (>8 h) recumbency in horses are listed in Table 21-1. Other causes of acute recumbency of shorter duration are usually obvious on initial examination.

### EPIDEMIOLOGY

The epidemiology of recumbent horses is covered in detail in the sections dealing with each of the specific diseases, and information on large series of recumbent horses is sparse. Overall, for 148 horses treated in a referral veterinary hospital with excellent resources and expertise to manage recumbent horses, there were 109 nonsurvivors and 39 survivors (case-fatality rate of 74%). Odds of death within the first 3 days of hospitalization increased with longer duration of clinical signs before presentation, with horses showing clinical signs for over 24 hours being 4.16 (95% confidence interval [CI] 1.04 to 16.59) times more likely to die; presence of band neutrophils (odds ratio [OR] 7.9, 95% CI 1.39 to 45.5); not using the sling (OR 4, 95% CI 1.1 to 15.7); and horses that were unable to stand after treatment (OR 231, 95% CI 23 to 2341). Increasing cost was associated with lower odds of death (OR 0.96, for each additional \$100 billed, 95% CI 0.93 to 0.99), likely because of greater financial resources increasing the chance of success.<sup>1</sup>

There does not appear to be any breed, age, or sex distribution beyond that anticipated for the specific diseases.

### EXAMINATION OF THE RECUMBENT HORSE

#### History

Careful questioning of the horse's attendants can reveal valuable information regarding the cause of recumbency. Causes such as observed trauma, foaling, and excessive unaccustomed exercise are readily determined from the history. In addition to inquiries about the cause of the recumbency, estimates of the duration of recumbency should be obtained from the attendants. This can often be best elicited by asking when the horse was last observed to be standing. A history of recent illness, abnormal behavior or unusual use immediately before the horse became recumbent is useful. The horse's age, sex, breed, and use should be determined. Information regarding management, vaccination and deworming status, feeding, and health of other horses can be revealing. Outbreaks of recumbency suggest either an infectious (equine herpesvirus-1) or toxic (botulism, ionophore) cause. Questions should be directed toward discerning the cause of the horse's recumbency rather than collecting information.

#### Physical Examination

Physical examination of recumbent horses is challenging but should be as complete as practical and safe. The examination should begin with a general assessment of the horse and its surroundings and can be directed at answering a series of questions:

- Are the surrounding conditions safe for the horse and people? Is the footing sound?
- Is there evidence of the horse struggling or thrashing?
- Has the horse defecated and urinated recently?
- Is there evidence of exposure to toxins or physical evidence of the reason for recumbency?

Examination of the horse should begin with measurement of heart rate, respiratory rate and temperature (rectal temperature might not be accurate if there is dilation of the anus), examination of mucous membranes and an assessment of its hydration, body condition and level of consciousness. The horse should be thoroughly examined for evidence of trauma. Although the examination should be complete, initial examination of cases for which the cause of recumbency is not immediately obvious should focus on the nervous and musculoskeletal systems.

- Is the horse alert and able to sit in sternal recumbency, or is it unconscious and in lateral recumbency? Can the horse rise with assistance?
- Is the horse's mentation normal?

- Are there any spontaneous voluntary or involuntary movements?
- Can the horse eat and drink?
- Are the cranial nerves normal?
- Is there evidence of trauma to the head or neck?
- Is there evidence of paresis or paralysis? Are only the hindlimbs involved, or are both the hindlimbs and forelimbs involved?
- Are the peripheral reflexes normal (withdrawal, patellar, cervicofacial, cutaneous, anal, penile)?
- Is cutaneous sensation present in all regions? If not, what are the anatomic boundaries of desensitized areas?
- Is the position of the limbs normal? Is there evidence of crepitus, swelling, or unusual shape of the limbs or axial skeleton?
- Are the horse's feet normal? Does it have laminitis? What is the response to application of hoof testers?
- Are abnormalities detected on rectal examination (fractured pelvis, distended bladder, fecal retention, pregnancy), provided that it is safe to perform one?

Other body systems should be evaluated as indicated or necessary. The heart and lungs should be auscultated, although detecting abnormal lung sounds in a recumbent horse is difficult. The horse should be rolled and thus a complete examination can be performed. Assisting the horse to stand using a rope tied to the tail and thrown over a rafter, or preferably using a sling, can be useful in assessing the severity of the horse's illness (i.e., can it stand at all?) and in facilitating a complete physical examination. If there is a suspicion that the horse has colic, a nasogastric tube should be placed to check for accumulation of liquid gastric contents, a rectal examination performed, and peritoneal fluid collected.

**Ancillary diagnostic** testing includes radiography of limbs and/or axial spine as indicated by the history or physical examination, myelography if a compressive lesion of the cervical spinal cord is suspected, endoscopic examination of the pharynx and guttural pouches (especially in horses with a history of falling; see section on rupture of the longus capitis muscle), ultrasonography of the chest and abdomen, collection of cerebrospinal fluid, and electromyography.

Hematologic abnormalities are sometimes reflective of the causative disease. Serum **biochemical abnormalities** are reflective of the causative disease and in addition are influenced by muscle damage caused by the horse being recumbent (increased creatine kinase and aspartate aminotransferase activity), inappetent (increased total and indirect bilirubin and triglyceride concentrations), and unable to drink or gain access to water (increased serum urea nitrogen, creatinine, sodium, chloride, total protein, and

**Table 21-1** Causes and diagnostic features of recumbency of more than 8 hours in duration in adult horses

Cause	Clinical signs and diagnosis	Treatment	Prognosis and comments
<b>Neurologic disease</b>			
Botulism <sup>3</sup>	Horse alert. Flaccid paralysis, dysphagia, weak corneal or palpebral reflex.  Often multiple animals affected. Toxin isolation in mice.	Administration of specific antitoxin or multivalent antitoxin.  Supportive care.	Can require prolonged treatment. Prognosis poor for recumbent horses.
Tetanus	Horse alert. Rigid paralysis. Signs worsened by stimuli. Often history of recent wound and lack of vaccination.	Tetanus antitoxin (IV or intrathecally). Penicillin. Wound debridement. Sedation (acepromazine, chloral hydrate). Minimize stimulation (dark, quiet stall).	Guarded prognosis.
Trauma—vertebral	Alert horse. Signs depend on site of lesion. Can be difficult to detect vertebral fractures in adult horses. Radiography.	None specific.	Poor prognosis.
Trauma—cranial	Unconscious or severely altered mentation. Seizures. Head wounds. Blood from ears and nostril. Imaging (radiography, CT, MRI).	Antiinflammatory drugs including flunixin meglumine, phenylbutazone, corticosteroids. Drugs to reduce swelling (mannitol and hypertonic saline). Control of seizures (diazepam, midazolam, barbiturates). Heroic craniotomy.	Very poor prognosis.
Cervical vertebral instability	Alert horse. Acute-onset ataxia and recumbency. Young horse (<4 years old). Radiography and myelography.	Antiinflammatory drugs. Rest. Surgical vertebral stabilization.	Poor prognosis.
Vestibular disease	Normal to depressed, depending on cause. Signs of vestibular disease include circling and falling to one side, head tilt, and nystagmus. Diagnosis by endoscopic examination of guttural pouches, radiography of skull, and examination of CSF.	Antibiotics, antiinflammatory drugs. Surgical or medical treatment of guttural pouch disease.	Poor to guarded prognosis.
Equine herpesvirus-1 myoencephalopathy	Usually alert horse. Recumbency follows period of posterior ataxia with fecal and urinary incontinence. Fever in early stages of disease. CSF xanthochromic. Viral isolation or detection of virus by PCR. Serology. Often multiple horses affected.	Supportive care. Valacyclovir or similar drug in early stages.	Guarded prognosis. Affected horses can be infectious.
Arboviral encephalitis (Eastern, Western, West Nile, Japanese B encephalitis)	Alert horse or altered mentation, depending on the disease. CSF consistent with inflammation. Viral isolation or detection by PCR. Serology.	Supportive care. Dexamethasone for West Nile encephalitis.	Epidemiology is characteristic. Prognosis is poor for recumbent horses. Vaccines available.
Migrating parasite larvae	Mentation depends on anatomic site of parasite. Eosinophils in CSF.	Ivermectin 400 µg/kg orally. Corticosteroids.	Sporadic disease.
Neoplasia (melanoma, lymphosarcoma, cholesterol granuloma)	Alert horse. Signs of spinal cord compression. Diagnosis by imaging (radiography, myelography, CT). CSF usually normal.	No specific treatment.	Hopeless prognosis.
Equine motor neuron disease	Alert horse. Good appetite. Profound muscle weakness and atrophy. Prolonged periods of recumbency but usually able to stand when stimulated.	Supportive care. Vitamin E.	Guarded to poor prognosis. Lifelong disease.
Equine protozoal myeloencephalitis	Variable mentation and signs of neurologic disease. Diagnosis based on neurologic examination and results of Western blot of CSF or serum.	Antiprotozoal medications.	Guarded to fair prognosis.
Rabies	Variable mentation. Protean signs of neurologic disease. Important zoonosis. Diagnosis by immunofluorescent antibody testing of brain.	No treatment. If suspected, then appropriate barrier isolation measures must be instituted until the horse dies or recovers, or another diagnosis is confirmed.	Rare cause of recumbency in horses.
Postanesthetic myelopathy	Acute-onset posterior paresis evident on recovery from general anesthesia.	Supportive care.	Poor to hopeless prognosis.
<b>Musculoskeletal disease</b>			
Acute rhabdomyolysis (exertional, atypical)	Alert horse. History of unaccustomed or strenuous exercise. Painful. Sweating. Firm painful muscles. Pigmenturia.  High CK and AST activity in serum.	Fluid diuresis. Pain control. Supportive care.	Guarded to fair prognosis. Can recur. Can progress to acute renal failure.

**Table 21-1** Causes and diagnostic features of recumbency of more than 8 hours in duration in adult horses—cont'd

Cause	Clinical signs and diagnosis	Treatment	Prognosis and comments
Laminitis	Alert horse. Assumes sternal recumbency easily. Bounding digital pulses. Pain on application of hoof tester to feet.	Pain control. Corrective shoeing.	Guarded to poor prognosis for long-term care.
Fracture of long bone or pelvis	Horse usually able to stand on three legs. Bilateral fracture of femurs. Diagnosis by physical examination and radiography.	Euthanasia.	
Foaling paralysis (obturator nerve paresis)	Dystocia. Mare unable to stand after difficult foaling. Legs excessively abducted.	Supportive care. Antiinflammatory drugs. Sling horse.	Guarded prognosis.
Bilateral femoral nerve paresis	Occurs in horses suspended by the hind limbs during anesthesia.	Supportive care.	Guarded prognosis.
Hyperkalemic periodic paralysis	Alert horse. Anxious. Muscle fasciculations. Muscle weakness. High serum potassium concentration. Electromyography. Unusual for recumbency to persist for < 1–2 hours. Diagnosis by detection of appropriate genome.	Administration of dextrose or calcium solutions. Prevention by administration of acetazolamide, feeding low-K <sup>+</sup> diet and selective breeding.	Guarded to good prognosis. Lifelong care needed.
<b>Environmental</b>			
Heat stress/exhaustion	Depressed mentation. Compatible history of exercise in hot and humid conditions or exposure to extreme heat. Hyperthermia.	Rapid cooling. Administration of fluids.	Guarded to poor prognosis. Death often associated with DIC.
Hypothermia	Depressed mentation. History of exposure to extreme cold. Hypothermia.	Warming. Prolonged care necessary.	Guarded to poor prognosis.
Lightning strike	Horses at pasture. History of electrical storm activity. One or more horses can be affected. There can be evidence of burns, fractures of long bones or the axial skeleton, or vestibular disease.	Supportive care. Euthanasia for animals with severe disease.	
Gunshot wounds	Horses at pasture. Often during hunting season. Can be malicious. Physical examination variable. Entry hole and exit hole can be difficult to identify.	Supportive care, depending on site of wound.	Horses that have been shot and are recumbent have a poor prognosis.
<b>Metabolic</b>			
Starvation, inanition	Alert horse. Grade 1 or 2 of 9 body condition score.	Careful refeeding and supportive care.	Poor to fair prognosis.
Hypocalcemia, hyponatremia	Depressed mentation. Seizures. Confirmed by measurement of serum electrolyte concentrations. Unusual cause of recumbency in adult horses.	Correction of electrolyte deficit. Gradual correction of hyponatremia.	Good prognosis.
Liver disease	Depressed, seizures, head pressing. Jaundice. Elevated serum concentrations of bilirubin, ammonia, and bile acids and increased activity of gammaglutamyl transpeptidase and sorbitol dehydrogenase.	Supportive care. Provision of hydration and nutrition. Correction of hypoglycemia. Administration of lactulose.	Poor prognosis. History of exposure to hepatotoxins.
Hypoglycemia	Seizures. Measurement of blood glucose concentrations. Iatrogenic or malicious, associated with insulin administration. Unusual cause in adult horses.	Administration of glucose intravenously.	
Water deprivation	Variable mentation from normal to seizures. Associated with inadequate water intake (e.g., broken bore or dry tank supplying horses at pasture).	Judicious rehydration. Provision of unrestricted access to water can result in water intoxication.	Cause is usually obvious (lack of access to water). Guarded prognosis.
Senile collapse	Alert horse. Old horse. History of progressive weakness. No other causes of recumbency identified.	Supportive care. Correction of metabolic abnormalities. Provision of good-quality nutrition.	Poor prognosis.
<b>Intoxications</b>			
Ionophores (monensin, salinomycin, etc.)	Alert. Acute-onset colic and muscle weakness. Recumbency. Diagnosis is based on history of exposure and measurement of drug concentrations in blood or tissues, and feed.	Supportive. No specific treatment.	Poor to guarded. Horses surviving the acute episode can have exercise intolerance as a result of persisting myocardial disease.

AST, aspartate transferase; CK, creatine kinase; CSF, cerebrospinal fluid; CT, computed tomography; DIC, disseminated intravascular coagulation; IV, intravenously; MRI, magnetic resonance imaging; PCR, polymerase chain reaction.

albumin concentrations). Cerebrospinal fluid is reflective of any inciting disease but is usually normal.

## MANAGEMENT AND CARE

The principles of care are treatment of the primary disease, prevention of further illness or injury, assisting the horse to stand, and provision of optimal nutrition and hydration. Median duration of hospitalization in one report of 148 horses treated at a referral hospital was 2.8 days (interquartile range of 1.5 to 8 days).<sup>1</sup>

Treatment of the primary disease is covered in other sections of this book. Similarly, maintenance of hydration and electrolyte status is covered elsewhere. Maintenance of normal hydration is sometimes problematic in recumbent horses because of limited access to water and unwillingness to drink. Provision of fresh, palatable water is essential. Intravenous or enteral (nasogastric intubation) administration of fluids and electrolyte solutions might be necessary in some recumbent horses, especially early in their illness.

Horses with diseases that cause recumbency often have problems with fecal and urinary incontinence or retention. Catheterization of the urinary bladder might be necessary to relieve distension in horses with neurogenic upper motor bladder or lower motor bladder dysfunction, or in male horses that are reluctant to urinate when recumbent. Catheterization of the bladder is often repeated. To minimize the risk of iatrogenic cystitis, the procedure should be performed aseptically. Administration of bethanechol might increase detrusor muscle tone and aid urination, and phenoxybenzamine (0.5 mg/kg intravenously over 15 minutes) might decrease sphincter tone in horses with upper motor neurone bladder.

Horses that can eat should be fed a balanced, palatable, and nutritious diet. Tempting horses with reduced appetite with treats such as apples, carrots, and horse treats might stimulate appetite for hay and grain. Horses that are unable to eat should be fed through a nasogastric tube. Slurries of alfalfa pellets or commercial diets can be administered through nasogastric tubes. The maintenance needs of a sedentary 425-kg horse are approximately 15 to 18 Mcal/d. The maintenance needs of a recumbent horse are unknown, but are probably less than that of normal sedentary horses.

## COMPLICATIONS—PREVENTION

A major challenge in managing recumbent horses is preventing further injury. Abnormalities caused by recumbency include abrasions and lacerations, gastric ulceration, corneal ulceration, pneumonia, cystitis, pigmenturia, muscle hemorrhage and tearing, impaction colic, laminitis, and catheter-site infection or inflammation.<sup>1</sup>

Recumbent horses often make repeated efforts to stand, which, although encouraging

to all involved, can result in further injury. An attempt to stand can injure the horse's head, especially the periorbital regions, and skin over bony prominences such as over the wing of the ilium. Minimization of further injury is achieved by use of a sling or tail rope to assist horses to stand; housing in a padded stall with deep, soft bedding (although this can interfere with the horse's ability to stand); and protection of the head and distal limbs with a helmet and bandages, respectively. Recumbent horses kept in well-grassed pasture often do well and have minimal self-inflicted trauma.

Decubital ulcers occur over pressure points, such as the wing of the ilium, point of the shoulder, and zygomatic arch, and can become severe. Recumbent horses that paddle can abrade the skin over limb joints, with subsequent increased risk of septic arthritis. Bandages, helmets, ointments such as silver sulfadiazine paste, and soft bedding minimize but do not eliminate these abrasions. Recumbent horses that cannot or do not voluntarily move from side to side should be rolled every 2 to 4 hours.

Peripheral pressure neuropathy can occur in recumbent horses. The radial nerve and facial nerve are most often affected. Prevention is achieved by use of padded bedding, slings, frequent rolling, and a helmet.

Recumbent horses can sustain muscle damage from pressure on large muscle groups. For large or well-muscled horses this can result in large increases in serum creatine kinase activity and myoglobinuria. Myoglobinuria can cause acute renal failure, although this degree of myoglobinuria in recumbent horses is unusual.

Pneumonia can occur as a result of recumbency. Horses that are dysphagic are at increased risk of aspiration of feed material and saliva, and hence development of aspiration pneumonia. Horses receiving corticosteroids are at increased risk of bacterial and fungal (*Aspergillus* spp.) pneumonia. Although not every recumbent horse should be administered antimicrobials, this is indicated in horses at increased risk of developing pneumonia. Antimicrobials should have a broad spectrum, including activity against *Streptococcus* spp., such as a combination of penicillin and an aminoglycoside.

Slings of horses is labor intensive and requires a sling that is designed for use with horses. Horses that accept being supported by a sling have increased chances of survival (OR of 4 for death for horses not using a sling [1.1% to 16%, 95% CI]) than do horses that cannot or will not use a sling.<sup>1</sup> Horses should not be lifted using hip slings intended for use with cattle. Use of these slings to lift horses by grasping over the wing of each ilium is inhumane and unsuccessful. There are slings designed specifically for use with horses (e.g., Anderson Sling Support Device).<sup>2</sup>

Horses in slings should be closely monitored and not allowed to hang in the sling.

The horses should be assisted to stand in the sling every 6 or 8 hours. The sling should be used to help the horse to get up and provide some support while it is standing, but the horse should not have all its weight borne by the sling for more than a few minutes. Horses that have an excessive amount of weight borne by the sling for a prolonged period of time have trouble breathing and might develop colic, rupture of the urinary bladder, diaphragmatic hernia, or rectal prolapse.

Potentially catastrophic complications include septic arthritis, radial nerve injury, bladder rupture, diaphragmatic hernia, rectal prolapse, colon torsion, and long bone fracture. The risk of these complications can be minimized by the practices detailed previously, but they cannot be eliminated.

## THIN SOW SYNDROME

### SYNOPSIS

**Etiology** The syndrome is the result of inadequate nutrition and unbalanced nutrition in pregnancy and lactation but may also result from parasitic or chronic infectious disease.

**Epidemiology** Loss of weight to the point of inanition, particularly in first- and second-litter gilts.

**Clinical findings** Inanition.

**Control** Recognition of the relation between voluntary feed intake in pregnancy and lactation; feeding based on condition scores.

Thin cow syndrome is a condition of sows, particularly sows at the end of lactation or in the early dry period where there has been tremendous lactational weight loss and this has not been regained. It was formerly common in outdoor or yard systems, particularly in the United Kingdom, but currently is rarely seen because management practices and nutritional knowledge have advanced markedly. There are a number of causes of wasting and the occurrence of thin sows.

## ETIOLOGY

Historically, the major cause of thin sow syndrome was the complete lack of awareness that sows needed to be fed correctly in pregnancy to prepare for farrowing and in lactation to provide milk for 9 or more piglets consuming 800+ ml of milk per piglet per day.

## EPIDEMIOLOGY

It emerged as a problem in the 1970s as a result of poor understanding of the interrelation between feed intake in pregnancy and that in lactation. The syndrome is most common in first- and second-litter gilts but can affect all parities when nutrition is inadequate. The voluntary intake of food by sows during lactation is inversely related to the intake in pregnancy. Consequently, sows that are fed at high levels during pregnancy will gain excessive weight during pregnancy but will voluntarily restrict feed intake during lactation and lose excessive weight during lactation. In contrast, sows that are fed what is basically a maintenance ration 2.0 to 2.5 kg (4.5 to 5.5 lbs) of a balanced sow ration during pregnancy will gain adequate weight for conceptus and body growth and during lactation will consume adequate feed for lactation requirements and lose minimal weight in this period. Knowledge of sow nutrition has improved such that major problems with this syndrome should not occur, but there is still a risk of inadequately feeding sows selected for lean genotype and high litter size and weaning weights. First- and second-litter gilts may require more feed to provide for body growth. This was combined with the move to intensive indoor housing of pregnant sows. Penning of sows exacerbated social dominance/submissive relationships.

Modern commercial highly bred sows do not have the subcutaneous fat reserves necessary for outdoor production and thus are prone to body-weight loss in exposed fields and yards. The second major group of causes is environmental. Often sows are kept in yards or arks with minimum straw for bedding, which alleviates to some extent low environmental temperatures. Environmental causes include cold or drafty housing, fluctuating temperatures, too high a temperature in the farrowing house, wet bedding, and lack of drinking water.

Early weaning increases the risk of thin sow syndrome, especially if the nutrition is inadequate. Afflicted animals were often on low-level feeding to avoid obesity.

Parasitic disease, particularly associated with infestation with *Oesophagostomum* spp. and *Hyostrogylus* spp., contributes to wasting in sows and the occurrence of thin sow syndrome.

Thin sows can be a component of the syndrome of infectious diseases such as cystitis and pyelonephritis.

## CLINICAL FINDINGS

Within a herd, thin sow syndrome develops over a period of months and often one or two pregnancy cycles, with a gradually decline in the body condition of the group until 20% to 30% of sows have a low body-condition score. No abnormalities are evident on clinical examination, but the sows fail to regain weight after weaning, particularly sows after

their first litter. The most critical period for weight loss is the first 2 weeks after weaning. Affected sows have a poor appetite but often show pica and excessive water intake and may be anemic.

## CONTROL

### Feeding During Pregnancy

Currently the risk for thin sow syndrome exists where it is assumed that all pregnant sows can be fed a standard amount of ration. Problems are likely to occur when sows are run in groups and fed as a group, where timid sows are likely to be bullied out of their required share of food. Individual feeders or stall feeding, and particularly electronic feeders, will prevent this.

### Feeding During Lactation

The critical issue is to ensure adequate feed and energy intake during lactation. This can be achieved by not feeding to excess during pregnancy, restricting the feed intake of sows in the first few days after farrowing to encourage better feed intake in later lactation, ensuring an adequate and constant supply of water, ad lib feeding during lactation, and providing a high-energy-density lactation diet.

In addition, enclosing the creep with heat for the piglets and thus the farrowing house can be kept at a lower temperature for the sow and controlling parasitic disease will help.

**Condition scoring** is a valuable guide to the feeding of individual sows and for a judgment of feeding practices in the herd as a whole. On a score of 1 to 5, it should be very rare to find sows with condition scores of 1 or 5. The optimum is to have sows entering the farrowing house between condition score 3 and 4 and not less than 2.5 at weaning. First- and second-parity sows in poor condition at weaning are best "skipped" at the first heat and mated on the second heat.

Methods for condition scoring and guidelines can be found at <http://www.defra.gov.uk/animalh/welfare/farmed/pigs/pb3480/pigstoc.htm>.

## WILD BOAR AS VECTORS FOR INFECTIOUS DISEASE

There is an increasing worldwide focus on wild boar and escaped domesticated (feral) pigs as a reservoir of infection for pig diseases of epizootic nature,<sup>1-3</sup> particularly in Europe and the United States, where the hunting fraternity has a vested interest in these animals. Wild animals have great potential as a source of both viral and parasitic diseases, and the wild boar (*Sus scrofa*) is no exception. In many cases, they are shy and retiring, frequently inhabiting woodland, where their numbers are not really appreciated. Where there is a high density, there is a high transmission rate of infection.<sup>4</sup>

There is wide variation in populations in different countries in Europe. It is the second most important wild ungulate in Europe and is important in Germany, France, Spain, Poland, and the Czech Republic; in the United States, they are found in 39 of 50 states.

Wild boar have become increasingly common across Europe because they free range. In Switzerland, the population of wild boar has shown a steady increase over the last 15 years.<sup>5</sup> Commercial pigs have also become increasingly reared outside, so the possibility of disease transmission has increased rapidly. To illustrate this, a recent study in Switzerland of contacts between piggeries and wild boar<sup>6</sup> showed that 5% of the piggeries recorded the presence of cross-bred pigs on their premises. The pigs of the Mangalitza breed were the most at risk of such matings. A study of the risk of such happenings was made,<sup>7</sup> and it showed that the risk was highest when the disease under consideration was spread by aerosol (e.g., African swine fever, classical swine fever) rather than those spread by venereal means (e.g., brucellosis). They can also possibly be a hazard to humans as well.<sup>8</sup>

There is a technique for assessing relative abundance and aggregation.<sup>9</sup>

Overall, the disease situation in the wild boar is not well understood. Various diseases are outlined in the following discussion; the diseases are arranged alphabetically.

## RISK FACTORS

The greater the distance between the outdoor pigs and the managing homestead, the greater the risk of intrusion by wild boar. Unsupervised units are definitely at risk. Close proximity to forest also increases the risk of disease. Piggeries with pasture paddocks are also at considerable risk from wild boar. Commercial hunting sites maintain an overabundant wild boar population.<sup>9,10</sup> The role of fences has been discussed.<sup>11</sup> Concentrated feed sources are a high point of contact, and these fields for outdoor pigs should be effectively fenced. Feral swine require dense vegetation for thermoregulation. They also require areas of surface water and moist areas in which to wallow.

## DISEASE IN GENERAL

Generally, if wild boar are farmed, then the diseases are the same as for domestic pigs.<sup>12</sup> A large study of wild boar in Campania in southern Italy<sup>13</sup> showed that 4.4% were positive for *Brucella* spp., 2.6% for *Leptospira interrogans*, 19.3% for *Salmonella* spp., 30.7% for Aujeszky's disease, 7.9% for porcine parvovirus, and 37.7% for porcine reproductive and respiratory virus, but all were negative for African swine fever, classical swine fever. Thus the wild boar does provide a challenge to the domestic pig if there is contact between the two groups.

## AFRICAN SWINE FEVER

Wild boar are natural hosts for African swine fever (ASF), but a survey in Spain in an area previously infected showed neither virus nor antibody,<sup>14</sup> suggesting that permanent recovery of freedom is possible. The outbreak was extremely expensive in Spain and took 30 years to eradicate. This was because of poor biosecurity, *Ornithodoros* ticks, and the presence of wild boar. The study suggested that even in highly dense wild boar populations, such as in the natural parks, ASF circulation cannot be maintained in the absence of other sources of infection. The recent incursion into Russia has shown wild boar affected in Russia, Ukraine, and Lithuania.

## ASTROVIRUSES

Astroviruses were found in the feces of wild boar in Hungary.<sup>15</sup>

## AUJESKY'S DISEASE

Aujesky's disease virus (ADV) has been found in wild boar in Switzerland.<sup>16,17</sup> Culling of wild boar appeared to have no effect on the presence of ADV.<sup>18</sup> It has now largely disappeared from domestic pigs in Europe.<sup>17,19</sup> However, it was found recently in wild boar in Austria.<sup>20</sup> In Germany, two cases of ADV were reported in 2010 and had central nervous system (CNS) signs and nonsuppurative panencephalitis.<sup>21</sup> It is quite a widespread infection in wild boar in some regions. In wild boar, ADV virus is relatively attenuated, and it may have adapted to coexistence with the specific host population. There is also a wide diversity in the wild boar population. It is probably spread by direct contact and not aerosols, especially over long distances. Currently, oral vaccination for wild boar is not an option, but it has been successful experimentally.<sup>22</sup> Fencing is the main control method. Adequate monitoring is the only real control.

## BRUCELLOSIS

The most commonly isolated strain from wild boar in central, eastern, and western Europe is *Brucella suis* biovar 2. It has been found in the Czech Republic, Hungary, Poland, Slovakia, Slovenia and Switzerland,<sup>16,23</sup> and Germany.<sup>24</sup> *B. suis* was found in 28.8% of wild boar, and antibodies were found in 35.8%.<sup>5</sup>

In Croatia, 424 sera from wild boar were looked at in 2003 to 2004,<sup>25</sup> and 27.6% were shown to have seropositivity.

In northeastern Spain, the presence of *Brucella* was studied in wild boar because in Spain the presence of fencing, supplemental feeding, and illegal restocking of wild boar have become common management practices to increase the number of wild boar in an area. They have been bred illegally, cross-bred to domestic pigs, or imported, particularly from France.<sup>26</sup> *Brucella* antibodies were detected in 28/256 samples (10.9%).<sup>27</sup> In the United States, spillover from wild boar to

domestic pigs has been suspected but never been confirmed (in the United States, there are also bison and elk as a possible source), but strain analysis can help in this situation.<sup>28</sup> In this study, *Brucella* isolates were found in 77% of pigs, and 68% had *B. suis* isolates that were biovar 1, with 92% in males and only 34% in females. The authors also pointed out that wild boar could also be a reservoir for *Brucella abortus* in addition to *B. suis*. In the southeastern United States (South Carolina), wild boar have antibodies to porcine parvovirus (PRV), *B. suis*, and porcine circovirus type 2 (PCV2), but not to Swine Influenza virus (SIV) or porcine reproductive and respiratory syndrome virus (PRRS). In North Carolina there was no PRV or *B. suis*, but 1/20 had PRRS, 86/120 had PCV2, and 9/19 had SIV. In other words, infection in wild and feral pigs can be highly local.

## CAMPYLOBACTER SPP.

*Campylobacter* strains were isolated from feral swine in California following an *Escherichia coli* O157:H7 outbreak associated with spinach. Of the swine samples, 40% were positive, and six species were isolated: *coli*, *fetus*, *hyointestinalis*, *jejuni*, *lanienae*,<sup>29</sup> and *sputorum*. The study highlighted the need to keep wild animals clear of vegetable crops and highlighted the potential of infecting humans, particularly hunters.

## CHLAMYDIAE

A high seroprevalence of Chlamydiaceae has been demonstrated in Spain,<sup>30</sup> but until the report of conjunctivitis and ocular lesions,<sup>31</sup> it was not possible to show diseases related to *Chlamydia*. The affected pig had ulcerations and corneal opacities. The lesions in the wild boar were similar to those seen in experimental infections of commercial pigs.

## CLASSICAL SWINE FEVER

In Germany, classical swine fever (CSF) has been present for several decades. The reverse transcription polymerase chain reaction (RT-PCR) has been used to study the evolution to CSF in wild boar.<sup>32</sup> Wild boar were an important source of outbreaks for domestic pigs. Many of the animals were less than 1 year old; thus, the removal of young animals, particularly boar, by hunting reduces the risk of infection. Oral immunization for wild boar was begun in 1993<sup>33</sup> (C-strain bait vaccine<sup>34</sup>) and does help in the control effort.<sup>35</sup> Younger animals are less efficiently vaccinated and are more frequently affected than older boar.<sup>36</sup> Baits may be more attractive to older pigs. The optimal vaccination time for pigs is October/November.<sup>37</sup> Increasing the level of baiting does not seem to improve the situation. Baiting is not of great usage in controlling CSF because of low bait usage (62%); however, it does help to describe patterns of

feral swine movement, facilitate observation, and improve efficacy.<sup>38</sup>

Most of the previous outbreaks in the wild boar population with high-pathogenicity CSF were largely self-limiting,<sup>39</sup> but morbidity and mortality rates in outbreak regions are high. Recent outbreaks have involved the less damaging genotype 2.3 strains. The change from high to moderate virulence prolonged the virus circulation. It is also possible that monitoring and detection have improved, leading to declining severity following an outbreak rather than selection against a highly virulent virus.

The multiplex RT-PCR can be used to differentiate natural CSF from vaccinated animals,<sup>40</sup> and the marker vaccine is safe.<sup>41</sup> The three outbreaks in northeastern France, between 2002 and 2011, occurred in wild boar and a pig herd in Moselle, and the third occurred in wild boar in the Bas-Rhin area. All were genotype 2.3 and were derived from lineages from the Rhineland-Palatinate lineages in Germany. The Bas-Rhin outbreak lasted until 2007, and the virus evolved slightly over this period.<sup>83</sup>

## CRYPTOSPORIDIA

Two species of *Cryptosporidia*, *C. suis* and *C. scrofarum*, were described in wild boar in central Europe (Austria, Czech Republic, Poland, and the Slovak Republic). In none of the detected cases was clinical disease found. In most cases the infections were single, but in some both species were found together. The PCR was a better detection method than the microscopic.<sup>81</sup>

## ESCHERICHIA COLI

*E. coli* O157:H7 was found in feral swine in central California near spinach fields responsible for disease outbreaks.<sup>42</sup> Not much is known about *E. coli* in wild boar, but it appears to be individual and diverse. In a study in central Europe, it was found that wild boar carried antimicrobial-resistant *E. coli* in their feces. In the wild boar, the level of resistance was 6%. Five multiresistant isolates producing extended-spectrum beta-lactamase (ESBL) were recovered from the wild boar.<sup>89</sup> The detection and characterization of O157:H7 and non-O157 Shiga-toxin-producing *E. coli* in wild boars have been described in wild boar in Spain.<sup>90</sup>

## ERYSIPELAS

In Iberian wild boar the prevalence was 15%,<sup>18</sup> and infection has been described in Spain.<sup>27</sup>

## FASCIOLA HEPATICA

The *Fasciola hepatica* parasite has recently been found in a feral wild boar in Scotland,<sup>43</sup> although it has been described previously in feral Nebrodi black pigs in Sicily, Italy.<sup>44</sup> Occasionally the flukes are found to be adults in the liver, although the pig is considered resistant to the development of liver fluke.

## FOOT-AND-MOUTH DISEASE

Contact with the virus in cattle occurs most commonly at water courses for feral and wild boar.<sup>45</sup>

## HEPATITIS E

Hepatitis E (Hep E) in humans is thought to be associated with eating raw pig meat or wild boar, particularly liver. Hunting is associated with a higher prevalence<sup>46-48</sup> of antibodies in humans. Wild boars in southeastern France may be a source of infection for humans.<sup>46</sup>

There is a high seroprevalence of antibodies to Hep E in forestry workers (31%) and wild boars (14%) in France<sup>49</sup> and in Iberian wild boars.<sup>50</sup> The wild boar prevalence is related to the geographic location. In Italy, there were seropositive wild boar.<sup>51</sup> In Germany, the prevalence in wild boars was studied using liver samples from wild boar, and 14.9% were found to be positive.<sup>52,53</sup> A further study in Germany showed a 29.9% prevalence, but it varied considerably between the regions that were analyzed. All the isolates were genotype 3 (3i, 3h, 3f, and 3e), but the type depended on the hunting spot.<sup>54</sup> It was found in all areas and all regions but more frequently in rural areas. There were three sources of infection: hunting, wild boar meat, and fecal contamination. Even in Japan there is a risk from wild boars.<sup>55</sup> In Spain, 28% of wild boar tested were found to be positive<sup>56</sup> and 12% in the Netherlands.<sup>57</sup> It was found in Croatia,<sup>58</sup> Czechoslovakia,<sup>59</sup> and Sweden.<sup>60</sup> Within these overall prevalence rates, there is evidence of quite high local prevalence rates.<sup>61</sup> The suspicion is that wild boar infection may spill over into the domestic pig population and then into the human population, but there is no proof that this happens.<sup>62</sup> Several studies in Germany have shown hepatitis E virus (HEV) genotype 3 within the wild boar population and in domestic pigs.<sup>52-54,96,97</sup>

## LEPTOSPIRA SPP.

In wild boar, antibodies to *Leptospira* spp. and leptospiral cells have been seen,<sup>63</sup> and they have been detected in Japan.<sup>64,65</sup> Wild boars (15.2%) were found to carry *Leptospira* more commonly than deer, although cases in both have increased rapidly in Japan in recent years. The supposition is that they wallow in the mud to keep cool and can get infected under these conditions. The suggestion is that wild boar leptospires may prove a hazard to hunters, meat-processing workers, and hunting dogs in Japan. A study in Swedish wild boar suggested that the infection was much less common than in the rest of Europe.<sup>66</sup> In Poland, the level of antibodies detected was 25%, in Germany it was 18%, and in Italy it was 12%.

## LYMPHADENITIS

In a study of lymphadenitis in wild boar in Brazil,  $\beta$ -hemolytic streptococci (10%),

*Mycobacterium* spp. (8.4%), and *Rhodococcus equi* (6.6%) were the most common cause of lesions.<sup>67</sup>

## MYCOBACTERIUM BOVIS

The risk of infection in wild boar is age dependent and correlates with abundance and spatial aggregation.<sup>9</sup> In some parts of Spain, the wild boar is a maximum risk for domestic pigs.<sup>1</sup> In south-central Spain, wild boar tuberculosis (TB) may be the main driver of bovine TB. Culling of 50% of the population of European wild boar (*Sus scrofa*) in south-central Spain showed that *M. bovis* reduced by 21% to 48%. In Portugal, in the 2005 to 2006 hunting season, 18/162 wild boars from 3/8 study areas were positive for *M. bovis*.<sup>68</sup> Detection of *M. bovis* was most consistently associated with variables linked to the wild ungulate's relative abundance; thus, wild boar may be a reservoir for *M. bovis*.

In New Zealand, the transmission of *M. bovis* to cattle occurs through the reservoir of the bush-tailed possum. In those areas where control of the possum was carried out, the level of *M. bovis* in the feral pigs was reduced. The feral pigs do not seem to pass the disease to other pigs.<sup>69</sup> Data from Corsica suggest that wild and domestic animals are in an epidemiologic bovine tuberculosis (bTB) transmission cycle.<sup>70</sup>

Experimental infection of wild boar with *M. avium* subsp. *avium* has been carried out and was similar to the natural disease.<sup>71</sup> The lesions in wild boar are frequently in the thoracic lymph nodes and lungs, suggesting that respiratory infection occurs. In the Iberian Peninsula, it may well be that the wild boar contribute to the persistence of the infection in domestic pigs, depending on the size of the local population.<sup>82</sup> *M. bovis* was first isolated from a feral wild boar in the United Kingdom in 2010,<sup>86</sup> although it had been isolated from farmed wild boar previously; there are now several pockets of wild boar in the United Kingdom countryside. Many lymph nodes, particularly the mandibular, retropharyngeal, and mesenteric, were affected. There was a granulomatous lymphadenitis with small numbers of acid-fast bacteria. Spoligotype 17 was identified and is also found in other wildlife in the area.

The immunopathology of granulomas in naturally infected wild boar has been described.<sup>87</sup> In wild boar, the pattern of infection is contained, not generalized. The majority of granulomas did not have any acid-fast bacteria, and only a few had multinucleate giant cells.

There was a large presence of T cells and macrophages exhibiting a high level of interferon gamma (IFN- $\gamma$ ) activity at all stages of granuloma development. A high level of nitric oxide production from macrophages was also found.

The influence of PCV2 on bTB in wild boar populations has been studied.<sup>88</sup> In

Spain, two of the risk factors for TB in wild boar include the density of the population and the age of the boar. The role of other pathogens has not been investigated. The presence of bTB in 551 hunted wild boar from southwestern Spain was studied. A statistical relationship was found between the prevalence rates of bTB and PCV2. Where PCV2 was highest, so was the occurrence of bTB. Wild boar with PCV2 were also more likely to have generalized lesions.

In a recent study in the United Kingdom of the hotspots for *M. bovis* infections, it was found that infected pigs were found on farms where there was poor biosecurity or where the animals were raised outdoors. In some cases, the strains found in pigs correlated better with the strains found in badgers rather than in cattle, suggesting that pigs could be a sentinel for detecting *M. bovis* in wildlife.<sup>91</sup>

In Spain, the intradermal bovine tuberculin test in wild boar was only approximately 77.4% effective (24/31). The enzyme-linked immunoabsorbent assay (ELISA) has been used more recently and may give a better result in wild boar.<sup>98</sup> Wild boar can act as maintenance hosts,<sup>99</sup> but they are usually regarded as a "dead-end" host.<sup>100</sup> A number of other species of *Mycobacteria* other than *M. bovis* and *M. avium* have been found in domestic pigs and wild boar in Brazil.<sup>101</sup>

## MYCOPLASMA HYOPNEUMONIAE

*Mycoplasma hyopneumoniae* (MH) is common in Swiss wild boar,<sup>72</sup> as detected by RT-PCR. There was little information on enzootic pneumonia (EP) in wild boar until the study in Spain in 2010,<sup>102</sup> which showed that antibodies were detected in 21% of 428 serum samples and in 20% of nasal swabs. MH was detected by nested polymerase chain reaction (nPCR) and in 8% (of 156) of lung samples. No gross lesions were seen in any of the pigs, but histologic lesions were seen in 18 of 63 (29%) of lung samples. The conclusion was that the EP lesions were likely to be subclinical.

## PARASITES

Over 30 species of parasites have been found in wild boars (in particular, flukes, tapeworms, and nematodes are included in this list).

## PORCINE CIRCOVIRUS TYPE 2

PCV2 has a variable prevalence in Europe, but there is a high prevalence in Spain in Iberian wild boar<sup>50</sup> and in Romania.<sup>73,92-94</sup> In Germany, only 0.3% of wild boar were positive compared with 8.7% of domestic pigs.<sup>74</sup> The wild boar had much lower levels of PCV2 load than domestic pigs.

In a study in Korea, the prevalence of PCV2 infection was found to be 4.98% (91/1825).<sup>95</sup> The PCV2 ORF2 sequences belonged solely to subgroups 1A/B and 1C of the PCV2b genotype.

## PORCINE PARVOVIRUS

Porcine parvovirus (PPV) is widespread in wild boar (14% to 77%) depending on the country but does not seem to cause lesions, although it may cause problems to wild boar sows in their first pregnancy in midgestation. The forces that drive the evolution of PPV are unknown. However, it appears that in the presence of antibodies, the neutral selection seems to be more important than adaptive evolution.<sup>103</sup> In wild boar populations, phylogenetic analysis has revealed that PPV is more diverse than in domestic pigs.<sup>104</sup> Thus, wild boar populations may have played a vital part in the emergence of new PPV phenotypes.

## PORCINE REPRODUCTIVE AND RESPIRATORY SYNDROME

In Spain there was a low prevalence of porcine reproductive and respiratory syndrome (PRRS) in wild boar,<sup>18</sup> whereas in Italy<sup>13</sup> and Germany it was quite high,<sup>61</sup> but it is probably not a reservoir status.<sup>27</sup> In China, high-pathogenicity PRRS may be transmitted in hybrid wild boar.<sup>6</sup>

## PORCINE SAPELOVIRUS

Porcine sapelovirus type 1 (PSV1) has recently been isolated from a wild boar in Japan. It was formerly known as porcine enterovirus A.<sup>105</sup>

## SALMONELLA SEROTYPES

Wild boar in northern Italy<sup>75</sup> (1313 boars) were examined, and 326 salmonellae were isolated (24.8%). Thirty different serovars were isolated from three different *Salmonella enterica* spp.

In a study of wild boars in the Latium region of Italy, 10.8% were positive; many serovars were found but *S. typhimurium* was only found in 1.8%. The most important point was that most of these salmonellae carried resistance genes, particularly to sulfonamides (92.5%) sulfonamide-trimethoprim (14.8%), colistin (14.8%), and streptomycin (18.5%), with the others at much lower levels.<sup>85</sup>

Wild boars may act as healthy carriers of a wide range of *Salmonella* species.<sup>76</sup> In a study in Australia of an isolated wild boar population, it was found that there were *Salmonella* spp. in 36.3% of fecal samples and 11.9% of mesenteric lymph nodes.<sup>77</sup> Thirty-nine serovars were found (29 in feces and 24 in the lymph nodes). The transmission is from old to young pigs, possibly through the water features.

Wild boar in Spain, northern Italy, Portugal, and Slovenia<sup>84</sup> have also been found to be seropositive or have had the organism isolated from wild boar populations.

## SWINE INFLUENZA

A survey in the United States showed wide state-to-state variation, with up to 14.4% positive for H3N2 in Texas<sup>106</sup> and with higher prevalence levels in the Carolinas.<sup>107</sup> In a

recent survey, 2% were positive for H1 and 40% for H3.<sup>108</sup> In Germany, 5.2% of pigs had antibodies to both H1N1 and H3N2.<sup>109</sup>

## TOXOPLASMA

A case of congenital toxoplasmosis has been described in a wild boar from Spain.<sup>79</sup> The histopathologic results suggest that the shot sow and her three fetuses all had toxoplasmosis. Myositis was found in many samples and interstitial pneumonia in the fetuses. The absence of cysts is consistent with the experimental infection reported in pigs.<sup>80</sup> The parasite was detected by PCR in nearly all the tissues.

## TRICHINELLA

*Trichinella* has been found in wild boar in Corsica,<sup>78</sup> where the muscle antibody ELISA was positive. It necessitates proper veterinary controls on wild boar meat and proper cooking of meat.

## CONTROL

Tight biosecurity to separate wild boar from domestic pigs is essential to prevent the incursion of disease into the domestic pig herds. Fencing of water tanks is something that is not normally considered, but it should be with wild boar. You can raise water tanks and thus cattle can drink but wild pigs cannot. Similarly, feeding deer with corn also attracts feral pigs.

## Multi-Organ Diseases Due to Bacterial Infection

### ANTHRAX

#### SYNOPSIS

**Etiology** *Bacillus anthracis*.

**Epidemiology** Global occurrence and often occurs as outbreaks. Spores survive in soil for many years and disease is enzootic in certain areas. Pastoral outbreaks associated with periods of climatic extremes. Outbreaks also associated with infected feedstuffs.

**Clinical findings** Ruminants and horses—acute/peracute disease characterized by fever, septicemia, and sudden death. This may be accompanied by subcutaneous edematous swellings in horses. More prolonged disease with cellulitis of the neck and throat in swine.

**Clinical pathology** Because of risk for human exposure hematology and blood chemistry are not performed. Demonstration of organism in blood or subcutaneous fluid.

**Necropsy findings** Carcass should not be opened if anthrax suspected; the diagnosis is made from the examination of aspirated carcass blood. Exudation of tarry blood from the body orifices of the cadaver, failure of the blood to clot, absence of rigor mortis and the presence of splenomegaly.

**Diagnostic confirmation** Identification of organism in blood or tissues by polychrome methylene blue stain of smear or by monoclonal antibody-fluorescent conjugates. Culture, Ascoli test, polymerase chain reaction (PCR).

**Treatment** Antibiotics, antiserum.

**Control** Prevention of further spread. Vaccination.

#### ETIOLOGY

*Bacillus anthracis*, a gram-positive, rod-shaped, aerobic, immobile, capsulated, spore-forming bacterium belonging to the family Bacillaceae is the causative agent of the disease.<sup>1</sup> Although the vegetative form of *B. anthracis* is not very robust, the spores persist in the environment for decades, easily withstand cold temperatures, and even survive in dried and salted hides. Sporulation occurs

with exposure of the bacillus to free oxygen, which is the case when it is shed from the host organism into the environment. Although ingested spores readily return to the vegetative state once the host organism is infected, the vegetative form is practically not encountered in the environment. Sporulation of *B. anthracis* requires an environmental temperature range between 12° and 42°C (53–107°F) and does not occur at temperatures below 9° to 12°C (48–53°F).<sup>2</sup>

#### EPIDEMIOLOGY Occurrence

Anthrax is a disease known since ancient times. It probably originated in sub-Saharan Africa and has spread to have a worldwide distribution. During the late nineteenth and early twentieth centuries, anthrax was the infectious disease with the highest case-fatality rate in domestic and wild animals. For instance, in 1923 an anthrax outbreak in South Africa was responsible for the death of an estimated 60,000 animals. The development of the so-called **Sterne vaccine** and the discovery of antibiotics in the middle of the last century provided effective tools to control the disease, which has lost its importance in large parts of the world since then. In recent years, anthrax received increased attention because it is a **potential agent of bioterrorism**. The reality of this threat became apparent after a bioterrorist attack in the fall of 2001 in the United States, when five letters sent by mail containing small amounts anthrax spores contaminated more than 30,000 people, killed 5 people, and infected 17.<sup>3</sup>

Currently anthrax is a sporadic disease in western Europe, North America, and Australia, although there are regions in these parts of the world where the disease remains enzootic. Such areas include specific zones in the North-Western Territories and Alberta in Canada and in eastern North and South Dakota, northwest Minnesota, and southwest Texas in the United States.<sup>1</sup> Anthrax is essentially absent from northern and central **Europe** but remains enzootic in Greece, Turkey, Spain, southern Italy, and Albania. The disease also persists in certain countries of **Latin America**, such as Bolivia, Peru, and Mexico, and is enzootic in Haiti. Endemic regions of **Asia** include the Philippines, South Korea, eastern India, the mountainous region of western China, and Mongolia.<sup>1</sup>

In tropical and subtropical climates with high annual rainfalls, the infection persists in the soil, and thus frequent, serious outbreaks of anthrax are commonly encountered. In some **African countries** the disease occurs every summer and reaches a devastating occurrence rate in years with a heavy rainfall. Wild fauna—including hippos, cape buffalo, and elephants—die in large numbers.

In **temperate, cool climates** only sporadic outbreaks derive from the soil-borne infection. Accidental ingestion of contaminated

bone meal or pasture contaminated by tannery effluent are more common sources. In this circumstance outbreaks are few, and the number of animals affected is small.

#### Source of the Infection

Infection can occur directly from the soil or from fodder grown on infected soil, from contaminated bone meal or protein concentrates, or from infected excreta, blood, or other discharges from infected animals. The initial source is often from old anthrax graves where the soil has been disturbed.

Spread of the organism within an area may be accomplished by streams, insects, dogs, feral pigs, and other carnivores, and by fecal contamination from infected animals and birds. Avian scavengers such as gulls, vultures, and ravens can carry spores over considerable distances, and the feces of carrion-eating birds can contaminate waterholes. Infected wildlife is also a source for domestic animals on common grazing land. Water can be contaminated by the effluent from tanneries, from infected carcasses, and by flooding and the deposition of anthrax-infected soil.

Introduction of infection into a new area is usually through contaminated animal products, such as bone meal, fertilizers, hides, hair, and wool, or by contaminated concentrates or forage. This form of transmission presents a particular danger because it can cause clinical disease silently anywhere, even where anthrax is unknown, and at any time of the year.<sup>1</sup> In recent years as many as 50% of consignments of bone meal imported into the United Kingdom have been shown to be contaminated with the anthrax bacillus. Outbreaks in pigs can usually be traced to the ingestion of infected bone meal or carcasses.

#### Transmission of the Infection

Infection gains entrance to the body by ingestion, inhalation, or through the skin. Although the exact mode of infection is often in doubt, it is generally considered that most animals are infected by the ingestion of contaminated food or water. Microwounds of the mucous membrane of the digestive are thought to serve as portal of entry for *B. anthracis*. The increased incidence of the disease on sparse pasture is thought to be attributable to both the ingestion of contaminated soil and to injury to the oral mucosa facilitating invasion by the organism.

Inhalation infection is thought to be of minor importance in animals, although the possibility of infection through contaminated dust must always be considered.<sup>2</sup> It has been proposed that inhalation of spores can lead to some sort of chronic carriage, with onset of disease any time after inhalation.<sup>2</sup> “Woolsorter’s disease” in humans is a result of the inhalation of anthrax spores by workers in the wool and hair industries, but even in these industries cutaneous anthrax is much more common.

**Biting flies**, mosquitoes, ticks, and other insects have often been found to harbor anthrax organisms, and the ability of some to transmit the infection has been demonstrated experimentally. However, there is little evidence that they are important in the spread of naturally occurring disease, with the exception of tabanid flies. The transmission is mechanical only, and a local inflammatory reaction is evident at the site of the bite. The tendency, in infected districts, for the heaviest incidence to occur in the late summer and autumn may be a result of the increase in the fly population at that time, but an effect of higher temperature on vegetative proliferation of *B. anthracis* in the soil is more likely.

An outbreak of anthrax has been recorded following the injection of infected blood for the purpose of immunization against anaplasmosis. There have been a number of reports of the occurrence of anthrax after vaccination, probably as a result of inadequately attenuated spores. Wound infection with *B. anthracis* occurs occasionally.

### Risk Factors

#### Host Risk Factors

The disease occurs in all vertebrates but is most common in cattle and sheep and less frequent in goats and horses. Humans occupy an intermediate position between this group and the relatively resistant pigs, dogs, and cats. In farm animals, the disease is almost invariably fatal, except in pigs, and even in this species the case-fatality rate is high.

Algerian sheep are reported to be resistant and, within all species, certain individuals seem to possess sufficient immunity to resist natural exposure. Whether or not this immunity has a genetic basis has not been determined. The most interesting example of natural resistance is the dwarf pig, in which it is impossible to establish the disease. Spores remain in tissues ungerminated, and there is complete clearance from all organs by 48 hours. The ability to prevent spore germination appears to be inherited in this species.

#### Pathogen Risk Factors

Pathogenic strains of *B. anthracis* possess two important virulence factors: the **capsule** and the **toxin complex**, consisting of **three proteins known as protective antigen (PA), lethal factor (LF), and edema factor (EF)**. These virulence factors are encoded in two plasmids, pXO1 (encoding PA, LF and EF) and pXO2 (encoding the capsule). Both plasmids are required for full virulence.

The ability of the bacillus to establish itself in the tissues of the host was found to be inherently dependent on the possession of a capsule. Variants of *B. anthracis* having lost the capsule were also found to have lost their virulence.<sup>4</sup> Although the presence of this polypeptide capsule was found to be an

important factor allowing the bacterium to multiply within the host, its precise mechanism of action is not entirely understood.<sup>2</sup> It was long held that its primary function was to discourage the phagocytic activity of lymphocytes and to neutralize anthracidal substances normally present in tissue, but this is not supported by results of more recent in vitro studies.<sup>2</sup> In any case, the capsule appears to facilitate the evasion of the bacillus from the host's immune system, possibly also by protecting surface antigens of the bacterium from exposure to antibodies.

As noted, the **anthrax toxin complex** consists of three synergistically acting proteins: **PA, LF, and edema factor (EF)**. Whereas independently each of these proteins is innocuous, the combination of them provokes death in infected animals. PA appears to be important for the binding to specific target cells and the introduction of LF and EF into these target cells. EF is an adenylate cyclase that triggers the abnormal production of cyclic-AMP, causing altered ion and water movement and thereby resulting in the edema formation that is characteristic of anthrax.<sup>2</sup> Alteration of the c-AMP signaling pathways was shown to disturb activation of immune cells. LF is a zinc-dependent protease that disrupts regulatory pathways in eukaryotic cells associated with phosphorylation. The mechanism through which this disruption leads to the known effects of LF remains to be fully determined.

#### Environment Risk Factors

Outbreaks originating from a soil-borne infection always occur after a major climate change, for example, heavy rain after a prolonged drought or dry summer months after prolonged rain, and always in warm weather when the environmental temperature is over 15°C (60°F). Sporulation of the vegetative state of *B. anthracis* shed into the environment rapidly occurs with environmental temperatures above 12°C (53°F), and thus vegetative bacilli are practically not found in the environment.<sup>5</sup> It has been proposed that spores may collect and concentrate in so-called storage areas. Spores have a high surface hydrophobicity, giving them a tendency to clump, become concentrated, and remain suspended in standing water, with further concentration on the soil surface as the water evaporates. This relationship to climate has made it possible to predict "anthrax years."

Other risk factors in the environment include close grazing of tough, scratchy feed in dry times, which results in abrasions of the oral mucosa, and confined grazing on heavily contaminated areas around water holes. Some genotypes appear to persist better in calcium-rich soils and organic soils, and poorly drained soils have risk in endemic areas.

### Economic Importance

In most developed countries, vaccination of susceptible animals in enzootic areas has reduced the prevalence of the disease to negligible proportions on a national basis, but heavy losses may still occur in individual herds. Loss occurs as a result of mortality but also from withholding of milk in infected dairy herds and for a period following vaccination.

### Zoonotic Potential

Anthrax has been an important cause of fatal human illness in most parts of the world, but in developed countries it is no longer a significant cause of human or livestock wastage because of appropriate control measures. However, it still holds an important position because of its potential as a zoonosis, and it is still an important zoonosis in developing countries. It is a **major concern as an agent of bioterrorism** and is listed as a category A agent by the U.S. Centers for Disease Control and Prevention.

An account of an outbreak in a piggery in the United Kingdom should be compulsory reading for veterinary students as an example of the responsibilities of veterinarians in a modern public-health-conscious and litigation-minded community.<sup>6,7</sup> In developing countries, anthrax can still be a major cause of livestock losses and a serious cause of mortality among humans who eat meat from infected animals and develop the alimentary form of this disease, or those who handle infected carcasses.

Cutaneous anthrax has occurred in veterinarians following postmortem examination of anthrax carcasses. The areas at particular risk for infection are the forearm above the glove line and the neck. Infection begins as a pruritic papule or vesicle that enlarges and erodes in 1 to 2 days, leaving a necrotic ulcer with subsequent formation of a central black eschar.

### PATHOGENESIS

Upon ingestion of the spores, infection may occur through defects or microwounds of the mucosa of the digestive tract. Alternatively, infection can occur through skin abrasions or skin lesions (e.g., from biting flies) or inhalation of spores.

From the site of entry spores are transported by macrophages to the regional lymph nodes, where they can enter the bloodstream and spread throughout the rest of the organism; septicemia, with massive invasion of all body tissues, follows.

The severity of the clinical signs depends on the infectious dose, the quality of the bacillary capsule, the amount of toxin produced, and the susceptibility of the host species. The previously mentioned toxin complex produced by *B. anthracis* causes edema and tissue damage, acute renal failure, terminal anoxia, and death resulting from shock. The characteristic terminal

hemorrhage to the exterior from orifices of the animal at death is caused by the action of the toxin on the endothelial cell lining of blood vessels, resulting in breakdown and bleeding.<sup>2</sup>

In pigs, localization occurs in the lymph nodes of the throat after invasion through the upper part of the digestive tract. Local lesions usually eventually lead to a fatal septicemia.

### CLINICAL FINDINGS

The incubation period after field infection is not easy to determine but is probably 1 to 2 weeks.

#### Cattle and Sheep

The disease occurs in a peracute and acute form in cattle and sheep.

The **peracute** form of the disease is most common at the beginning of an outbreak. The animals are usually found dead without premonitory signs, the course being probably only 1 to 2 hours, but fever, muscle tremor, dyspnea, and congestion of the mucosae may be observed. The animal soon collapses, and it dies after terminal convulsions. After death, discharges of blood from the nostrils, mouth, anus, and vulva can occur.

The **acute** form runs a course of about 48 hours. Severe depression and listlessness are usually observed first, although they are sometimes preceded by a short period of excitement. The body temperature is high, up to 42°C (107°F), the respiration rapid and deep, the mucosae congested and hemorrhagic, and the heart rate much increased. No food is taken, and ruminal stasis is evident. Pregnant cows may abort. In milking cows, the yield is very much reduced, and the milk may be bloodstained or deep yellow in color. Alimentary tract involvement is usual and is characterized by diarrhea and dysentery. Local edema of the tongue and edematous lesions in the region of the throat, sternum, perineum, and flanks may occur.

#### Pigs

In pigs, anthrax may be acute or subacute. There is fever, with dullness and anorexia, and a characteristic inflammatory edema of the throat and face. The swellings are hot but not painful and may cause obstruction to swallowing and respiration. Bloodstained froth may be present at the mouth when pharyngeal involvement occurs. Petechial hemorrhages are present in the skin, and when localization occurs in the intestinal wall, there is dysentery, often without edema of the throat. A pulmonary form of the disease has been observed in baby pigs that inhaled infected dust. Lobar pneumonia and exudative pleurisy were characteristic. Death usually occurs after a course of 12 to 36 hours, although individual cases may linger for several days.

#### Horses

Anthrax in the horse is always acute but varies in its manifestations with the mode of infection. When infection is by ingestion, there is septicemia with enteritis and colic. When infection is by insect transmission, hot, painful, edematous, subcutaneous swellings appear about the throat, lower neck, floor of the thorax and abdomen, prepuce, and mammary gland. There is high fever and severe depression, and there may be dyspnea as a result of swelling of the throat or colic as a result of intestinal irritation. The course is usually 48 to 96 hours.

### CLINICAL PATHOLOGY

Hematology and blood chemistry examinations are not conducted because of the risk for human exposure. In the living animal the organism may be detected in a stained smear of peripheral blood. The **reference standard** for diagnosis is the detection, by **microscopic examination**, of a clearly defined metachromatic capsule on square-ended bacilli (often in chains) in a blood smear stained with polychrome methylene blue. The blood should be carefully collected in a syringe to avoid contamination of the environment. When local edema is evident, smears may be made from aspirated edema fluid or from lymph nodes that drain that area. For a more certain diagnosis, especially in the early stages when bacilli may not be present in the bloodstream in great numbers, blood culture or the injection of syringe-collected blood into guinea pigs is satisfactory.

Fluorescent antibody techniques are available for use on blood smears and tissue sections. Monoclonal antibodies are also used to provide specific identification of anthrax organisms.

The Ascoli test can be used to demonstrate antigen in severely decayed tissue samples, and a nested PCR technique has been used to demonstrate antigen in environmental samples; PCR methods can also be used to confirm the identity of bacterial isolates. If other detection methods fail, experimental animal inoculation can be attempted.

As the carcass decomposes and the vegetative forms of *B. anthracis* die, diagnosis by smear is more difficult; an immunochromatographic test for antigen has been developed that has high specificity and does not give positive results in recently vaccinated cattle. In cases where antibiotic therapy has been used, the identification from blood smears or culture may be difficult, and animal passage may be necessary.

Because antibodies develop in the late stage of disease serology will be of use only for retrospective studies and only in species with low susceptibility to *B. anthracis*, such as pigs. In these cases acute and convalescent sera can be assayed for their antibody titer by means of an ELISA.

**Shipping infectious material presents risk for spread of the pathogen and human exposure.** Before planning to ship infectious material to a diagnostic laboratory, local authorities and the diagnostic laboratory should be consulted. The reader is further referred to the guidelines of the World Health Organization (WHO) for the transport of infectious substances.<sup>8</sup>

### NECROPSY FINDINGS

There is a striking absence of rigor mortis, and the carcass undergoes gaseous decomposition, quickly assuming the characteristic “sawhorse” posture. All natural orifices usually exude dark, tarry blood that does not clot. **If there is a good reason to suspect the existence of anthrax, the carcass should not be opened.** If a necropsy is carried out, the failure of the blood to clot, widespread ecchymoses, bloodstained serous fluid in the body cavities, severe enteritis, and splenomegaly are strong indications of the presence of anthrax. The enlarged spleen is soft, with a consistency likened to blackberry jam. Subcutaneous swellings containing gelatinous material and enlargement of the local lymph nodes are features of the disease in horses and pigs. Lesions are most frequently seen in the **soft tissues of the neck and pharynx** in these species.

To confirm the diagnosis on an **unopened carcass**, peripheral blood or local edema fluid should be collected by needle puncture. Because the blood clots poorly, jugular venipuncture may permit sample collection. Smears prepared from these fluids should be stained with polychrome methylene blue and examined. These fluid samples can also be used for bacteriologic culture if smear results are equivocal. The smears should be prepared and interpreted by an experienced and qualified microbiologist.

If decomposition of a carcass is advanced, a small quantity of blood may be collected from the fresh surface of an amputated tail or ear. A portion of spleen is the specimen of choice for bacteriologic culture if the carcass has been opened.

Anthrax is a **reportable disease** in many countries, requiring the involvement of government regulatory agencies when the disease is suspected or when the diagnosis is confirmed. Representatives of these agencies can often facilitate sample collection and transportation to an appropriate laboratory. **If anthrax is suspected, then shipping diagnostic samples via the mail or courier systems is strongly discouraged** (see previous discussion).<sup>8</sup>

### Samples for Confirmation of Diagnosis

- Bacteriology—unopened carcass: blood or edema fluid in sealed, leakproof container; opened carcass: previously described samples plus spleen (local lymph nodes in horses, pigs) in sealed,

leakproof containers (direct smear, culture, bioassay)

- Histology—formalin-fixed spleen/local lymph nodes if carcass has been opened (light microscopy)

**Note the zoonotic potential of this organism when handling the carcass and submitting specimens.**

### DIFFERENTIAL DIAGNOSIS

There are many causes of sudden death in farm animals, and differentiation is often difficult. Diseases where there can be multiple deaths suggestive of anthrax include the following:

- Lightning strike
- Peracute blackleg
- Malignant edema
- Bacillary hemoglobinuria
- Hypomagnesemic tetany

### TREATMENT

Severely ill animals are unlikely to recover, but in the early stages, particularly when fever is detected before other signs are evident, recovery can be anticipated if the correct treatment is provided. Penicillin (20,000 IU/kg BW twice daily) has had considerable vogue, but concerns have been raised in recent years because of the occasional appearance of  $\beta$ -lactamase-producing strains that were thus resistant to penicillin. The range of occurrence rates of penicillin-resistant strains reported in the literature is broad, ranging from 0% to 11.5%.<sup>2</sup> Reports of naturally occurring resistance to penicillin among fresh animal isolates are exceedingly rare.<sup>2</sup> Penicillin has remained the recommended antibiotic in both animals and humans, at least in developing countries, where it is affordable and available almost everywhere. Because of the susceptibility of *B. anthracis* to a broad range of antimicrobials, a wide range of alternative choices exists among them tetracyclines, aminoglycosides, macrolides, and chinolones. It is desirable to prolong treatment to at least 5 days to avoid a recrudescence of the disease.

Antibiotics are effective against *B. anthracis*, but there are currently no effective therapeutic options against toxemia, which persists even after antimicrobial therapy may have eliminated the bacteria.<sup>1</sup>

The treatment of anthrax in livestock is legally prohibited in certain countries. In those countries the destruction of animals with clinical signs of anthrax without spilling of blood is required. Some countries even require the slaughter of the entire herd following a case of anthrax, a procedure that is considered unnecessary and wasteful.<sup>2</sup>

### TREATMENT AND CONTROL

#### Treatment

Penicillin G sodium/potassium (20,000 IU/kg IV every 12h at least as loading dose IV) (R-2)

Procaine penicillin (22,000 IU/kg IM every 12h or 44,000 IU/kg IM q24h) (R-2)

Oxytetracycline (10 mg/kg IV or IM every 24h) (R-2)

Anthrax hyperimmune serum (R-2)

#### Control

Anthrax vaccine (R-1)

Anthrax hyperimmune serum to animals at risk (R-2)

Procaine penicillin (44,000 IU/kg every 24h to animals at risk) (R-2)\*

Oxytetracycline (long-acting formulation 20 mg/kg every 72h to animals at risk) (R-2)\*

\*Antibiotics administered within 7 to 10 days of vaccination with anthrax vaccine will impair efficacy of vaccine.<sup>2</sup>

### CONTROL

The control of meat- and milk-producing animals in infected herds in such a way as to avoid any risk to the human population is a special aspect of the control of anthrax. When an outbreak occurs, the placing of the farm in quarantine, the destruction of discharges and cadavers, and the vaccination of survivors are part of the animal disease control program and indirectly reduce human exposure. Prohibition of movement of milk and meat from the farm during the quarantine period should prevent entry of the infection into the human food chain.

**Disposal of infected material** is most important, and hygiene is the biggest single factor in the prevention of spread of the disease. Infected carcasses should not be opened but immediately burned in situ together with manure, bedding, and soil contaminated by discharges. Deep burial, with an ample supply of quicklime, may also be used but is less desirable because it bears the risk of groundwater contamination. If the carcass and infectious material cannot be disposed of immediately, a liberal application of 5% formaldehyde on the carcass and its immediate surroundings will discourage scavengers.

All suspected cases and in-contact animals must be segregated until cases cease, and for 2 weeks thereafter the affected farm must be kept in quarantine to prevent the movement of livestock. The administration of hyperimmune serum to in-contact animals may prevent further losses during the quarantine period, but prophylactic administration of a single dose of long-acting tetracycline or penicillin is a much commoner tactic. Because currently used anthrax vaccines contain live attenuated

bacteria, they should not be used in combination with antimicrobial therapy.

**Disinfection of premises**, hides, bone meal, fertilizer, wool, and hair requires special care. When disinfection can be carried out immediately, before spore formation can occur, ordinary disinfectants or heat (60°C [140°F]) for a few minutes are sufficient to kill vegetative forms. This is satisfactory when the necropsy room or abattoir floor is contaminated. When spore formation must be expected to have begun (i.e., within a few hours of exposure to the air), disinfection is almost impossible by ordinary means. Strong disinfectants such as 5% Lysol require being in contact with spores for at least 2 days. Strong solutions of formalin or sodium hydroxide (5% to 10%) are probably most effective. Peracetic acid (3% solution) is an effective sporicide; if applied to the soil in appropriate amounts (8 L/m<sup>2</sup>), it is an effective sterilant. Infected clothing should be sterilized by soaking in 10% formaldehyde. Shoes may present a difficulty, and sterilization is most efficiently achieved by placing them in a plastic bag and introducing ethylene oxide. Contaminated materials should be damp and left in contact with the gas for 18 hours. Hides, wool, and mohair are sterilized commercially by gamma-irradiation, usually from a radioactive cobalt source. Special care must be taken to avoid human contact with infected material; if such contact does occur, the contaminated skin must be thoroughly disinfected. The source of the infection must be traced and steps taken to prevent further spread of the disease. Control of the disease in a feral animal population presents major problems.

### Immunization

Immunization of animals as a control measure is extensively used. Veterinary anthrax vaccines contain spores from attenuated strains of *B. anthracis* and are classified into two categories:

- **Live attenuated vaccines, capsulated and nontoxic (cap +/tox-).** Strains used in these vaccines are devoid of the plasmid pX01 that encodes the toxin complex of *B. anthracis* (e.g., Pasteur vaccine).
- **Live attenuated vaccines, noncapsulated and toxigenic (cap-/tox+).** Strains in these vaccines lost the plasmid pX02 encoding the capsule antigen (e.g., Sterne vaccine).

The sporulation character of both vaccine classes has the advantage of keeping the live vaccine viable over long periods. The **Pasteur vaccines** have the disadvantage that the various animal species show varying susceptibility to the vaccines, and anthrax may result from vaccination in some cases. This has been largely overcome by preparing vaccines of differing degrees of virulence for use in different species and in varying circumstances. Another method of overcoming the

virulence is the use of saponin or saturated saline solution in the vehicle to delay absorption. This is the basis of the carbozoo vaccine.

The **Sterne vaccine** has overcome the risk of causing anthrax by vaccination and produces a strong immunity. It is the vaccine used in most countries. Although only one dose was originally thought to be necessary, with cases ceasing about 8 days after vaccination, it now appears that two vaccinations are necessary in some situations.

Currently only a few countries use Pasteur vaccines, whereas the Sterne vaccine is widely used because it is characterized by its elevated protective capacity and very low residual residence.<sup>1</sup>

A febrile reaction does occur after vaccination; the milk yield of dairy cows will be depressed, and pregnant sows will probably abort.

When the disease occurs for the first time in a previously clean area, all in-contact animals should either be treated with hyper-immune serum or be vaccinated. The measures used to control outbreaks, and the choice of a vaccine depend largely on local legislation and experience. Ring vaccination has been used to contain outbreaks of the disease, and in enzootic areas annual revaccination of all stock is necessary. Surface contamination of a pasture (as opposed to deep soil contamination) can persist for 3 years, and cattle grazing these pastures should be revaccinated annually for this period. In endemic areas cattle are routinely vaccinated yearly.

Milk from vaccinated cows is usually discarded for 72 hours after the injection in case the organisms in the vaccine should be excreted in the milk. Ordinarily the organisms of the Sterne vaccine do not appear in the milk and cannot be isolated from the blood for 10 and 7 days, respectively, after vaccination. Vaccinated animals are usually withheld from slaughter for 45 days.

Deaths as a result of anthrax have occurred in 3-month-old llamas after vaccination with a Sterne vaccine and may occur in goats. Older crias and adults were unaffected. It was assumed that the dose of vaccine was excessive for such young animals. In these species two vaccinations 1 month apart with the first dose one-quarter of the standard dose can be used.<sup>1</sup>

## BOVINE TUBERCULOSIS

### SYNOPSIS

**Etiology** *Mycobacterium bovis* and, to a lesser extent, *Mycobacterium caprae*.

**Epidemiology** All age groups and species are susceptible, but infection is predominantly in cattle and pigs. Infected cattle are the main source of infection, but wildlife reservoirs are important in some regions and preclude the eradication of bovine tuberculosis in some countries. Inhalation is the major method of transmission between cattle. Pigs get primarily infected orally. Zoonosis, with most common route of infection through consumption of unpasteurized dairy products; other routes of infection include inhalation and direct contact.

**Clinical findings** Progressive emaciation, capricious appetite, and fluctuating temperature with signs referable to localization, such as respiratory disease, pharyngeal obstruction, reproductive disorder, and mastitis. In pigs, the disease is subclinical, but tuberculous lesions in cervical lymph nodes.

**Clinical pathology** Tuberculin testing. Single intradermal test is the official test in most countries, with the single intradermal comparative test for cattle suspected as false-positive reactors; interferon-gamma testing.

**Necropsy findings** Tuberculous granulomas may be found in any of the lymph nodes, or there may be generalized tuberculosis.

**Diagnostic confirmation** Culture of organism or identification by polymerase chain reaction (PCR) or other molecular techniques.

**Control** Test and slaughter. Most countries have official eradication programs.

### ETIOLOGY

Bovine tuberculosis is defined as infection of any bovine with disease causing mycobacterial species within the ***Mycobacterium tuberculosis complex (MTC)***.<sup>1</sup> The MTC comprises a range of mycobacterial species, including *Mycobacterium tuberculosis*, *M. bovis*, *M. africanum*, *M. microti*, *M. canettii*, *M. pinnipiedi* and *M. caprae*, but the most common etiologic agents of bovine tuberculosis are *M. bovis* and to a lesser extent to *M. caprae*. *M. caprae* was previously considered

to be a subspecies of *M. bovis* but is now recognized as genetically distinct species within the MTC.<sup>2</sup>

Mycobacteria are acid-fast gram-positive bacteria of the family Mycobacteriaceae. These organisms can survive for months outside the animal host, particularly in a cold, dark, and moist environment. At temperatures between 12° and 24° C (54–75° F), survival times between 18 and 332 days have been reported.<sup>2</sup>

*M. bovis* is the mycobacterial species most commonly associated with tuberculosis in cattle. A wide range of species, including humans, are susceptible to *M. bovis* infection, but only cattle and in certain geographic regions some wildlife species function as maintenance hosts for *M. bovis*. Cattle, goats, and pigs are most susceptible to infection, whereas sheep and horses show a high natural resistance. *M. caprae*, formerly designated as *M. tuberculosis* subsp. *caprae* and later as *M. bovis* subsp. *caprae*, was initially only recognized as the main etiologic agent of caprine tuberculosis, but is currently also recognized as a common etiologic agent of tuberculosis in cattle, domesticated pigs, wild boar, wild and farmed red deer, and camelids in many Central and western European countries.<sup>3</sup>

### EPIDEMIOLOGY Occurrence

During the first part of the twentieth century, bTB was widespread and present in most parts of the world, with herd prevalence rates of up to 63% and animal prevalence rates in the range of 20% to 45%. With the introduction of rigorous bTB control programs in many developed countries during the second half of the twentieth century, the occurrence of bTB in the cattle population of these countries decreased dramatically, and many countries were able to virtually eradicate the disease and are now classified as officially bTB free (OTF). bTB is a disease notifiable to the World Organization of Animal Health (OIE) and is included in the so called OIE List A, comprising “transmissible diseases that are considered to be of socioeconomic and/or public health importance within countries and that are significant in the international trade of animals and animal products.”<sup>2</sup> Clinical tuberculosis in animals is now a rarity in countries with eradication programs in place; occasional smaller outbreaks affecting one or few herds, however, occur regularly even in countries recognized as OTF. The presence of the disease is usually signaled by detection in carcasses at abattoirs.

Within the European Union, where all member states have TB eradication programs in place, the herd prevalence of bTB has been relatively stable in recent years, with rates between 0.37% and 0.67% from 2007 to 2012.<sup>4</sup> Thirteen member states of the European Union, including France, Germany,

Belgium, Poland, and Sweden, in addition to Norway and Switzerland, have the status of OTF, nonofficially free member states are, among others, the United Kingdom (Great Britain and Ireland), Italy, Greece, Spain, and Portugal.<sup>4</sup> A slight increase in the herd prevalence in nonofficially TB-free member states from 0.46% to 1.26% was recorded between 2007 and 2012.<sup>4</sup> The highest herd prevalence rates in 2012 were reported from Great Britain (10.40%), Ireland (4.37%), Spain (1.18%), and Greece (0.41%).<sup>4</sup> Herd outbreaks of *M. bovis* infection were recorded in several OTF member states in 2012, including France (169 herds), Germany (23 herds), Poland (7 herds), the Netherlands (2 herds), and Belgium and Slovenia (1 herd each). Three herds infected with *M. caprae* were identified in Austria.<sup>4</sup> With the national herd prevalence remaining below 0.1%, the OTF status of affected countries is not suspended.

In the United States, all states with exception of Michigan and California only have cattle herds certified as officially free of bTB. *M. bovis* infection of white-tailed deer, which is a maintenance host, remains a significant barrier to the U.S. bTB eradication program. *M. bovis* is still endemic in the white-tailed deer population in northeastern Michigan and northern Minnesota, presenting a potential source of infection for the local cattle population in that region. The number of confirmed cases of TB in Michigan livestock could, however, be reduced to single-digit figures since 2005.<sup>5</sup>

Australia obtained OTF status in 1997 after nearly 30 years of sustained bTB eradication. In New Zealand, where the eradication is complicated by the presence of the possum, also functioning as maintenance host for *M. bovis*, the implemented eradication program was highly successful in reducing the number of infected herds from 1700 in the mid-1990s to 66 in 2012.<sup>5</sup>

### Source of Infection

#### Cattle

Infected cattle are the main source of infection for other cattle. Organisms are excreted as aerosol in exhaled air and in sputum, feces (from both intestinal lesions and swallowed sputum from pulmonary lesions), milk, urine, vaginal and uterine discharges, and discharges from open peripheral lymph nodes. Animals with gross lesions that communicate with airways, skin, or intestinal lumen are obvious disseminators of infection. Cattle in the early stages of the disease, before any lesions are visible, may also excrete viable mycobacteria in nasal and tracheal mucus. In experimentally infected cattle, excretion of the organism commences about 90 days after infection.

#### Wildlife Reservoirs

A large number of wildlife and feral species can be naturally infected with *M. bovis* or *M.*

*caprae*. Although most wildlife and feral animals are unimportant as sources for infection to cattle, in some areas of the world certain species function as significant maintenance hosts and reservoirs for infection in cattle. These reservoirs escape traditional test and slaughter control programs and result in regions where the disease remains endemic in cattle herds.

- In areas of southwestern **England** and the Republic of **Ireland**, infected **badgers** (*Meles meles*) are significant in the epidemiology of the disease in cattle, and infection of cattle is thought to be from badger urine contamination of pastures. Badgers have also been found to make nocturnal visits to farm buildings and cattle troughs to feed, during which they defecate and urinate directly onto the cattle feed.
- In **New Zealand** infection occurs in the **brush-tail possum** (*Trichosurus vulpecula*) and produces lesions in peripheral lymph nodes with discharging sinuses. Much of New Zealand's residual problem with bTB is in cattle running on the pasture–bush margin, where there is ample opportunity for cattle–possum contact. Infection of cattle is thought to occur when curious cattle sniff moribund possums.
- **Mule deer** (*Odocoileus hemionus*), white-tailed deer (*O. virginianus*), elk (*Cervus elaphus canadensis*), and **bison** (*Bison bison*) in **North America** and red deer in Great Britain and Ireland can all act as maintenance hosts and in some regions spread infection to cattle through comingling or sharing of winter feed, resulting in foci of herd infections.
- **Buffaloes** (*Syncerus caffer*) in **South Africa** and water buffaloes (*Bulbalis bulbalis*) in the Northern Territory of **Australia** can also act as maintenance hosts.
- High infection rates approaching 50% have been reported in the **wild boar** (*Sus scrofa*) population of the **Iberian Peninsula**, where this species is regarded as maintenance host for *M. bovis*.<sup>6</sup> In northwestern Italy, wild boar are considered as spillover hosts that are unable to maintain infection without continued introduction from other species.<sup>7</sup>

### Methods of Transmission

In most cases infection occurs through inhalation or ingestion and, to a lesser degree, contact through penetration of the agent through breaks in the skin. Inhalation is the almost invariable portal of entry in housed cattle, and even in those at pasture it is considered to be the principal mode of transmission.

### Ingestion

Infection by ingestion is possible at pasture when feces contaminate the feed and communal drinking water and feed troughs, but a large infective dose is required. Under natural conditions, stagnant drinking water containing the pathogen may cause infection up to 18 days after its last use by a tuberculous animal, whereas a running stream does not represent an important source of infection to cattle in downstream fields.

The survival of the organism in the environment is influenced by temperature, moisture, exposure to the desiccating effect of sunlight, and ultraviolet light. The organism can survive for long periods in feces and soil, but most studies show that survival on pasture is measured in weeks rather than months and that environmental contamination of pasture is not of major importance in the epidemiology of the disease in cattle.

### Other Routes

The drinking of infected milk by young animals is a common method of transmission where the disease is endemic, but mammary infection occurs late in the course of the disease and is less common in countries with advanced control programs. Other uncommon routes of infection include intrauterine infection at coitus, by the use of infected semen or of infected insemination or uterine pipettes, and intramammary infection by the use of contaminated teat siphons or by way of infected cups of milking machines. The feeding of tuberculous cattle carcasses to pigs has also caused a severe outbreak of the disease. Unusual sources of infection are infected cats, goats, and even humans. Stockmen with genitourinary infections have transmitted infection to cattle through urinating in the cattle environment.

### Risk Factors

#### Environment Risk Factors

Housing predisposes to the disease, as do high stocking intensity and a large number of animals on a farm, and thus the disease is more common and serious where these forms of husbandry are practiced. The closer the animals are in contact, the greater is the chance that the disease will be transmitted.

Among beef cattle the degree of infection is usually much lower because of the open-range conditions under which they are kept. However, individual beef herds may suffer a high morbidity if infected animals are introduced and large numbers of animals have to drink from stagnant water holes, especially during dry seasons.

#### Host Risk Factors

Zebu (*Bos indicus*) type cattle are thought to be much more resistant to tuberculosis than European cattle, and the effects on these cattle are much less severe, but under

intensive feedlot conditions a morbidity rate of 60% and a depression of weight gain can be experienced in tuberculous Zebu cattle.

**Pigs** are susceptible to infection with *M. bovis*, and disease levels in general reflect those in the local cattle population from which the infection derives, either by the ingestion of dairy products or by grazing over the same pasture as cattle. The lower relative prevalence in pigs is attributable to a number of factors, particularly the tendency of the disease to remain localized in this species and the early age of slaughter. Prevalence is higher in older pigs. When the disease is common among dairy cattle in an area, 10% to 20% of the local pigs are likely to be infected. Tuberculosis in pigs is now rare in countries with bTB control programs in place, but reports from Portugal and Spain showing that *M. bovis* strains can circulate in cattle, pigs, and wild boar indicate that infection of domesticated and feral pigs can be of epidemiologic relevance under certain circumstances.<sup>5</sup>

Infection of **goats** with *M. bovis* or *M. caprae* has a worldwide occurrence and is well recognized in many European countries with a large small ruminant population, such as the United Kingdom, Italy, Portugal, Spain, and Greece. In countries that are not officially free of bTB, infection can circulate between cattle and goats, particularly if these species are kept in close proximity to each other and share pastures or water sources. This underscores the importance to include caprine flocks in the TB surveillance in these countries, which, however, is not done in most cases.<sup>8</sup>

**Sheep** have historically been considered to be resistant. However, the increasing number of reports of TB infection in this species either with *M. bovis* or *M. capra*, particularly in non-TB-free countries, suggests that the prevalence of infection in sheep may have been underestimated.<sup>8</sup> Experience in New Zealand has shown that the disease can be quite prevalent in this species, with up to 5% of flocks being infected, probably as a result of a high prevalence in local cattle and possums.

In **horses** the disease occurs rarely, largely as a result of limited exposure to infection, but natural resistance also appears to play a part.

Over the past decades, infection with *M. bovis* and also with *M. microti* has been diagnosed with increased frequency in **New World camelids (NWCs)**, particularly in regions that are not free of bTB.<sup>8</sup> NWCs are highly susceptible to infection with *M. bovis* and *M. microti*, and they may function as reservoir of the disease for cattle and wildlife.<sup>8</sup> A complicating factor is that antemortem diagnosis of infection with *M. bovis* is difficult in NWC. Diagnostic tests successfully used to control and eradicate tuberculosis in cattle were found to have a low sensitivity and specificity in NWC.<sup>8</sup>

Tuberculosis can be a problem in **farmed deer** and may also be encountered in elk, wild deer of various species, water buffalo, camels, bison, elephants, wild carnivores, monkeys and other wild fauna, and birds. Most are dead end-hosts, but some may act as important reservoirs of infection for cattle, as mentioned earlier. Infection with *M. bovis* in **zoo animals** may present a particular problem because of the longer life expectancy of potentially infected animals and the relatively close contact with other species, including humans.

### Pathogen Risk Factors

The causative organism is moderately resistant to heat, desiccation, and many disinfectants. It is readily destroyed by direct sunlight unless it is in a moist environment. In warm, moist, protected positions, it may remain viable for weeks.

### Economic Importance

bTB is a serious infectious disease of cattle and other ruminant species and has been classified as disease of socioeconomic and public health importance that is significant in the international trade of animals and animal products by the World Organization for Animal Health (OIE). bTB is under strict control in most developed countries but still has important economic and social implications in the beef and dairy cattle industry of countries affected by the disease. Incurred costs not only result from losses of cattle because of tuberculosis, decreased productivity, and losses of carcass value, but also from control and eradication measures. On a national level, costs are incurred for increased regulation, animal movement control, and enforcement of compliance and indemnification programs. Trade restrictions for farms, regions, or countries that are not certified as OTF will add to the economic damage.

### Zoonotic Importance

Historically, bTB was an important zoonotic disease transmitted from cattle to humans through the consumption of unpasteurized dairy products and to a lesser extent through direct animal contact when the organism is inhaled or penetrates the body through a break in the skin. In countries where bTB is still endemic, it presents an occupational hazard for farmers, veterinarians, workers in the meat industry and slaughterhouse, and hunters. The widespread occurrence of tuberculosis in exotic animals maintained in captivity adds to the public health importance of these infections.

With introduction of pasteurization of dairy products as standard procedure and intensive veterinary surveillance of the cattle population, in many countries the diseases has lost its importance as zoonotic disease. Whereas over 30% of all human TB cases were attributable to infection with *M. bovis*

before introduction of pasteurization, this number has plummeted to less than 2% of all confirmed cases today.<sup>9</sup> Nonetheless, in regions of the world where bTB control programs have not been implemented and the disease in cattle remains endemic, this condition is still an important zoonotic disease. In these countries, between 10% and 20% of all human cases of tuberculosis are associated with infection with *M. bovis*.<sup>10</sup> The currently increasing incidence of tuberculosis in humans, particularly in immunocompromised humans, has led to a renewed interest in the zoonotic importance of *M. bovis*.

In the United States, the Centers for Disease Control and Prevention (CDC) records approximately 220 cases of tuberculosis in humans associated with *M. bovis* every year, which is equivalent to less than 2% of all human cases of tuberculosis.<sup>11</sup> The highest percentage levels on a national basis are recorded in Mexico with 13.8%, Uganda with 7%, and Nigeria with 5% of all human TB cases caused by *M. bovis*.<sup>10</sup>

Within the European Union, a total of 125 confirmed cases of human *M. bovis* infections were recorded in 2012. Most cases were reported from Germany (44 cases), followed by the United Kingdom (35 cases), Spain (15 cases), Italy (9 cases), and the Netherlands (8 cases); Switzerland, a non-EU member state, reported 5 confirmed cases in that year.<sup>4</sup>

### PATHOGENESIS

Tuberculosis spreads in the body by two stages, the primary complex and postprimary dissemination. The **primary complex** consists of the lesion at the point of entry and in the local lymph node. A lesion at the point of entry is common when infection is by inhalation. When infection occurs via the alimentary tract, a lesion at the site of entry is unusual, although tonsillar and intestinal ulcers may occur. More commonly the only observable lesion is in the pharyngeal or mesenteric lymph nodes.

A visible primary focus develops within 8 days of entry being effected by the bacteria. **Calcification** of the lesions commences about 2 weeks later. The developing necrotic focus is soon surrounded by granulation tissue, monocytes, and plasma cells, and the pathognomonic "tubercle" is established. Bacteria pass from this primary focus, which is in the respiratory tract in 90% to 95% of cases in cattle, to a regional lymph node and cause the development of a similar lesion there. The lesions in the lungs in cattle occur in the caudal lobes in 90% of cases. In calves fed tuberculous milk, the primary focus is likely to be in the pharyngeal or mesenteric lymph nodes, with hepatic lesions as the major manifestation of postprimary spread.

**Postprimary dissemination** from the primary complex may take the form of acute miliary tuberculosis, discrete nodular lesions in various organs, or chronic organ

tuberculosis caused by endogenous or exogenous reinfection of tissues rendered allergic to tuberculo-protein. In the latter case, there may be no involvement of the local lymph node. Depending on the sites of localization of infection, clinical signs vary, but because the disease is always progressive, there is the constant underlying toxemia, which causes weakness, debility, and the eventual death of the animal.

In cattle, horses, sheep, and goats, the disease is progressive; although generalized tuberculosis is not uncommon in pigs, localization as nonprogressive abscesses in the lymph nodes of the head and neck is the most common finding.

## CLINICAL FINDINGS

### Cattle

Although signs referable to localization in a particular organ usually attract attention to the possible occurrence of tuberculosis, some general signs are also evident. Some cows with extensive miliary tubercular lesions are clinically normal, but in most cases progressive emaciation unassociated with other signs occurs, which should arouse suspicion of tuberculosis. A capricious appetite and fluctuating temperature are also commonly associated with the disease. The hair coat may be rough or sleek. Affected animals tend to become more docile and sluggish, but the eyes remain bright and alert. These general signs often become more pronounced after calving.

### Lungs

Pulmonary involvement is characterized by a chronic cough as a result of bronchopneumonia. The cough is never loud or paroxysmal, occurring only once or twice at a time, and is low, suppressed, and moist. It is easily stimulated by squeezing the pharynx or by exercise and is most common in the morning or in cold weather. In the advanced stages when much lung has been destroyed, dyspnea with increased rate and depth of respiration becomes apparent. At this stage, abnormalities may be detected by auscultation and percussion of the chest. Areas with no breath sounds and dullness on percussion are accompanied by areas in which squeaky crackles are audible, often most audible over the caudal lobes. Tuberculous pleurisy may occur but is usually symptomless because there is no effusion. Involvement of the bronchial lymph nodes may cause dyspnea because of constriction of air passages, and enlargement of the mediastinal lymph node is commonly associated with recurrent and then persistent ruminal tympany.

### Intestine

Rarely, tuberculous ulcers of the small intestine cause diarrhea. Retropharyngeal lymph node enlargement causes dysphagia and noisy breathing as a result of pharyngeal obstruction. Pharyngeal palpation, or

endoscopy, reveals a large, firm, rounded swelling in the dorsum of the pharynx. Chronic, painless swelling of the submaxillary, prescapular, precrural, and supramammary lymph nodes is relatively rare.

### Uterus

Reproductive disorders include uterine tuberculosis, which is uncommon with bovine strains except in advanced cases. Spread by contiguity from the uterus causes peritonitis, bursitis, and salpingitis, with the lesions in the salpinx taking the form of small enlargements containing a few drops of yellow fluid. In tuberculous metritis, there may be infertility, or conception may be followed by recurrent abortion late in pregnancy, or a live calf is produced that in most cases dies quickly of generalized tuberculosis. Lesions similar to those of brucellosis occur on the placenta.

In cows that fail to conceive, there may be a chronic purulent discharge heavily infected with the organism, and the condition is very resistant to treatment. A number of cows will have an associated tuberculous vaginitis affecting chiefly the ducts of Gartner. Rare cases of tuberculous orchitis are characterized by the development of large, indurated, painless testicles.

### Mastitis

Tuberculous mastitis is of major importance because of the danger to public health, risk of spread of the disease to calves, and the difficulty of differentiating it from other forms of mastitis. Its characteristic feature is a marked induration and hypertrophy, which usually develops first in the upper part of the udder, particularly in the rear quarters. Palpation of the supramammary lymph nodes is essential in all cases of suspected tuberculous mastitis. Enlargement of the nodes with fibrosis of the quarter does not necessarily indicate tuberculosis, but enlargement without udder induration suggests either tuberculosis or lymphomatosis. In the early stages, the milk is not macroscopically abnormal, but very fine floccules appear later and settle after the milk stands, leaving a clear, amber fluid. Later still, the secretion may be an amber fluid only.

### Pigs

Pigs get infected through oral ingestion of the pathogen, leading to primary lesions in the oropharyngeal lymph node and the digestive tract. Tuberculous lesions in cervical lymph nodes usually cause no clinical abnormality unless they rupture to the exterior. Generalized cases present a syndrome similar to that seen in cattle, although tuberculous involvement of the meninges and joints is more common.

### Horses

As in pigs, infection in horses commonly occurs through the digestive route, again

leading to primary lesions in the oropharyngeal lymph node and the digestive tract.<sup>12</sup> The commonest syndrome in horses is caused by involvement of the cervical vertebrae in which a painful osteomyelitis causes stiffness of the neck and inability to eat off the ground. Less common signs include polyuria, coughing as a result of pulmonary lesions, lymph node enlargement, nasal discharge, and a fluctuating temperature.

### Sheep and Goats

Bronchopneumonia is the commonest form of the disease in these species and is manifested by cough and terminal dyspnea. In some goats, intestinal ulceration, diarrhea, and enlargement of the lymph nodes of the alimentary tract occur. In both species the disease is only slowly progressive, and in affected flocks many more reactors and necropsy-positive cases are often found than would be expected from the clinical cases that are evident. In kids the disease may be more rapidly progressive and cause early death.

### New World Camelids

Infection of a camelid herd with either *M. bovis* or *M. microti* may go unnoticed until one or several animals die, presenting suspicious lesions at necropsy. Affected animals may either be found dead or show signs of general distress with weight loss and respiratory symptoms before dying.<sup>13</sup>

## CLINICAL PATHOLOGY

The antemortem diagnosis of bovine tuberculosis still presents a challenge because all available and routinely employed tests suitable for antemortem diagnosis have limitations regarding sensitivity and specificity.<sup>14</sup> Diagnostic tests for bTB can broadly be classified into direct and indirect diagnostic tests, with direct tests identifying the presence of the causative agent in the host and indirect tests using immunologic markers to determine whether an infection had occurred in an individual animal. Current bTB eradication programs are based on a screening and slaughter policy, and all use indirect tests determining the presence of a cellular or humoral immune response to a challenge with bovine tuberculin. Knowledge of the various tests used, including their deficiencies and advantages, is essential.

### Direct Tests

Direct tests targeted at directly identifying the agent in postmortem specimens include microscopic examination, culture, and nucleic acid recognition methods. Direct tests targeted at identifying the causative agent in an animal form part of the passive abattoir surveillance that is an integral part of all bTB eradication programs and can be applied on samples collected during postmortem examination. All carcasses of slaughtered cattle are visually screened for

characteristic gross pathologic findings that may be indicative of infection. Histopathology, culture, and molecular methods are then used to identify bacteria in abnormal tissue. Passive abattoir surveillance is considered highly cost effective but has the major drawback of lack of sensitivity. Extensive lesions are present in advanced stages of tuberculosis only, which have become a rarity in regions with ongoing bTB surveillance; small organ lesions are easily missed during abattoir meat inspection.<sup>2</sup>

The collection and pooling of samples from several grossly unremarkable lymph nodes from the head and thorax has been suggested as suitable material for bacteriologic culture.

### Microscopic Examination

Mycobacteria can be demonstrated microscopically in smears and tissue material from clinical samples. Special stains such as the Ziehl-Neelsen or fluorescent acid-fast stain are used to determine the presence of acid-fast bacteria, which, together with the characteristic histologic lesions, can lead to a presumptive diagnosis; however, the diagnosis requires further confirmation.<sup>2</sup> Particularly in ruminants, histologic lesions contain few bacteria which may lead to a negative result, although *M. bovis* can be isolated in cultures.

### Culture

Specimens for culture are first homogenized following decontamination and are then centrifuged. The sediment is used for microscopic examination and culture. Cultures are incubated on specific media at 37°C (99°F) for at least 8 weeks, but preferably 10 to 12 weeks. If growth occurs, smears are prepared using specific acid-fast stains. Growth of *M. bovis* is generally observed between 3 and 6 weeks of culture.<sup>2</sup> Because *M. bovis* must be differentiated from other species of the *M. tuberculosis* complex, further testing is required. The major disadvantage of cultures is the long turnaround time, and the primary limitation results from the poor quality of samples often submitted to the diagnostic laboratory.

### Nucleic Acid Recognition Methods

The polymerase chain reaction (PCR) is a laboratory technique for identifying the presence of bacteria-specific DNA that has been extensively evaluated for the detection of *M. tuberculosis* complex in specimens of human and, more recently, also of animal origin. In principle, the PCR presents an attractive diagnostic procedure allowing for the identification and differentiation of specific pathogens. The method is rapid, cost effective, and easy to standardize. For the diagnosis of tuberculosis in animals, however, commercial kits and in-house methods have been evaluated with unsatisfactory results.<sup>2</sup> The reasons why the PCR

does not yet fulfill its diagnostic potential as diagnostic test for tuberculosis are various. False-positive and false-negative results have not only been attributed to the low number of bacteria often present in samples, but also to difficulties with the decontamination methods, the presence of polymerase enzyme inhibitors in the samples, and difficulties in extracting DNA from mycobacteria that possess a robust cell wall.<sup>15</sup> Current molecular methods are therefore not yet considered adequate for direct detection of *M. bovis*, either from ante- or postmortem samples.<sup>15</sup>

### Indirect Tests

Indirect tests can again be subdivided into cellular-immunity-based and humoral-immunity-based diagnostic tests. Cellular-immunity-based tests determine the occurrence of a delayed hypersensitivity reaction in general in the form of swelling after intradermal application of tuberculin protein. These so-called intradermal tuberculin tests are the standard diagnostic tools of bTB eradication programs used for ante-mortem diagnosis of *M. bovis* infection.

Blood-based cellular immunity tests include the interferon- $\gamma$  test, which is now accepted as complementary test in many national bTB eradication programs and is recognized as alternative test of international trade, and the lymphocyte proliferation assay. Humoral-immunity-based tests are serologic diagnostic tools that determine the presence of specific antibody indicating prior exposure to antigen of *M. bovis*.

### Intradermal Tuberculin Test

The intradermal tuberculin test is the standard diagnostic tool for detection of bTB and consists of the intradermal injection of **bovine tuberculin purified protein derivative (PPD)** into a skin fold of a specific location of the body and the subsequent detection of swelling as a result of delayed hypersensitivity 72 hours later.<sup>2</sup> Because of differences in sensitivity of the skin of different body parts, different approaches for the intradermal tuberculin test are in use. The **caudal skin fold** at the base of the tail (**caudal fold test [CFT]**) is used primarily for practicality reasons in the United States, Canada, and New Zealand, and formerly also in Australia, whereas in Europe and the United Kingdom a **cervical skin fold** of the lateral aspect of the neck is used for the so-called **single intradermal test (SIT)**. Applying the intradermal test in the cervical region results in higher sensitivity and specificity compared with the caudal skin fold but is more labor intensive because it requires better restraint of the animal and clipping of the skin.<sup>16</sup> Whereas the interpretation of the CFT consists of manual palpation to determine swelling approximately 72 hours after injection, the interpretation of the SIT and SICT (described in the following discussion) is done by measuring the thickness of the

skinfold before and 72 hours after injection using calipers.

Where the presence of paratuberculosis (John's disease), avian tuberculosis, or a high prevalence of infection with environmental mycobacteria is suspected, nonspecific sensitization must be considered. In these cases, the **single intradermal comparative test (SICT)**, consisting of the simultaneous intradermal administration of bovine and avian tuberculin on two different injection sites of the neck, either one on each side or both on the same side approximately 12 cm apart and one above the other, is administered. The test is read 72 hours later and the reaction to both tuberculins compared with each other. The greater of the two reactions indicates the organism responsible for the sensitization. This test is not generally intended for primary use in detecting reactors but only to follow up known reactors to determine the infecting organism. Its use as a primary test is recommended when a high incidence of avian tuberculosis or John's disease is anticipated or when vaccination against John's disease has been carried out. The comparative test is adequate to differentiate between vaccination against John's disease and tuberculosis, and the distinction is easier the longer the time between vaccination and testing.

Historically, other tests using bovine tuberculin to determine hypersensitivity—such as the vulvar, ophthalmic, or palpebral test; the short thermal test; and the Stormont test—have been used but are now obsolete.

### Special Aspects of Sensitivity to Tuberculin

- Potency and standardization of tuberculins: Modern-day tuberculin used for diagnostic purposes is a purified protein derivative (PPD) of bovine or avian tuberculin that is prepared from the heat-treated products of growth and lysis of *M. bovis* (or *M. avium* in the case of avian tuberculin). Production methods have in the meantime largely been standardized, and with PPD being a licensed product, it requires production under good manufacturing practice conditions that comply with official requirements of the World Organization for Animal Health (OIE).<sup>2</sup> The standardized preparation is meant to ensure that the final product contains a precise concentration of standardized quality; nevertheless, the protein content of tuberculin does not precisely predict its biological activity or potency, which is a critical parameter strongly affecting the outcome of the test.<sup>14</sup> Potency testing is therefore required as further step in the manufacturing process to standardize product quality, which is done by comparing the potency to a reference standard in guinea pigs. It must,

however, be noted that the clinical potency determined in tuberculous guinea pigs is not necessarily representative of the clinical potency in cattle.<sup>16</sup> A bovine tuberculin is considered adequate for diagnosis as part of an official test program when providing a minimum of 2000 IU PPD per dose, with an estimated potency of between 66% and 150%.<sup>14</sup>

- **Dose:** The dose of tuberculin must be at least 2000 IU of bovine (or avian for the SCIT) tuberculin; in cattle with diminished allergic sensitivity, higher doses of up to 5000 IU may be required. In any case the injection volume should not exceed 0.2 mL.<sup>2</sup> The exact dose for the particular tuberculin that is officially prescribed must be strictly adhered to when the cervical skin test is used. In the United States 0.1 mL is recommended for herds of unknown status and 0.2 mL in known infected herds when cases with low sensitivity are to be carefully sought. The method of injection of tuberculin also has some importance when the cervical site is used. A careful intradermal injection produces the largest swelling, and a quick thrust produces the least.
- **Desensitization during tuberculin testing:** When a suspicious reactor is encountered, the question of when to retest is complicated by the phenomenon of desensitization caused by the absorption of tuberculin and other foreign proteins. Desensitization is more marked and of longer duration after an (accidental) subcutaneous than after an intradermal injection. After an SID test the period of desensitization is short, but as a practical procedure, it is recommended that animals giving a suspicious result to an SID test not be retested before 60 days.

The desensitization phenomenon can be used to obscure a positive reaction. If tuberculin is injected and thus the test is made in the desensitized period, no reaction will occur in infected animals.

- **Postparturient desensitization:** Tuberculous cattle go through a period of desensitization immediately before and after calving, and as many as 30% give false-negative reactions returning to a positive status 4 to 6 weeks later. The loss of sensitivity is probably a result of the general immunologic hyporeactivity that occurs associated with parturition. Calves drinking colostrum from infected dams give positive reactions for up to 3 weeks after birth even though they may not be infected.
- **Anergy:** Anergic animals are those with visible lesions of tuberculosis but that do not react to a cutaneous delayed hypersensitivity test. The number of these can be reduced by being careful to

inject sufficient tuberculin (2000 IU) at the right site and to read the test at 72 hours. There is still a residuum of cases that do not respond, especially those with extensive pulmonary involvement.

### Summary of Testing Procedures in Cattle

In summary, it is usual to use the single intradermal test as a routine procedure.

Annual testing of all cattle, quarantine of test-positive herds, and a movement ban into TB-free areas have historically been effective in TB control schemes. The sensitivity and specificity of the skin test are moderately high, but false-positive and false-negative reactions occur.

**False-positive reactions** (no gross lesion reactors) may be given by the following:

- Animals sensitized to other mycobacterial allergens, including those of human or avian tuberculosis or paratuberculosis (Johne's disease); relatively nonpathogenic mycobacteria (e.g., skin tuberculosis); and, by ingestion, nonpathogenic mycobacteria in permanent waters inhabited by birds, or poultry litter fed to cattle when the birds are infected with *M. avium*
- Animals sensitized to other allergens (e.g., *Nocardia farcinicus*)
- Animals injected with irritants at the injection site before reading of the tuberculin test, when compensation rates for reactors exceed true cattle prices

The proportion of false-positive reactions is likely to increase as control programs progress toward eradication and can undermine farmers' confidence in the control program. Reactors that are thought to be nonspecific should be retested by the comparative test in the cervical region 7 days after the response to the SID or CFT. Alternatively, cattle can be retested using the whole-blood interferon-gamma assay 8 to 28 days after the skin test.

**False-negative reactions** may be given by the following:

- Advanced cases of tuberculosis
- Early cases until 6 weeks after infection
- Cows that have calved within the preceding 6 weeks
- Animals desensitized by tuberculin administration during the preceding 8 to 60 days
- Old cattle
- Low-potency tuberculin or bacterial contamination of the tuberculin
- Variable dose with multidose syringes

### Tuberculin Testing in Other Species

#### Pigs

The most generally used method is the SID test, injecting 0.1 mL of standard-potency mammalian tuberculin into a fold of skin at the base of the ear, but the test is relatively inaccurate in this species. The test is read 24 to 48 hours later; an increase in skin

thickness of 5 mm or more constitutes a positive reaction. In positive animals the skin thickening often exceeds 10 mm and shows superficial necrosis and sloughing.

If the animal is infected with *M. avium*, the maximum skin thickening may not occur until 48 hours after injection. When no attempt is being made to determine the type of infection, mixed avian and mammalian tuberculins may be used and the test read at 24 to 48 hours. If avian tuberculin alone is used, the test should be read at 48 to 72 hours, and an increase in skin thickness of 4 mm is classed as positive.

Many suspicious reactions occur in pigs because of the tendency of lesions to regress and the sensitivity to tuberculin to diminish, with maximum sensitivity occurring 3 to 9 weeks after infection. A retest in 6 to 8 weeks should determine whether or not the disease is progressing. Although positive reactors may in time revert to a negative status, there may be macroscopic lesions in these animals at necropsy. However, viable organisms are not usually recoverable from the lesion, the infection apparently having been overcome.

Some decrease in skin sensitivity after parturition occurs in sows infected with *M. bovis* but may not occur when the infection is associated with *M. avium*. Comparative tests work efficiently in this species, with little or no reaction to heterologous tuberculin.

#### Horses

The results obtained with subcutaneous and intradermal tuberculin tests are very erratic and must be assessed with caution, especially when the test is positive because many false-positives occur. The horse appears to be much more sensitive than cattle to tuberculin, and much smaller doses of standardized tuberculin are required. As little as 0.1 mL of PPD tuberculin is sufficient to elicit a positive reaction, and testing may provoke an anaphylactic reaction. No safe recommendations can be made on tests in this species because of lack of detailed information, but the occurrence of a systemic reaction with a positive cutaneous test can be accepted as indicating the presence of infection.

#### Sheep and Goats

The single intradermal test is relatively inaccurate, with some tuberculous animals giving negative reactions, although on the basis of results achieved in experimentally infected goats, it is adequate. The test injection is usually given in the caudal fold as in cattle, but injection into the skin of the inside of the thigh of sheep is also satisfactory. An increase in thickness of 5 mm in the fold constitutes a positive reaction.

#### New World Camelids

Diagnostic tests used for in vivo identification of cattle infected with *M. bovis* are considered highly unreliable in NWCs because

they have demonstrated a lack of sensitivity and specificity when applied according to the protocol used in cattle.<sup>8</sup> In dromedaries the diagnostic performance of the SCIT was found to be improved somewhat when the test was performed on the axillar skin and read after 5 days, although a considerable number of animals also reacted to avian tuberculin.<sup>15</sup>

### Interferon- $\gamma$ Assay (IFN- $\gamma$ )

An in vitro assay of cell-mediated reactivity by detection and quantitation of  $\gamma$ -interferon known as the interferon- $\gamma$  assay (IFN- $\gamma$ ) is licensed and commercially available in some countries. It is based on the detection of IFN- $\gamma$  liberated from white blood cells in whole-blood cultures incubated with PPD tuberculin and has the advantage that tested cattle need only be handled once. It can detect infected cattle as early as 3 to 5 weeks after infection even with low exposure level. It also has value in retesting skin-test-positive cattle that may be false-positive reactors, but for this purpose it should be used between 8 and 28 days after skin testing because assay reactions are diminished if conducted on samples taken at the 3-day reading revisit after skin testing. Ideally, the test should be set up in the laboratory on the same day as sampling or, at the most, after overnight storage of the blood. Current testing is with *M. bovis* PPD, which can contain cross-reacting antigens to other mycobacterial species, and more specific and sensitive tests using antigens specific to *M. bovis* are being evaluated.

A recent meta-analysis reported an estimated sensitivity of 67%, which is superior to the SCIT, and a specificity of 96%, which is inferior to the SCIT, for the IFN- $\gamma$ .<sup>16</sup> The IFN- $\gamma$  is available as commercial test kit and is now approved as official diagnostic test in several national bTB eradication and control programs, including programs in the European Union, the United States, New Zealand, and Australia.

### Lymphocyte Proliferation Test

Like the IFN- $\gamma$  test, the lymphocyte proliferation test is an in vitro test that is conducted either on whole blood or purified lymphocytes and determines and compares the reactivity of peripheral lymphocytes to avian and bovine tuberculin. The test result is the difference in reactivity of lymphocytes to bovine (B) and avian (A) tuberculin; the B-A value is calculated and compared with a cutoff value. The test is not used for routine diagnostics because it requires the handling of radioactive material and long incubation periods.<sup>2</sup>

### Serologic Tests for Diagnosis of Tuberculosis

In the final stages of a tuberculosis eradication program, the percentage of reactors, which are not in fact tuberculous, increases

to the point where a more discerning test than the one based on cutaneous hypersensitivity is required. Most of the tests tried so far have been serologic ones. Their aim is to identify anergic animals and cases sensitized by some other bacteria.

Serologic tests, including complement fixation, fluorescent antibody, direct bacterial agglutination, precipitin, and hemagglutination tests, have been developed but have little potential value for the routine diagnosis of tuberculosis.

Early enzyme-linked immunosorbent assay (ELISA) tests to crude mycobacterial antigens had limited value, but an ELISA that examines antibody to defined antigens of *M. bovis* before and after skin testing appears useful in detecting nonspecific reactors.

Serologic tests may, however, be of some value for the diagnosis of tuberculosis in domestic animal and wildlife species such as farmed deer, NWCs, badgers, nonhuman primates, or elephants, where cellular-immunity-based diagnostic tests are not available and intradermal tuberculin test have been proven unreliable.<sup>2</sup>

### NECROPSY FINDINGS

#### Cattle, Sheep, and Goats

These show similar lesions with a standard distribution. Tuberculous granulomas may be found in any of the lymph nodes, but particularly in bronchial, retropharyngeal, and mediastinal nodes. In the lung, miliary abscesses may extend to cause a suppurative bronchopneumonia. The pus has a characteristic cream to orange color and varies in consistency from thick cream to crumbly cheese. Tuberculous nodules may appear on the pleura and peritoneum.

All localized lesions of tuberculosis tend to stimulate an enveloping fibrous capsule, but the degree of encapsulation varies with the rate of development of the lesion. Generalized cases are denoted by the presence of **miliary tuberculosis**, with small, transparent, shot-like lesions in many organs, or by pulmonary lesions that are not well encapsulated and caseated. The presence of bronchopneumonia or hyperemia around pulmonary lesions is highly suggestive of active disease. Cases with tuberculous mastitis or discharging tuberculous metritis must also be considered as likely to be potent spreaders of the infection.

Chronic lesions are characteristically discrete and nodular and contain thick, yellow to orange, caseous material, often calcified and surrounded by a thick, fibrous capsule. Although such lesions are less likely to cause heavy contamination of the environment than open lesions, affected animals are important as sources of infection. It should be noted that suspect cattle slaughtered as part of bovine tuberculosis eradication programs may be culture-positive and yet have no typical gross or microscopic lesions.

### Pigs

Generalized tuberculosis, with miliary tubercles in most organs, is seen in pigs, but the common finding is localization in the tonsils and the submaxillary, cervical, hepatic, bronchial mediastinal, and mesenteric lymph nodes. The nodes are markedly enlarged and consist of masses of white, caseous, sometimes calcified, material, surrounded by a strong, fibrous capsule and interlaced by strands of fibrous tissue. Because of the regressive nature of the disease in pigs, these lesions are often negative on culture.

### Horses

The characteristic distribution of tubercles in horses includes the intestinal wall, mesenteric lymph nodes, and spleen. The cut surface of these firm nodules has a fleshy appearance similar to that of neoplastic tissue. There is also a tendency for lesions to develop in the skeleton, particularly the cervical vertebrae.

Histologically, there is some variation between the domestic species with regard to features such as mineralization and the degree of tissue necrosis. In some cases acid-fast bacilli may be difficult to demonstrate using conventional stains. A comparison of the infection in cattle and cervid species suggests that tuberculosis should be considered in cervids even when the lesions have a suppurative and necrotizing character, with a minimal granulomatous component. Culture of *M. bovis* is difficult and time consuming, and it poses a considerable public health risk. Methods such as immunoperoxidase staining and PCR can permit detection of the organisms while minimizing public health risks.

### Samples for Confirmation of Diagnosis

- Bacteriology—affected lymph nodes, lung, granulomas from viscera (culture [has special growth requirements], PCR)
- Histology—formalin-fixed samples of these tissues (light microscopy, immunohistochemistry, PCR)

**Note the zoonotic potential of this organism when handling the carcasses and submitting specimens.**

### DIFFERENTIAL DIAGNOSIS

Because of the chronic nature of the disease and the multiplicity of signs caused by the variable localization of the infection, tuberculosis is difficult to diagnose on clinical examination. If the disease occurs in a particular area, it must be considered in the differential diagnosis of many diseases of cattle. In pigs, the disease is usually so benign that cases do not present themselves as clinical problems and are found only at necropsy. The rarity of the disease in horses, sheep, and goats makes it an unlikely diagnostic risk, except in groups that have

*Continued*

had abnormally high exposure to infected cattle. Differential diagnoses include the following:

- Mycobacteriosis associated with the *M. avium-intracellulare* complex and atypical
- Mycobacteria and *M. tuberculosis* in particular in pigs
- Lung abscess as a result of aspiration pneumonia
- Pleurisy and pericarditis following traumatic reticulitis
- Chronic contagious bovine pleuropneumonia
- Upper respiratory disease
- Actinobacillosis
- Bovine leukosis
- Lymphadenopathy
- Other causes of mastitis

## TREATMENT

Treatment of tuberculosis in cattle is not permitted in countries with an established bTB eradication program, requiring removal of reactors from the herd. Treatment may, however, be permitted in some cases, such as in valuable zoo animals.

Because of the progress being made in the treatment of human tuberculosis with such drugs as isoniazid, combinations of streptomycin and *para*-aminosalicylic, and other acids, the treatment of animals with tuberculosis has undergone some examination, and claims have been made for the efficiency of long-term oral medication with isoniazid both as treatment and as control. It is not a favored option in eradication-conscious countries.

## CONTROL

Eradication of bTB has been virtually achieved in many countries. The methods used have depended on a number of factors, but ultimately the **test and slaughter policy** has been the only one by which effective eradication had been achieved.

### Control on a Herd Basis

Control in a herd rests on removal of the infected animals, prevention of spread of infection, and avoidance of further introduction of the disease.

### Tuberculin Testing

Detection of infected animals depends largely on the use of the intradermal tuberculin test. All animals over 3 months of age should be tested and positive reactors disposed of according to local legislation. Suspicious reactors are retested at intervals appropriate to the test used. At the initial test, a careful clinical examination should be conducted on all animals to ensure that there are no advanced clinical cases that will give negative reactions to the test. Doubtful cases and animals likely to have reduced sensitivity, particularly old cows and those that have calved within the previous 6 weeks, may be

tested by one of the special sensitivity or serologic tests described previously or retested subsequently. The single comparative intradermal test (SCIT) should be used where infection with *M. avium* is anticipated or where a high incidence of reactors occurs in a herd not showing clinical evidence of the disease.

### Retesting

Until recently, if the incidence of reactors was high at the first test or if “open” lesions were found at necropsy in culled animals, emphasis was placed on repeat testing at short intervals to avoid the situation in which the spread of the disease might overtake the culling rate. It is now thought that all animals with tuberculosis should be regarded as equally potent disseminators of the infection. Retests of the herd should be carried out at 3-month intervals until a negative test is obtained. A further test is conducted 6 months later, and if the herd is again negative, it may be classed as free of the disease. Subsequent check tests should be carried out annually.

### Prevention of Spread

Hygienic measures to prevent the spread of infection should be instituted as soon as the first group of reactors is removed. Feed troughs, water troughs, and drinking cups should be cleaned and thoroughly disinfected. Suspicious reactors being held for retesting should be isolated from the remainder of the herd. Separation of infected and susceptible animals by a double fence provides practical protection against spread of the disease.

It is important that calves being reared as herd replacements be fed on tuberculosis-free milk, either from known free animals or pasteurized. Rearing calves on skim milk from a communal source is a dangerous practice unless the skim milk is sterilized. All other classes of livestock on the farm should be examined for evidence of tuberculosis. Farm attendants should be checked because they may provide a source of infection.

If a number of reactors are culled, attention must be given to the possibility of infection being reintroduced with replacements, which should come from accredited herds. Failing this, the animals should be tested immediately, isolated, and retested in 60 days. Infection from other herds should be addressed by preventing communal use of watering facilities or pasture and by maintaining adequate boundary fences.

It is inadvisable to attempt a control program until it can be guaranteed that all animals can be gathered, identified, tested, and segregated, a difficult proposition in cattle run on extensive range country with little manpower and few fences.

### Control on an Area Basis

The method used to eradicate bovine tuberculosis from large areas will depend on the

incidence of the disease, methods of husbandry, attitude of the farming community, and the economic capacity of the country to stand losses from a test and slaughter program.

## Education

An essential first step is the prior education of the farming community. Livestock owners must understand the economic and public health significance of the disease, its manifestations, and the necessity for the various steps in the eradication program. Eradication must also be compulsory because voluntary schemes always leave foci of infection. Adequate compensation must be paid to encourage full cooperation by way of payment for animals destroyed or bonuses for disease-free herds or their milk or beef.

## Staging

It is essential at the beginning of a program to determine the incidence and distribution of the disease by tuberculin testing of samples of the cattle population and a meat inspection service. Eradication can commence in herds and areas that have a low incidence of the disease. These will provide a nucleus of tuberculosis-free cattle to supply replacements for further areas as they are brought into the eradication scheme.

## Vaccination

Vaccination may offer a major alternative to test and slaughter in the control of bovine tuberculosis but currently suffers from both lack of efficacy and the problem of vaccinated cattle reacting to current tests for TB. Vaccination may be used as a temporary measure when the incidence of tuberculosis is high and a routine test and slaughter program may be economically impossible until it is lowered, or when an eradication program cannot be instituted for some time but it is desired to reduce the incidence of the disease in preparation for eradication.

*Bacillus Calmette-Guérin* (BCG) vaccination is the only method available for field use. Vaccination must be repeated annually, and the vaccinated animal remains positive to the tuberculin test. Calves must be vaccinated as soon after birth as possible and do not achieve immunity for 6 weeks. The immunity is not strong, and vaccinated animals must not be submitted to severe exposure. In field circumstances where the disease is prevalent, only modest results, if any, can be expected.

There are a number of newer, prospective vaccines, including subunit and synthetic peptide vaccines, antigenically improved BCG, attenuated mutants of *M. bovis*, and protective antigens expressed in attenuated live vaccine vectors. Detection of vaccinated cattle from naturally infected cattle could be possible with vaccine-specific antigens in the interferon-gamma assay.

## Test and Slaughter

When the overall incidence of tuberculosis is 5% or less, compulsory testing and the slaughter of reactors is the only satisfactory method of eradication. A combination of lines of attack is usually employed.

Accredited areas are set up by legislation, and all cattle within these areas are tested and reactors removed. Voluntary accreditation of individual herds is encouraged outside these areas. In some countries, focal points of extensive infection outside accredited areas have been attacked under special legislation.

When an area or country has been freed from the disease, quarantine barriers must be set up to avoid its reintroduction. Within the area, the recurrent cost of testing can be lessened by gradually increasing the interest period to 2 and then to 3 or even 6 years as the amount of residual infection diminishes. Meat inspection services provide a good observation point should any increase in incidence of the disease occur. Among range beef cattle it is usual to check samples of animals at intervals rather than the entire cattle population.

## Problems in Tuberculosis Eradication

Complete eradication of tuberculosis has not really been achieved in any country. In many, a state of virtual eradication has been in existence for years, but minor recrudescences occur. In the final stages of an eradication program a number of problems achieve much greater importance than in the early stages of the campaign. The major problems that arise are as follows.

### No-Visible-Lesion Reactors

The percentage of reactors with no gross lesions or no visible lesions (NVL) at slaughter rises steeply as the disease prevalence decreases. In part this occurs because gross examination has poor sensitivity for detection of infection, but it is also inevitable given the falling prevalence of disease and the specificity of the tuberculin test. NVL reactors create administrative and public relations difficulties. Resolution of this problem awaits the validation of the interferon-gamma assay or other accepted serologic tests.

### "Breakdowns"

Individual herds that have been accredited after a number of free tests may be found to have the disease again, often with a very high incidence. This may be because an anergic carrier has been left in the herd and tests have been too far apart or because of a break in the security of the herd, with infection from purchased cattle or transmission between cattle in neighboring herds.

### "Traceback"

A principal source of information on the location of infected herds in the final stages

of a program could be a traceback originating from infected animals at packing plants. It is often impossible, and a major advance would be a suitable method of identifying individual animals that could be utilized up to the killing floor. The two most popular methods are fabric labels stuck on the rump with skin contact glue and wraparound plastic or metal tail-tags bearing an identification number for the farm of origin. They have two problems. They can be removed at the abattoir and reused; they fall off if the tail is docked, a popular practice in some areas. Electronic identification might solve this problem but meets political and other resistance in many countries. Recent experience with bovine spongiform encephalopathy and other concerns for food safety will likely remove this resistance, and most countries have or are developing effective traceback programs.

### Large Herds

Another kind of difficulty in eradication is where cattle are run under very extensive conditions on large ranches or stations as in North America, South America, and Australia. There can be difficulty in ensuring a complete muster, and there is a great need for a test that does not require that cattle be held in a mustering site for 3 days before the test is read. Problems with continuing infection also occur in large intensive dairies where the policy is test and cull, and the whole dairy cannot be depopulated at one time.

### Wildlife Reservoirs

Spread to cattle from wild fauna is a major problem in the United Kingdom, where badgers and deer are important sources of infection; in New Zealand, where the brush-tailed possum plays the same role; and a risk from deer exists in several countries. In New Zealand, the possum is considered a pest and does considerable damage to the ecosystem; possum control programs are accepted. However, the badger in Britain, and deer in most countries, are protected species and suitable control programs, acceptable to animal protectionists, are difficult to negotiate in this sensitive area of public relations. DNA fingerprinting can establish sources of infection and the importance of wildlife reservoirs to cattle.

### Control of Tuberculosis in Pigs

*M. bovis* infection in pigs usually results from the feeding of infected milk, skim milk, or whey to pigs or allowing cattle and pigs to graze the same pasture. The first step in the control of tuberculosis in a pig herd is to remove the source of infection, and then to test and remove the reacting animals, which is not an efficient procedure because of the relative inaccuracy of the tuberculin test in this species. The nonprogressive nature of the disease means that transmission between

pigs is unlikely to occur to a significant extent, except perhaps in breeding animals.

## TUBERCULOSIS ASSOCIATED WITH MYCOBACTERIUM TUBERCULOSIS

*Mycobacterium tuberculosis* is occasionally isolated from cattle or pig livestock with tuberculous lesions, but this is rare. Outbreaks of tuberculosis in animals associated with *M. tuberculosis* of human origin are transitory, and removal of tuberculous humans from the environment usually results in the disappearance of positive reactors in cattle.

In recent years a considerable increase in the occurrence rate of tuberculosis associated with *M. tuberculosis* was noticed among the wildlife population of South African zoos.<sup>1</sup> The considerable genetic diversity of strains involved in cases of TB in wild animals suggests that animals contracted the

infection from human visitors to the zoos rather than from an internal source. This development is considered to be the result of the human tuberculosis epidemic in South Africa spilling over to wild animals.<sup>1</sup>

*M. tuberculosis* has been isolated from a subset of pig carcasses that have been condemned because of the presence of tuberculous lesions at two slaughterhouses in Ethiopia.<sup>2</sup> The presence of *M. tuberculosis* in pig carcasses suggests transmission of the pathogen between both species and supports the idea that pigs may indeed not be dead-end hosts for mammalian tuberculosis.<sup>2</sup>

In cattle herds, the reactors and necropsy lesions are most common in the young stock. Many reactors have no visible lesions; those that do occur are small and confined to the lymph nodes of the digestive and respiratory systems. Pigs may develop minor lesions in lymph nodes, but sheep, goats, and horses appear to be resistant. *M. tuberculosis* infections in pigs are usually the result of feeding offal from a tubercular household or contact with a tuberculous attendant.

## MYCOBACTERIOSIS ASSOCIATED WITH MYCOBACTERIUM AVIUM INTRACELLULARE COMPLEX AND WITH ATYPICAL MYCOBACTERIA

### SYNOPSIS

**Etiology** *Mycobacterium avium-intracellulare* complex and other mycobacteria.

**Epidemiology** Ubiquitous in nature. Infection by ingestion. High concentration can build up in animal bedding of various types. Domestic or wild birds are a source of classic avian tuberculosis serovars. Can cause disease in humans particularly when immunocompromised.

**Clinical findings** Most infections are of the draining lymph nodes of the alimentary tract and are subclinical, but they can result in carcass condemnation. Generalized cases manifest with chronic weight loss and diarrhea.

**Clinical pathology** Tuberculin testing in cattle and swine. Culture, polymerase chain reaction (PCR).

**Necropsy findings** Microgranulomas, with or without caseation, in lymph nodes.

**Control** Reduction of environmental contamination.

## ETIOLOGY

The *M. avium-intracellulare* complex (MAC) comprises two mycobacterial species: *M.*

*avium* and *M. intracellulare*. *M. avium* is further subdivided into four subspecies: *M. avium* subsp. *avium*, *M. avium* subsp. *paratuberculosis*, *M. avium* subsp. *sylvaticus*, and *M. avium* subsp. *hominissuis*. The classical *M. avium* serovars are the cause agents of tuberculosis in poultry, whereas *M. avium* subsp. *hominissuis* is an opportunistic pathogen primarily infecting swine and humans. *M. avium* subsp. *paratuberculosis* is the causative agent of paratuberculosis in cattle and small ruminants (Johne's disease) and is discussed in the corresponding chapters of this book.

The MAC comprises ubiquitous opportunistic pathogens of a large range of species, and in livestock these pathogens have the most importance in swine. Tuberculosis associated with these organisms in livestock is usually not manifest clinically and is not a major disease problem, but infected animals react to the intradermal tuberculin test, creating difficulty in *M. bovis* tuberculosis eradication programs. Outbreaks in pig herds can cause significant losses because of carcass condemnation. In pigs, a significant proportion of reactors to tuberculin are attributable to infection with organisms of this complex, and infected cattle and pigs are potential sources of infection for the increasing number of MAC (particularly *M. avium* subsp. *hominissuis*) infections in humans.

## EPIDEMIOLOGY

### Occurrence

Lymphadenitis in pigs associated with these organisms is reported from all continents.

### Source and Transmission

Organisms of the MAC are ubiquitous in nature and can be isolated from soil, plants, water, and animal feed and animal bedding. Infected birds nesting in animal or feed buildings are the most common source of *M. avium* subsp. *avium* and contaminate feed and water supplies. In contrast, isolates of *M. avium* subsp. *hominissuis* are commonly isolated from the environment and can be isolated from various species of flies and beetles that inhabit the ground, bedding, and feed in farm environments. Several studies have confirmed the role of peat that is used for bedding or as feed additive as source of infection with *M. avium* subsp. *hominissuis* for piglets.<sup>1</sup> The organisms are resistant to acidic environments, which allows them to survive in the acidic, humid environments of peat bogs and decomposed feces, and the lipopolysaccharide bacterial wall promotes survival in environments inside and outside barns for extended periods of time.<sup>2</sup>

**Ingestion** appears the normal route of infection, and pigs infected with *M. avium* subsp. *hominissuis* excrete the organism in **feces**.<sup>3</sup> In pigs the use of dirt floors or deep litter, rather than bare concrete or slats, increases the risk of infection and the development of macroscopic lymphadenitis in large numbers of pigs. The length of time that

pigs are kept on the litter is also important, and severe outbreaks can occur in pigs kept on litter for the entire period from weaning to slaughter. Sawdust, straw, peat, and wood shavings have all been found to be highly contaminated. Sphagnum moss contaminated with *M. cookii* and environmental exposure to other mycobacteria may result in sensitization of cattle to bovine tuberculin.

*M. avium* subsp. *avium* is the cause of tuberculosis in domestic and wild birds, which are infected by ingestion of contaminated feed or soil and excrete large numbers of organisms in feces. Although infection in domestic livestock is commonly contracted from domestic poultry, from soil-borne infection, or from pen floors or feeds contaminated by wild birds, pig-to-pig transmission can also occur.

## Economic Importance

Clinical disease is not important, but at slaughter organs with tuberculous lesions are discarded, and the entire carcass may be condemned or require heat treatment before being released for human consumption.

## Zoonotic Importance

Infections with atypical mycobacteria are not uncommon in humans and have higher prevalence in immunocompromised humans. Members of the MAC, in particular *M. avium* subs. *hominissuis*, cause both pulmonary infections in immunocompetent individuals and disseminated diseases in acquired immunodeficiency syndrome. Another typical manifestation of *M. avium* infection is lymphadenitis in the head and neck region of children.<sup>4</sup>

Animals, or animal products, may be a source for human infection, but direct associations are difficult to prove. Although not clinically ill, human workers have been found to be infected on farms when the disease occurred in pigs. It is likely that infections in humans and animals on the one farm come from the one source, but it is also possible that spread from animals to humans occurs.

## CLINICAL AND NECROPSY FINDINGS

### Cattle

With classic avian tuberculosis, sensitivity to tuberculin may disappear soon after cattle are removed from contact with infected birds. Infection with this group of organisms produces microgranulomas in lymph nodes. Local lesions may persist in the mesenteric lymph nodes, the meninges, and in the uterus and udder, and occasional cases of open pulmonary tuberculosis have been observed. In uterine infections recurrent abortion may occur, and mammary localization causes induration and involvement of lymph nodes, similar to the lesions associated with *M. bovis*. Generalized tuberculosis can occur in up to 50% of cases.

## Goats and Sheep

Goats and sheep appear to have a strong natural resistance to infection with *M. avium* complex. A high incidence of avian tuberculosis has been observed in a herd of goats, and although the disease progresses slowly, this species may act as reservoirs for other species. Animals with progressive disease show anorexia and chronic diarrhea and wasting.

## Deer

Infection in wild and farmed deer occurs and may serve as a source of infection for carrion-eating birds.

## Horses

Horses are resistant to infection with *M. avium* complex, although rare, generalized cases of tuberculosis have been reported in this species. It is possible that disease occurs only in horses that are immunosuppressed by other factors. A common history is chronic diarrhea and weight loss. Less common manifestations include dermatitis, alopecia, and skin ulceration. Granulomatous enteritis is commonly present at necropsy. Two cases have been recorded in which the lesions in the cervical lymph nodes were accompanied by lesions in cervical vertebrae. The lesions were similar to those seen in cervical vertebral osteomyelitis associated with *M. bovis*.

## Pigs

Infection is usually sporadic in pigs in herds but in some herds can be enzootic.<sup>5</sup> The naturally occurring disease is nonprogressive and usually restricted to the lymph nodes of the head and neck and the mesenteric lymph nodes. Occasional generalized cases with involvement of liver, lungs, and kidneys occur; an outbreak of pulmonary tuberculosis associated with *M. avium* and clinical symptoms such as wasting and abortion has been reported in pigs. The lesions may be free of suppuration and resemble neoplastic tissue, but granulomatous and occasionally caseous lesions in lymph nodes also occur. Similar lesions are associated with *Rhodococcus equi*. Granulomatous lesions that develop in the tonsils and intestinal wall result in the passage of organisms in the feces for at least 55 days, and transmission to in-contact pigs occurs readily.<sup>1</sup>

Tuberculosis produced experimentally in pigs by the oral administration of *M. avium* is generalized, provided the inoculation dose is sufficiently large. Transmission from these pigs to contact pigs occurs. Vaccination of pigs with BCG vaccine provides partial protection against experimental infection with *M. avium*.

## CLINICAL PATHOLOGY

The lesions at postmortem or slaughter inspection are characteristic, but culture and identification of the organism is required for

confirmation. Growth is slow, and PCR technologies offer faster diagnosis, with some ability to distinguish between individual species and serovars. Smears of lesions associated with some of these agents do not stain positive with acid-fast stains.

## Tuberculin Testing

With infections in cattle, sensitivity to tuberculin occurs to both avian and bovine tuberculin, but is greater to avian tuberculin. With atypical mycobacteria the response is also short-lived, with significant changes in sensitivity occurring between successive tests. The comparative tuberculin test is becoming more widely used because of the growing importance of these infections. It is not uncommon to have more than one species of mycobacteria causing disease in a herd at the one time.

The single intradermal comparative tuberculin (SCIT) test consisting of the simultaneous intradermal injection of bovine and avian tuberculin has been used to differentiate between infections with MAC and *M. bovis*, which pertains to the *M. tuberculosis* complex (MTC) in swine. Animals infected with mycobacteria of the MTC tend to show a stronger reaction to bovine than to avian tuberculin, whereas animals previously exposed to organisms of the MAC show a reverse reaction.<sup>3</sup>

Tuberculin skin testing in horses is not conducted because 70% of clinically normal horses show positive reactions.

## TREATMENT AND CONTROL

Treatment is not usual, except possibly in horses. Antimicrobial treatment in humans for this complex of organisms includes amikacin, ciprofloxacin, rifampin, and the macrolide azithromycin.

In swine herds with enzootic infection, culling on the basis of skin sensitivity is usually not practical because of the high prevalence of infection and high environmental contamination. Control procedures concentrate on the reduction of environmental contamination by a change from bedding to solid or slatted floors, frequent washing and disinfection of pen floors, separate weaner and grower facilities, and exclusion of wild birds from buildings and feed areas.

## YERSINIOSIS

### ETIOLOGY

There are pathogenic and nonpathogenic strains of *Yersinia pseudotuberculosis* and *Yersinia enterocolitica*. The pathogenic strains of both organisms possess chromosomal and plasmid-mediated virulence determinants.

*Y. pseudotuberculosis* can be divided into 15 major serogroups, based on O-antigens, some of which can be further divided into subgroups on the basis of type-specific somatic and flagellar antigens. There is variation in animal and human pathogenicity between the serogroups.

*Y. enterocolitica* is divided into six major biotypes, designated as 1A (generally regarded as nonpathogenic), and 1B, 2, 3, 4, and 5. It is serologically heterogeneous, with 54 serotypes originally identified on the basis of somatic antigens, which was subsequently simplified to 18 serogroups.<sup>1</sup> Bioserotypes may be host-specific. Serotypes O:2, O:3, O:5, O:8, and O:9 have been most often associated with infection in farm animals and humans. Other serotypes appear to be largely nonpathogenic, although virulence factors have recently been detected in some biotypes previously regarded as nonpathogenic. Serotype O:9 is antigenically very similar to *Brucella* spp., and infection with this serotype is a cause of false-positive reactions to *Brucella* agglutination and complement fixation tests.

### EPIDEMIOLOGY

#### Occurrence

Yersiniosis has worldwide occurrence, although there appear to be regional differences in the species of animal infected, the prevalence of disease, and the organism involved. *Y. pseudotuberculosis* has historically been associated with sporadic pyemic disease in sheep manifest with extensive abscessation of internal organs such as liver and spleen. Subsequently, *Y. pseudotuberculosis* and *Y. enterocolitica* have been associated with enterocolitis in cattle, sheep, pigs, goats, buffalo, and farmed and feral deer. Enteric disease in ruminants has been most reported from Australia, New Zealand, and the United States.<sup>2</sup>

#### *Yersinia pseudotuberculosis*

*Y. pseudotuberculosis* is a common inhabitant of the intestine in a wide variety of domestic and wild mammals. Wild birds and rodents are also reservoirs of the organism, and fecal-oral spread on pastures and in water is a major method of transmission. Spring migratory birds can spread pathogenic types over long distances, although these are usually not associated with disease in ruminants.

There may be differences in the host specificity of different serotypes and strains. Rodents and birds may be the major reservoirs for serotypes I and II, which infect deer and goats, whereas sheep and cattle may be maintenance hosts for serotype III.

In an Australian study, *Y. pseudotuberculosis* serotype III was isolated from the feces of healthy sheep in 5% of flocks examined, although the prevalence was probably much higher because only a small number of sheep were sampled in each flock. Infection was more common in young sheep and occurred during the winter and spring months, and excretion of the organism persisted for 1 to 14 weeks. A 23-year retrospective study of disease caused by *Y. pseudotuberculosis* in goats in California found that cases occurred predominantly in winter and spring and were clustered in certain years. The most common syndromes were enteritis and/or typhlocolitis (64%), abscessation (14%), and abortion (12%).<sup>2</sup>

In cattle, the organism has been found without disease in up to 26% of normal cattle and on 84% of farms tested. The fecal excretion that occurs in clinically normal sheep and cattle possibly results from a subclinical infection of the intestine; experimental challenge of ruminants can result in the establishment of the organism in the intestine, with the presence of microscopic abscessation in the lamina propria and serologic conversion in the absence of clinical disease.

Enteric disease associated with this organism in both cattle and sheep appears to occur as the result of a heavy infection pressure in animals that are debilitated from other influences. These include cold wet weather, inanition and starvation, trace-element deficiency, change of diet, management procedures such as marking, and, in farmed deer, procedures such as capture, yarding, and recent transport.

In sheep, attack rates in the flock for clinical disease have ranged from 1% to 90%, with a mean of 18% and a population mortality varying from 0% to 7%. *Y. pseudotuberculosis* may also cause sporadic abortion in cattle, goats, and sheep. In sheep, abortion rates of 1% to 9% are recorded, with abortion occurring in the latter part of pregnancy and without clinical illness in the ewes. The organism is the cause of occasional cases of bovine caprine mastitis, epididymitis, and orchitis in rams, and it may be found in sporadic cases of abscessation and lymphangitis in ruminants.

#### *Yersinia enterocolitica*

*Y. enterocolitica* is less commonly associated with clinical disease in farm animals, although apparently healthy animals can excrete strains that are potentially pathogenic for humans for much of the year. Diarrhea associated with this organism can occur in sheep, and the organism can be isolated from affected lambs. However, harmful strains of *Y. enterocolitica* tend to be less pathogenic to sheep and goats than pathogenic strains of *Y. pseudotuberculosis*.

Enterocolitis is recorded in sheep and goats. Biotype 5, serotype O:2,3 has been isolated from some of these. In an Australian

survey in the early 1990s this organism was detected in 17% of flocks and was isolated from young sheep at all seasons of the year. In a study of goat flocks in New Zealand, 80 of 82 *Y. enterocolitica* isolated from 18 flocks were biotype 5 O:2,3.<sup>3</sup> Young goats (those < 1 year old) had from 2.2 to 12.9 times the risk of shedding potentially pathogenic isolates than older goats. Clinical disease appears to be predisposed by the same stress factors as apply with disease associated with *Y. pseudotuberculosis*. For example, *Y. enterocolitica* was isolated from the caecum of lambs with severe diarrhea grazing fodder beet in the United Kingdom.<sup>4</sup> The weather at the time of the outbreak was cold and wet, and the yearling sheep were seen congregating around pools of water in the paddock. Parasitism and poor nutrition were also thought to be contributing factors. Disease is typically recorded in sheep less than 1 year of age, with attack rates varying from 2% to 55% and population mortalities ranging from 0.3% to 17%. *Y. enterocolitica* is also an occasional cause of abortion in sheep, and this has been reproduced experimentally.

Whereas *Y. enterocolitica* is commonly isolated from pigs, and pigs are a major reservoir for human disease, it is a rare cause of clinical disease in pigs, although clinical enteric disease can be produced by experimental challenge of colostrum-deprived pigs. Normal pigs challenged with serotype O:3 excreted the organism in feces but were fecal-culture-negative 10 weeks after challenge and at slaughter, even though the organism could be isolated from the tonsils at slaughter. Pigs seroconverted 19 days after challenge and remained seropositive until slaughter 70 days later.

#### Zoonotic Implications

##### *Yersinia pseudotuberculosis*

Human infection with *Y. pseudotuberculosis* is primarily manifest with septicemia, and renal failure is a sequela. In addition to food-borne infection, the consumption of water contaminated by animal feces appears to be a major risk factor. Raw milk consumption is also a risk. Human cases are usually sporadic, although outbreaks have been reported from Finland and Russia.<sup>5</sup>

##### *Yersinia enterocolitica*

Gastrointestinal disease associated with *Y. enterocolitica* appears to have increasing prevalence in humans, being the third most commonly reported zoonosis in Europe, and can be associated with a reactive arthritis as a sequela. Septicemia does occur but is largely limited to those with other underlying disease. The bioserotype most often associated with human disease is 4/O:3, with other bioserotypes including 2/O:5,27, 1B/O:8, and 2/O:9.<sup>1</sup> Pigs are a major reservoir for *Y. enterocolitica*, and pork and pork products are sources for human infection.<sup>6</sup> Bioserotype 4/O:3, in particular, is

commonly isolated from the tonsils and pharynx of pigs at slaughter and less commonly from feces. The rate of isolation varies geographically and with farm source, and it has been suggested that pathogen-free breeding is a method for control. A high rate of biotype 1A, which is a common isolate from livestock and generally thought to be non-pathogenic for humans, was isolated from sheep feces, but not tonsil, from sheep at slaughter in Gotland, Sweden.<sup>6</sup> Recently, the virulence gene *ail* (adhesion invasion locus) has been identified in some strains of *Y. enterocolitica* biotype 1A, and thus a more thorough examination of these biotypes may be justified.<sup>7-9</sup>

In contrast to Australia and New Zealand, it is thought that in Europe the pig is the only domestic animal consumed by humans that regularly harbors pathogenic *Yersinia*. There is an apparent increasing prevalence of bioserotype 4/O:3 infections in humans in the Northern Hemisphere, and pigs and pork products are considered to be important sources. A survey in Great Britain comparing isolates of *Y. enterocolitica* from cattle, sheep, and pigs with those from humans over a 2-year period did not find a strong correlation between pathogenic serotypes isolated from the two groups, with the exception of isolates from pigs. The importation of meat products has been incriminated as the vehicle of introduction of pathogenic serotypes into Japan. There would appear to be an increased risk for infection in humans handling pigs at slaughter and in veterinarians in pig practice.

Bioserotype 3/O:5,27 is common in animals in the United Kingdom, but not isolated from humans. This bioserotype increased the secretion of the cytokines IL-6 and IL-8 from macrophages infected in vitro, compared with other biotype 3 and 4 isolates.<sup>10</sup> It was proposed that these differences in the interaction of the bacteria with the host immune system may explain why this bioserotype is not pathogenic for humans.

#### PATHOGENESIS

Invasion of the intestinal epithelium is followed by inflammation in the mucosa and the formation of microabscesses in the lamina propria and mesenteric lymph nodes. Ulcers and disruption of the intestinal mucosa lead to loss of fluid and function. The intestinal lesions are accompanied by villous atrophy and lead to malabsorption and ill-thrift, diarrhea, or a combination of the two.

#### CLINICAL FINDINGS

Affected animals may present with a syndrome of chronic ill-thrift and in a wasted condition with or without diarrhea. Where diarrhea is present, the feces are watery, foul-smelling, and black in color, but occasionally they also contain mucus and blood. Diarrhea persists for 2 to 3 weeks in an individual animal and may require the removal of soiled

wool (“crutching” or “dagging”) to reduce the risk of fly strike.

### CLINICAL PATHOLOGY

There is a neutrophilia with a left shift. Affected animals are often hypoproteinemic and anemic, although this may be a reflection of the underlying malnutrition. In experimental infections antibody develops by 9 to 19 days after infection and may be an aid to diagnosis. The organism can be isolated from the feces. Multiplex PCR, capable of detecting 10 pathogenic serotypes of *Y. enterocolitica*, and real-time PCR have been developed to discriminate pathogenic *Y. enterocolitica* from other members of this genus.<sup>11</sup>

### NECROPSY FINDINGS

There are liquid intestinal contents but usually no gross findings. Some sheep may have thickening of the mucosa of the small intestine and the cecum and colon, and the mesenteric lymph nodes may be enlarged and edematous.

The characteristic findings on histopathology consist of a segmental suppurative erosive enterocolitis. Microabscesses, consisting of aggregations of neutrophils with prominent colonies of gram-negative coccobacilli, are present in the mucosa. Lesions are most prevalent in the jejunum and ileum and are accompanied by atrophy of villi and hyperplasia of cryptal epithelium. Microabscesses may coalesce to produce extensive erosions, and there may be microabscesses in the liver.

The placenta from sheep that have aborted in association with *Y. pseudotuberculosis* is thickened and edematous, with necrotic debris in the intercotyledonary zone, and must be differentiated from enzootic abortion.

### Samples for Confirmation of Diagnosis

- Bacteriology—jejunum, ileum, colon, mesenteric lymph node (culture—sometimes requires cold enrichment)
- Histology—formalin-fixed jejunum, ileum (several sections), colon, mesenteric lymph node (light microscopy)

**Note the zoonotic potential of this organism when handling the carcasses and submitting specimens.**

### DIFFERENTIAL DIAGNOSIS

The major differential is the syndrome of weaner ill-thrift, caused mainly by undernutrition and gastrointestinal parasitism, and other agents that cause diarrhea, such as salmonellosis.

### TREATMENT AND CONTROL

Isolates vary in their sensitivity to antibiotics, and a sensitivity test is advisable. Most

isolates show in vitro sensitivity to the aminoglycosides, to tetracyclines, and to sulfonamides or a combination of sulfonamides and trimethoprim. Sulfonamides and trimethoprim are reported not to be effective in the treatment of yersiniosis in cattle; long-acting tetracyclines are recommended for the treatment of both infections, in combination with supportive therapy.

A vaccine is available for deer in New Zealand, but in other countries there is no specific control for ruminants and pigs. Live attenuated oral vaccines have been evaluated in laboratory animals and afforded good cross-protection against heterologous strains of *Y. pseudotuberculosis*.<sup>12</sup> In grazing animals mitigating the effects of parasitism, particularly during winter, and maintenance of good nutrition are thought to be important factors in avoiding clinical disease.

## TULAREMIA

### SYNOPSIS

**Etiology** *Francisella tularensis* subsp. *tularensis* in North America; *Francisella tularensis* subsp. *holarctica* in Asia, Europe, and North America.

**Epidemiology** Primarily wild animal disease with wide occurrence in the Northern Hemisphere. Among domesticated animals,

cats and lambs are most, and pigs less, susceptible; seasonal, associated with heavy tick infestation. Tabanidae, rodents, and lagomorphs function as hosts and vectors. Zoonosis, potential bioterrorist agent.

**Clinical findings** Tick infestation. Fever, stiffness of gait, diarrhea, weight loss, recumbency. Wool break.

**Clinical pathology** None specific.

**Necropsy findings** Subcutaneous swellings at site of tick attachment, lymphadenitis, and septicemia in sheep. Pigs have pleuritis, pneumonia, and abscessation of submaxillary and parotid lymph nodes.

**Diagnostic confirmation** Identification of agent by immunohistochemistry, polymerase chain reaction (PCR) or culture; serology in survivors.

**Treatment** Tetracyclines, streptomycin.

**Control** Tick control, repellents.

### ETIOLOGY

*Francisella tularensis*, the causative organism of tularemia is a gram-negative, nonspore-forming coccobacillus pertaining to the family Francisellaceae. The bacterium survives in the environment for prolonged periods. Viable bacteria can be found after weeks and months in the carcasses and hides of infected animals and in fomites, which include grain, straw, dust and water. It is highly resistant to freezing and can survive in meat of infected animals stored at  $-15^{\circ}\text{C}$  ( $5^{\circ}\text{F}$ ) for 3 years.<sup>1</sup>

Currently, four subspecies with different animal hosts and different geographic distribution are recognized:<sup>2</sup>

- *F. tularensis* subsp. *tularensis* (type A): This is the most virulent subspecies; it is found in North America and associated with rabbits, ticks, and sheep.
- *F. tularensis* subsp. *holarctica* (*palaeartica*, type B): This subspecies is less virulent and is found in Asia, Europe and North America. It is often isolated in association with streams, ponds, lakes, and rivers. Beavers and muskrats in North America and lemmings and beavers are presumably responsible for maintaining the water association of this bacterium. There is evidence suggesting that the pathogen can persist in water (possibly associated to protozoa) for prolonged periods of time.
- *F. tularensis* subsp. *mediasiatica*: This serotype has only been isolated in Kazakhstan and Turkmenistan. Little is known about its virulence, but is considered to comparable to that of subsp. *holarctica*.
- *F. tularensis* subsp. *novicida*: This strain has thus far only been isolated from humans; it has been linked to waterborne transmission in Australia,

Spain, and the United States. The strain of subsp. *novicida* isolated in Australia is the only one identified in the Southern Hemisphere thus far.

### EPIDEMIOLOGY

Tularemia is a highly contagious disease occurring principally in wild animals, but it may transmit to farm animals and cats, causing septicemia and high mortality. It can occur either as epizootics or as sporadic disease. It is a zoonosis that is responsible for approximately 100 clinical cases in humans every year in the United States.

### Occurrence

Tularemia is primarily restricted in its occurrence to countries in the **Northern Hemisphere** and occurs in most of them. In the United States tularemia is recognized in all states except Hawaii. It is most prevalent in the central-western states of the United States, including Missouri, Arkansas, Oklahoma, South Dakota, and Kansas.<sup>3</sup> In Europe, the disease is more prevalent in eastern European countries and less common in continental western Europe.<sup>2</sup> Epidemics affecting the human population have occurred in Spain, Portugal, Sweden, and Kosovo.

### Risk Factors

#### Animal Risk Factors

*F. tularensis* has a wide host range and is recorded in over 100 species of bird and wild and domestic animals. Common wild animal hosts include rabbits, muskrats, beavers, and a variety of rodents, including voles, squirrels and lemmings. Disease in domesticated animals most commonly occurs in **cats and sheep** and to a lesser extent in pigs, dogs, and horses; cattle appear to be relatively resistant but can be infected in association with heavy tick infestation. Sheep and pigs of all ages are susceptible, but most losses occur in lambs; in pigs, clinical illness occurs only in piglets. There is a sharp seasonal incidence, with the bulk of cases occurring during the spring months. The morbidity rate in affected flocks of sheep is usually about 20% but may be as high as 40%, and the mortality rate may reach 50%, especially in young animals.

#### Transmission

The **major reservoirs** and transmitters of the infection are rabbits, hares, wild rodents, **ticks**, and flies. The principal mammalian target host in North America is the cottontail rabbit (*Sylvilagus* spp.). With sheep, transmission occurs chiefly by the bites of the wood tick, *Dermacentor andersoni*, and from *Haemaphysalis otophila*, with the ticks becoming infected in the early part of their life cycle when they feed on rodents. In Europe, *Ixodes ricinus* and *Dermacentor reticulatus* are vectors. Transmission to pigs and horses is thought to occur chiefly by tick bites, but **mechanical transmission** to

laboratory animals does occur with tabanid and blackflies. In the former Soviet Union and northern Europe, the bacterium has been demonstrated to be transmitted by mosquitoes.<sup>2</sup> Tabanid flies, which include the horsefly and the deerfly, have been implicated as vectors in the western United States and northern Europe.<sup>1</sup> At least 20 flea species were identified as potential vectors, although their role in the spread of the disease is uncertain. Neither in flies nor mosquitoes the pathogen was confirmed to reside in the salivary glands, suggesting that they may function as mechanical rather than biological vectors.

In contrast, **transstadial** and **transovarial transmission** occurs in the tick. The adult ticks infest sheep, and pastures bearing low shrubs and brush are particularly favorable to infestation. The ticks are found in greatest numbers on the sheep around the base of the ears, top of the neck, throat, axillae, and udder.

#### Pathogen Risk Factors

There is little information concerning virulence mechanisms of *F. tularensis*. The capsule appears to be a necessary component for expression of full virulence and protects against serum-mediated lysis. The lipopolysaccharide has unusual biological and structural properties and low toxicity in vitro and in vivo.

Pronounced differences in virulence between subtypes are well established. *F. tularensis* subsp. *tularensis* is by far the most virulent subspecies for all affected species and is associated with the highest mortality rates in animals and humans.

### Zoonotic Implications

Humans can acquire *F. tularensis* from various sources. Most exposures appear to result from the handling of infected rabbits and other wildlife (e.g., during hunting activities), but infections can arise from **bites** of ticks and haematophagus flies, from the **ingestion** of contaminated meat and water, and from the bite or scratch of infected cats. Inhalation of aerosolized bacteria appears to be a less common route of infection but is associated with respiratory tularemia, which has the highest fatality rate of all clinical presentations of tularemia.<sup>2</sup> The disease is an occupational hazard to hunters and workers in the sheep industry in areas where the disease occurs. Spread of the disease to humans may also occur in abattoir workers who handle infected sheep carcasses. Person-to-person transmission has not been documented.

*F. tularensis* is one of the most infectious pathogens known in human medicine, with an extremely low infectious dose (10 bacteria when injected subcutaneously and 25 bacteria when inhaled as aerosol). Because of its high infectivity, the fact that it causes infection through inhalation in combination with

its stability in aerosols, *F. tularensis* is recognized as **potential bioterrorist agent**.

### PATHOGENESIS

Tularemia is an acute septicemia, but localization occurs, mainly in the parenchymatous organs, with the production of granulomatous lesions.

### CLINICAL FINDINGS

#### Sheep

The incubation period has not been determined. A heavy tick infestation is usually evident.

The **onset** of the disease is slow with a gradually increasing stiffness of gait, dorsiflexion of the head, and a hunching of the hindquarters; affected animals lag behind the group. The pulse and respiratory rates are increased, the temperature is elevated up to 42°C (107°F), and a cough may develop. There is diarrhea, the feces being dark and fetid, and urination occurs frequently, with the passage of small amounts of urine. Body weight is lost rapidly, and progressive weakness and recumbency develop after several days, but there is no evidence of paralysis, with the animal continuing to struggle while down. Death occurs usually within a few days, but a fatal course may be as long as 2 weeks. Animals that recover commonly shed part or all of the fleece but are solidly immune for long periods.

#### Pigs

The disease is latent in adult pigs, but young piglets show fever up to 42°C (107°F), accompanied by depression, profuse sweating, and dyspnea. The course of the disease is about 7 to 10 days.

#### Horses

In horses, fever (up to 42°C [107°F]) and stiffness and edema of the limbs occur. Foals are more seriously affected and may show dyspnea and incoordination in addition to the previously mentioned signs.

### CLINICAL PATHOLOGY

**Isolation of the pathogen** can be attempted from impression smears or fixed specimens of organs such as liver, spleen, bone marrow, kidney, or lung and from blood smears. Immunologic methods such as the fluorescent antibody test are considered most reliable to identify the agent.<sup>4</sup> Polymerase chain reaction (PCR) protocols are now widely used to confirm the presence of bacterial DNA.

**Serologic tests** are the standard tests used for the diagnosis of tularemia in humans. In veterinary medicine serology may be employed for epidemiologic surveys of animal species resistant to the infection, but it is of limited value in susceptible species that commonly die before seroconversion occurs. The agglutination test is the most commonly used test for the diagnosis of tularemia, with a titer of 1:50 being regarded as

a positive test in pigs. Serum from pigs affected with brucellosis does not agglutinate tularemia antigen, but serum from pigs affected with tularemia agglutinates brucellosis antigen. Cross-agglutination between *F. tularensis* and *Brucella abortus* is less common in sheep, and an accurate diagnosis can be made on serologic grounds because of the much greater agglutination that occurs with the homologous organism. Titers of agglutinins in affected sheep range from 1:640 to 1:5000 and may persist at levels of 1:320 for up to 7 months. A titer of 1:200 is classed as positive in sheep. In horses the titers revert to normal levels in 14 to 21 days.

Enzyme-linked immunosorbent assays (ELISAs) are available to identify either IgM, IgA, or IgG in infected animals. Because IgM levels are sustained for prolonged periods after infection, a high titer cannot be used as an indication for recent infection.<sup>4</sup>

### NECROPSY FINDINGS

In sheep, large numbers of ticks may be present on the hides of fresh carcasses. In animals that have been dead for some time, dark-red subcutaneous areas of congestion up to 3 cm in diameter are found and may be accompanied by local swelling or necrosis of tissues. These lesions mark the attachment sites of ticks. Enlargement and congestion of the lymph nodes draining the sites of heaviest tick infestation are often noted. Pulmonary edema, congestion, or consolidation are inconsistent findings.

In pigs the characteristic lesions are pleuritis, pneumonia, and abscessation of submaxillary and parotid lymph nodes. The organisms can be isolated from the lymph nodes and spleen and from infected ticks. Isolation can also be effected by experimental transmission to guinea pigs. Techniques such as immunoperoxidase staining of fixed specimens and PCR of fresh tissues can circumvent the need for culture of this zoonotic agent.

### Samples for Confirmation of Diagnosis

- Bacteriology—lung, liver, lymph node, spleen, kidney, bone marrow, blood (immunohistochemistry, PCR, culture—requires cystine-enriched media)
- Histology—previously mentioned tissues fixed in formalin (light microscopy, immunohistochemistry)

**Note the zoonotic potential of this organism when handling the carcasses and submitting specimens.**

### DIFFERENTIAL DIAGNOSIS

The occurrence of a highly fatal septicemia in sheep during spring months when the sheep are heavily infested with *Dermacentor Andersoni* should suggest the possibility of tularemia, especially if the outbreak occurs in an enzootic area.

**Tick paralysis.** This occurs in the same area and at the same time of the year as tularemia but is not accompanied by fever, and there is marked flaccid paralysis. Recovery from tick paralysis occurs commonly if the ticks are removed.

**Other septicemias** include *P. trehalosi* in sheep and *Haemophilus* spp. in sheep and cattle. These are unusual in the age group in which tularemia occurs and are not associated with tick infestation. In pigs, local lesions can resemble tuberculosis.

**Anthrax.**

### TREATMENT

Streptomycin, gentamicin, tetracyclines, and fluorochinolones are effective treatments in humans and companion animals. Oxytetracycline (10 mg/kg body weight [BW] IV or IM every 24 hours).

### TREATMENT AND CONTROL

#### Treatment

Streptomycin (10 mg/kg IM every 24h) (R-2)  
Oxytetracycline (10 mg/kg IV or IM every 24h) (R-2)  
Enrofloxacin (2.5 mg/kg IM/SC every 24 hours for 3 to 5 days) (R-2)

#### Control

Tick control  
Repellents

### CONTROL

An outbreak of tularemia in sheep can be rapidly halted by spraying or dipping with an insecticide to kill the vector ticks. In areas where ticks are enzootic, sheep should be kept away from shrubby, infested pasture or sprayed regularly during the months when the tick population is greatest. An experimental live attenuated vaccine has been developed, but there is no routine vaccination of livestock.

## MELIOIDOSIS

### SYNOPSIS

**Etiology** *Burkholderia pseudomallei*.

**Epidemiology** Ubiquitous soil saprophyte endemic to Southeast Asia, northern Australia, and the South Pacific. Occurs primarily 20° north and south of the equator. Transmission is by inhalation of contaminated dust and cutaneous abrasion. Primarily a disease of sheep and goats and humans, occasional disease in horses, and subclinical infection in pigs.

**Clinical findings** Septicemia, weakness, recumbency, and death in sheep. Septicemia, pneumonia, and lymphangitis in horses.

**Clinical pathology** Culture, serology, allergic skin test.

**Necropsy findings** Abscessation of internal organs.

**Treatment and control** General hygienic procedures. Little specific information available.

### ETIOLOGY

*Burkholderia pseudomallei* is the sole cause. There is considerable genetic variability, and strains vary in pathogenicity. The organism causes latent (asymptomatic), acute, or chronic disease, depending largely on the host resistance to the organism.<sup>1</sup>

### EPIDEMIOLOGY

#### Occurrence

The disease occurs almost exclusively in tropical countries 20° north and south of the equator and is endemic in Southeast Asia, Asia, and northern and subnorthern areas of Australia. Disease occurs in rodents, rabbits, pigeons, humans, animals in zoologic gardens, dogs, cats, horses, pigs, goats, alpacas, reptiles, and camels, but rarely in cattle.<sup>2-6</sup> In domestic animals the disease has occurred in outbreak form in pigs, goats, and sheep in Australia; in the Caribbean area and in Cambodia; in horses in Malaysia and Iran; in pigs and cattle in Papua New Guinea and Australia; in horses in France in 1976 to 1978; and in cattle in Argentina. Goats appear to be more susceptible than cattle or horses.<sup>4</sup>

The incidence rate in Thailand during 2006 to 2010 was 1.6 cases per 100,000 goats, 0.02 cases per 100,000 pigs, and 0.01 cases per 100,000 cattle. There were reports of the disease in a single camel, crocodile, deer, horse, monkey, and zebra. However, incidence rates varied considerably with region of the country, with rates as high as 101 cases per 100,000 goats and 19 cases per 100,000

people.<sup>4</sup> The estimates for animals are likely an underrepresentation of the actual incidence of the disease because not all dead animals are subject to postmortem examination.

### Risk Factors

The risk factors for occurrence of melioidosis on small ruminant farms in Malaysia include the following: bush clearing around farms (odds ratio [OR] = 661, 95% confidence interval [CI] = 112–3884,  $P = 0.037$ ), *B. pseudomallei* present in the soil (OR = 623, 95% CI = 103–3768,  $P = 0.046$ ), other animal species present (OR = 796, 95% CI = 114–5599,  $P = 0.037$ ), and flooding or waterlogging conditions (OR = 1195, 95% CI = 139–1026,  $P = 0.024$ ).<sup>7</sup>

### Source and Methods of Transmission

In endemic areas the organism is a ubiquitous soil saprophyte and is present in moist soil and waterholes which are the primary reservoirs from which most infections are acquired. A variety of free-living amoebae, including *Acanthamoeba* and *Hartmannella* spp., are potential hosts to *B. pseudomallei*. The majority of cases in livestock are associated with the “wet season” and exposure to surface water and mud. Infection occurs through inhalation, ingestion, in association with skin wounds via contaminated dust particles or water, or by insect bites. Infected animals pass the organism in their feces, and the disease in rodents runs a protracted course, making these animals important reservoirs of infection.

### Pathogen Risk Factors

*B. pseudomallei* is very hardy and can survive in water at room temperature for up to 10 years, in muddy water for up to 7 months, and in soil in the laboratory for up to 30 months.<sup>1</sup> The organism can survive in contaminated injectable drugs and has ability to survive for some time in cetrimide 3% and chlorhexidine 0.3% solution. Varying degrees of virulence are observed in different strains of the organism, but starvation or other conditions of stress appear to increase the susceptibility of experimental animals to infection.

### Experimental Production

The disease can be produced experimentally in goats, sheep, rats, mice, hamsters, and pigs.

### Zoonotic Implications

Humans are at risk for infection within endemic areas, and although this can be zoonotic, it can also occur without direct animal contact through inhalation. The disease of humans presents with various clinical pictures ranging from asymptomatic state, to localized infection such as pneumonia, to acute fatal septicemia.

Veterinarians and animal owners are at risk from localized or generalized infection from infected animals. Pregnant women handling goats aborting with this infection have risk for infection and abortion. Infected areas are often rural in nature, and pasteurization of commercially sold milk should be ensured, as should condemnation of infected carcasses at abattoirs.

### Pathogenesis

The pathogenesis of melioidosis involves infection of animals by *B. pseudomallei* in the environment, with subsequent transepithelial spread in infected macrophages. There is initial bacteremia or septicemia and subsequent localization in various organs. Experimentally induced melioidosis in goats induced by percutaneous administration of the organism is characterized by septicemia with undulating fever, wasting, anorexia, hindlimb paresis, mastitis, and abortion.<sup>8</sup> Necropsy lesions include widely scattered microabscesses after intraperitoneal injection and a chronic disease with abscesses in the lungs and spleen when the infection is administered subcutaneously. In pigs, experimental infection results in a generalized chronic infection.

### CLINICAL FINDINGS

#### Sheep

Signs consist mainly of weakness, respiratory disease, and recumbency, with death occurring in 1 to 7 days. In experimentally infected sheep, a severe febrile reaction occurs and is accompanied by anorexia, lameness, and a thick, yellow exudate from the nose and eyes. Some animals show evidence of central nervous system involvement, including abnormal gait, deviation of the head and walking in circles, nystagmus, blindness, hyperesthesia, and mild tetanic convulsions. The disease is usually fatal. Skin involvement is not recorded.

#### Goats

The syndrome may resemble the acute form as seen in sheep, but it more commonly runs a chronic course with abscessation. Mastitis is common in infected goats, with one study finding mammary infection in 35% of infected goats.

#### Pigs

Disease is usually chronic and manifested by cervical lymphadenitis, but in some outbreaks there are signs similar to those in other species. In such outbreaks slight posterior paresis, mild fever, coughing, nasal and ocular discharge, anorexia, abortion, and some deaths may occur.

#### Horses

The syndrome is one of an acute metastatic pneumonia with high fever and a short course. Cough and nasal discharge are minimal, and there is a lack of response to

treatment with most drugs. Other signs in horses include colic, diarrhea, and lymphangitis of the legs. Subacute cases become debilitated and emaciated and develop edema. Affected horses may survive for several months. A case of acute meningoencephalitis is described in a horse. The onset was sudden and manifest with violent convulsions.

### CLINICAL PATHOLOGY

The organism is easily cultured and may be isolated from nasal discharges. The organism can be differentiated from *B. mallei* on multiplex quantitative PCR (qPCR) or using a PCR allelic discrimination assay.<sup>9,10</sup> Injection into guinea pigs and rabbits produces the typical disease. An allergic skin test using melioidin as an antigen, a complement fixation test (CFT), and an indirect hemagglutination (IHA) test are available. An ELISA is available that can detect antibodies to *B. pseudomallei* in goats.<sup>11</sup> The IHA test is recommended for screening and the CFT for confirmation in cases of active melioidosis in goats and pigs. Affected horses can give a positive reaction to the mallein test.

### NECROPSY

Multiple abscesses in most organs, particularly in the lungs, spleen, and liver, but also in the subcutis and the associated lymph nodes, are characteristic of the disease in all species. In sheep respiratory infection is common, and these abscesses in the lung contain thick or caseous, green-tinged pus similar to that found in *Corynebacterium pseudotuberculosis* lesions. Lesions in the nasal mucosa proceed to rupture, with the development of ragged ulcers. An acute polyarthritis, with distension of the joint capsules by fluid containing large masses of greenish pus, and acute meningoencephalitis have been observed in experimental cases.

A high incidence of lesions in the aorta of goats is reported in Australia. Nine out of 43 (21%) goats had aortic lesions at autopsy. Seven of these goats died as a result of a ruptured aortic aneurysm.

### DIAGNOSTIC CONFIRMATION

Culture of the organism confirms the diagnosis.

### DIFFERENTIAL DIAGNOSIS

#### Sheep

Caseous lymphadenitis

Actinobacillosis

#### Horses

Glanders

Strangles

#### Pigs

Tuberculosis

## TREATMENT

Treatment is unlikely to be undertaken in farm animals because of the nature of the disease and the risk of exposure to humans. Little information is available on satisfactory treatments of melioidosis in farm animals, but recommendations for humans are available. Penicillin, streptomycin, chlortetracycline, and polymyxin are ineffective, but in vitro tests suggest that oxytetracycline, novobiocin, chloramphenicol, and sulfadiazine are most likely to be valuable, with oxytetracycline the preferred drug. In horses, chloramphenicol is an effective treatment.

## CONTROL

There is currently no vaccine for melioidosis.<sup>12</sup>

Prevention involves removing animals from the contaminating source. Water supplies can be chlorinated. This and the elimination of infected animals and the disinfection of premises should be the basis of control procedures. Housed animals can be removed from soil by raising them from the ground on wooden slats or with concrete or paved floors. Treatment of soil with lime reduces the risk (OR = 0.028) of animals developing melioidosis.<sup>7</sup>

## HEARTWATER (COWDRIOSIS)

### SYNOPSIS

**Etiology** *Ehrlichia* (*Cowdria*) *ruminantium*, a rickettsial organism.

**Vectors** *Amblyomma variegatum* and *Amblyomma hebraeum*.

**Epidemiology** Endemic disease of cattle, sheep, goats and wild ruminants in Africa and the Caribbean; high mortality in exotic animals.

**Clinical signs** High fever, nervous signs, diarrhea, and death if acute; may be mild and inapparent.

**Clinical pathology** Nonspecific.

**Diagnostic confirmation** Rickettsial colonies in capillary endothelium (brain preparations), polymerase chain reaction (PCR).

**Lesions** Ascites, hydrothorax, hydropericardium, and severe pulmonary edema.

**Differential diagnosis list** Anthrax, rabies, cerebral babesiosis, cerebral theileriosis, meningitis or encephalitis.

**Treatment** Short- and long-acting tetracyclines.

**Control** Vaccination based on infection and treatment methods, tick control, and chemoprophylaxis.

## ETIOLOGY

*Ehrlichia* (*Cowdria*) *ruminantium* is a gram-negative, intracellular rickettsial organism in the order of Rickettsiales. It occurs in colonies or morulae with a predilection for the vascular endothelium and stains blue with Giemsa stain. The organism is coccoid, 0.2 to 0.5 microns in diameter. It can now be cultivated in vitro, and it can also grow in mice. Cyclical development takes place in intestinal and salivary epithelia of ticks. Widely ranging *E. ruminantium* genotypes with differing cross-protection capacities usually circulate simultaneously in the same region, leading to a poor vaccine efficacy.<sup>1</sup> However, all isolates obtained at different geographic levels (village, region, and continent) possess a major antigenic protein 1 (MAP1) that is conserved.<sup>2</sup> This protein is used for serologic diagnosis, but the antigen cross-reacts with other *Ehrlichia* spp., including *E. equi*, the cause of equine granulocytic ehrlichiosis. Variants of *E. ruminantium* that do not cause disease in livestock have also been reported from South Africa.<sup>3</sup>

## EPIDEMIOLOGY

### Occurrence

Heartwater was first recognized in South Africa in the nineteenth century.<sup>4</sup> The disease is limited in its occurrence to sub-Saharan Africa, including the islands of Madagascar, Sao Tome, Reunion, Mauritius, Zanzibar, and Mayotte in the Indian Ocean. It is also present on the three Caribbean islands of Guadeloupe, Marie-Galante, and Antigua, where it threatens the American mainland because of the risk of spread of its tick vector by migratory birds or by uncontrolled movement of animals.<sup>5</sup> Heartwater is one of the main causes of death in imported breeds of cattle, sheep, and goats in endemic areas.

### Measures of Disease Occurrence

In endemic areas, morbidity and mortality rates are low, but the percentage of seropositive titers for heartwater could be as high as 100% in adult cattle, depending on the abundance of tick vectors. In Tanzania,

antibodies to *E. ruminantium* were found in 68.6% of the sheep and 64.7% of the goats examined by ELISA, but the infection was unevenly distributed within districts.<sup>6</sup> Case mortality can be as high as 100% in peracute cases in sheep and goats and as low as 0 to 10% in cattle. The disease is less severe in indigenous breeds and related game animals reared in enzootic areas, some of which may become symptomless carriers. The N'Dama breed in West Africa is reported to be well adapted to heartwater, partly because it can resist tick burdens under traditional farming system. Conversely, the Angora goat is highly susceptible, and Merino sheep are moderately so.

## Method of Transmission

Heartwater is transmitted by many ticks of the *Amblyomma* genus, especially by *A. variegatum* (the tropical bont tick) mostly in western, central, and eastern Africa and the Caribbean, and by *A. hebraeum* mostly in southern Africa. The geographic distribution of the ticks appears to be spreading. Infection in ticks is transmitted transstadially and possibly transovarially. A single infected tick can transmit the disease to the host, and this can occur 1 to 2 days after attachment as nymph or 2 to 3 days as adult. Vertical transmission to calves and lambs in utero and in colostrum milk has been reported. Several wild ruminants can be infected and become subclinical carriers and reservoirs. Tick feeding on them can transmit the disease to domestic ruminants. In the Caribbean, cattle egrets are suspected to spread *A. variegatum* between islands. However, recent molecular studies of isolates from the Caribbean and Africa would suggest that there was a simultaneous introduction of several strains of *E. ruminantium* from Africa into the Caribbean.<sup>7</sup> Nevertheless, heartwater is considered to be a threat to the American mainland, where potential vectors such as *A. maculatum* are present but do not harbor the disease or where the vector may be introduced by migratory birds and become established. Similarly, southern Italy is considered at risk of introduction and establishment of infected *Amblyomma* ticks through migratory birds.<sup>8</sup> The organism does not infect humans.

## Risk Factors and Immune Mechanisms

Animals at greatest risk are exotics imported into endemic areas and at times when the vector population is high, usually during the rains. Angora goats are also highly susceptible and therefore difficult to immunize by the current method of infection and treatment. Cattle and sheep recovering from the disease are immune for 6 months to 4 years but may be carriers for 8 months or longer. Immunity is related to the ability of lymphocytes in infected animals to produce interferon gamma (IFN- $\gamma$ ).<sup>9</sup> An age-dependent

resistance has long been recognized, and young animals were thought to have innate resistance. This was later shown to be attributable to low-grade infection of the young in colostrum cells or following intrauterine transmission. In small ruminants, the resistance begins to wane at the age range of 4 and 12 weeks when they are most susceptible.<sup>10</sup>

### ECONOMIC IMPORTANCE

Heartwater is the most important rickettsial infection of ruminants in Africa and the second most important tick-borne disease after East Coast fever. In southern Africa, it is regarded as the most important disease of ruminants. In general, heartwater is a more serious problem where *A. habraeum* is the vector. In countries or regions where there is endemic stability, losses from heartwater are minimal until new animals are introduced or moved from nonendemic to endemic areas. On the other hand, because most losses are in exotic animals, heartwater is a major constraint to livestock improvement in sub-Saharan Africa. Furthermore, it has the potential to spread from North Africa to Europe and from the Caribbean to the American mainland.

### Biosecurity Concerns

Heartwater requires the vector tick to get established in any community. Therefore there is concern about possible illegal importation of infected animals or ticks to the southern United States where potential vectors exist. Migratory birds can also introduce infected ticks to parts of the Mediterranean countries where the environment is suitable for the establishment of *Amblyomma*.

### PATHOGENESIS

There is limited new information on the pathogenesis of heartwater. The rickettsial organisms are introduced into the host in the saliva of an infected tick. They multiply in reticuloendothelial cells of the local lymph node, rupture the cells, and are released into the circulation, where they invade endothelial cells of blood vessels in all organs, where further multiplication takes place. Organisms can be found in phagosomes of circulating neutrophils but are more abundant in endothelial cells. Invasion of vascular endothelium causes increased vascular permeability, leading to edema, especially in the lungs, body cavities, and the brain, by mechanisms that are not understood because infected endothelial cells show minimal cytopathic effects. Brain edema is responsible for the nervous signs, severe hydropericardium will impair cardiac function, and severe pulmonary edema with hydrothorax would lead to death from asphyxia. In goats, renal ischemia and nephrosis have been described, and irreversible kidney damage may be the cause of death in such cases.

### CLINICAL FINDINGS

The incubation period is 1 to 3 weeks after transmission in tick saliva. Depending on the susceptibility of individual animals and the virulence of the infecting organism, the resulting disease may be peracute, acute, subacute, or mild and inapparent. Peracute cases show only high fever, prostration, and death with terminal convulsions in 1 to 2 days. Acute cases are more common and have a course of about 6 days. A sudden febrile reaction is followed by inappetence, listlessness, and rapid breathing, followed by the classical nervous syndrome that is characteristic of heartwater. It comprises ataxia, chewing movements, twitching of the eyelids, circling, aggression, apparent blindness, recumbency, convulsions, and death. Profuse, fetid diarrhea is frequent.

Subacute cases are less severe but may terminate in death in 2 weeks or the animal may gradually recover. The mild form is often subclinical and is seen mainly in indigenous animals and wild ruminants with high natural or induced resistance. The case-mortality rate in peracute cases is 100%; in acute cases, 50% to 90%; and in calves at less than 4 weeks of age, it is 5% to 10%; most animals recover in mild cases.

### CLINICAL PATHOLOGY

Hematologic changes in heartwater are not specific, but there may be thrombocytopenia, neutropenia, eosinopenia and lymphocytosis. Confirmatory diagnosis is based on identifying the rickettsia in capillary endothelial cells using a Giemsa-stained squash preparation of brain tissue at postmortem. The rickettsiae occur as blue to reddish-purple colonies or morulae of five to several hundred coccoid organisms (0.2 to 0.5 microns in diameter) in the cytoplasm of the cells close to the nucleus. An immunohistochemical staining technique has also been described. Injection of blood into sheep may also be used as a diagnostic procedure because sheep are highly susceptible.

The polymerase chain reaction (PCR) assay is preferred for confirmatory diagnosis in a sick animal. To this end, a quantitative pCS20 real-time PCR has been developed and can be performed within 2 hours in live animals; it is also an effective assay for epidemiologic surveillance and monitoring of infected animals, and it can be used by paraveterinary staff.<sup>11-12</sup> However, it cross-reacts with at least two other *Ehrlichia* spp. Nested pCS20 PCR is highly sensitive and can be used to detect infected ticks.<sup>13</sup> A more sensitive and highly specific new test has been reported. It is the loop-mediated isothermal amplification (LAMP) assay, in which DNA amplification is completed in 1 hour.<sup>14</sup> Assays using two sets of LAMP primers designed from the pCS20 and sodB genes were more sensitive than conventional pCS20 PCR assay. LAMP detected 16 different isolates from geographically distinct countries, and

no cross-reaction was observed with genetically related Rickettsiales. Because of its simplicity and specificity, LAMP also has the potential for use in clinical laboratories in resource-poor countries where heartwater is endemic and for active screening in areas under threat of introduction of the disease.

Serologic tests are used for surveys, and the two tests recommended are indirect fluorescent antibody (IFA) and ELISA. The close antigenic relationship between *E. ruminantium* and other *Ehrlichia* spp. often leads to false positives. The ELISA based on recombinant MAP1 protein of *E. ruminantium* is more sensitive, but all serologic assays have poor sensitivity and specificity.

### NECROPSY FINDINGS

Standard lesions are ascites, hydrothorax, and hydropericardium. Pulmonary edema is often severe, accompanied by copious froth in the tracheobronchial airways. There may be subserosal hemorrhages in most cavities. Lymph nodes are swollen and wet, and the spleen is markedly enlarged. In goats with nephrosis, the kidneys will be soft. Although hemorrhages have been described in the brain, this organ often has no remarkable gross lesions; microscopically, there is perivascular mononuclear infiltration and edema along with presence of rickettsial colonies in capillary endothelial cells. The colonies disappear quickly as autolysis sets in. Foci of malacia may be present. Tissues for histopathology should include brain, lungs, lymph nodes, spleen, and kidneys. In addition, squash preparations of brain should be submitted for direct staining with Giemsa or for PCR detection.

### DIFFERENTIAL DIAGNOSIS

In endemic areas, heartwater should be suspected in susceptible animals infected with *Amblyomma* and having a fever of unknown origin, especially when accompanied by nervous signs. The clinical and pathologic findings are not specific, and the diagnosis must be based on detection of rickettsial organisms.

The peracute form should be differentiated from anthrax and the acute form from rabies, sporadic bovine encephalomyelitis, tetanus, cerebral forms of theileriosis, babesiosis, trypanosomiasis, meningitis, listeric or other encephalitis, hypomagnesemia, and poisoning with strychnine, lead and organophosphates. Appropriate laboratory tests are utilized to eliminate these differentials.

### TREATMENT

#### TREATMENT AND CONTROL

##### Treatment

Oxytetracycline (10–20 mg/kg IM in early stages) (R-1)

Sulfamethazine (55 mg/kg SC) (R-2)  
Hyperimmune serum (R-4)

#### Control

Infection and treatment with tetracycline IM  
or with doxycycline implant SC (R-1)  
Attenuated vaccine from cell culture (R-1)  
Vector control (R-1)

Field cases of heartwater are difficult to treat successfully because available drugs are effective only in early febrile stages before neurologic signs develop. In the early stages, short-acting tetracyclines (oxytetracycline at 10 to 20 mg/kg BW or doxycycline at 2 mg/kg) and long-acting forms at reduced doses are effective. Sulfonamides (e.g., sulfamethazine) were also used in the early stages but are less effective. Hyperimmune serum is reported to be of no curative value. Supportive therapy to reduce either the pulmonary edema or the neurologic signs or to stabilize membranes in general is being investigated, but with little success.

Chemoprophylaxis involves administration of tetracyclines or subcutaneous implantation of doxycycline in susceptible animals when they are introduced into an endemic area. Results are not always predictable.

#### CONTROL

Heartwater has traditionally been controlled by four different approaches: controlling the tick vector by dipping, establishing endemic stability, performing immunization by infection and treatment, and preventing the disease by regular administration of prophylactic antibiotics.<sup>15</sup> Control efforts have been hindered by abundance of ticks in endemic areas, by high rate of the carrier state following infection, and by lack of efficient vaccine in the field as a result of the high genetic diversity of strains circulating in any given area.<sup>16</sup>

Past efforts to control heartwater were based on intensive acaricide treatment to control ticks in endemic areas. It involved frequent use of acaricides (plunge dipping) up to 52 times a year. This has now been shown to be environmentally unfriendly and economically unsustainable, and it would invariably lead to animals that remained always susceptible. For example, it was observed in Zimbabwe that large farms applying acaricides very frequently (more than 30 times per annum) had higher morbidity and mortality than farms applying acaricides less frequently.

Long-acting acaricides have largely replaced the earlier ones applied frequently. Apart from being more environmentally friendly, occasional use of acaricides helps in the establishment of endemic stability in treated animals because they can still be exposed to low levels of infection. For example, flumethrin 1% pour-on at 45-day intervals was found to provide effective

protection of Friesian-Zebu crossbred cattle against important ticks, but it must be applied correctly at the recommended dose. Pure Zebu and N'Dama cattle would probably require less frequent applications. Flumethrin pour-on is gradually replacing plunge dipping for the control of ticks and tickborne diseases in general.

Vaccination is based on infection and treatment regimen that was first developed more than 50 years ago. It involves an intravenous injection of virulent organisms in cryopreserved sheep blood, followed by treatment with tetracyclines at the first indication of fever. The exposure of calves and lambs up to 3 weeks of age, without treatment, is considered optimal for the development of resistance, but kids may still be susceptible. Vaccination may lead to some deaths, the immunity may wane in absence of reinfection, and animals may become carriers. Nevertheless, the use of inactivated vaccines from cell-cultured *E. ruminantium* combined with an adjuvant led to a reduction in mortality from heartwater in cattle, sheep, and goats exposed to field challenges in Botswana, Zambia, Zimbabwe, and South Africa. Recently, an attenuated vaccine from *E. ruminantium* (Welgevonden) stock given intramuscularly was found to provide protection against virulent homologous needle challenge in Merino and Angora goats; injection did not produce disease, and protection was for at least 12 months after immunization.<sup>17</sup> In the Gambia, an attenuated vaccine was found to be superior to an inactivated vaccine for sheep.<sup>18</sup> Mass production of *E. ruminantium* variants from different regions of sub-Saharan Africa is one of the difficulties that must be overcome in producing a heartwater vaccine from cell culture.<sup>19</sup> Recently, a process for the large-scale production of a ready-to-use inactivated vaccine against heartwater was described.<sup>20</sup>

Experimental studies using DNA recombinant vaccines so far have met with only limited success, and none has been as effective as immunization with live organisms.<sup>9,21</sup> The development of a universal recombinant vaccine would require increased knowledge of *E. ruminantium* biology, including virulence mechanisms.<sup>5</sup> So far, the goal of producing an effective vaccine against the disease in the field still remains frustratingly just beyond reach.<sup>4</sup>

What is advocated today is integrated control based on the establishment of endemic stability by vaccination or natural challenge and general reduction in tick infestation through periodic application of long-acting insecticides when warranted.

### HISTOPHILUS SEPTICEMIA OF CATTLE (HISTOPHILUS SOMNI OR HAEMOPHILUS SOMNUS DISEASE COMPLEX)

#### SYNOPSIS

**Etiology** *Histophilus somni* (formerly *Haemophilus somnus*)

**Epidemiology** High prevalence of infection in cattle population; low incidence of disease. Occurs in North American feedlot cattle, in the United Kingdom, and in some European countries. Young growing cattle are most commonly affected. Originally, thrombotic meningoencephalitis (TME) was most common lesion, but pleuropneumonia and myocarditis are more common now. Several virulence factors of organism may account for different forms of disease. Organism resides in respiratory and reproductive tracts of both females and males.

**Signs** Thrombotic meningoencephalitis with fever, ataxia, joint swellings, weakness, recumbency, and death in 12 to 24 hours; pleuropneumonia and myocarditis with rapid death; reproductive failure with abortion.

**Clinical pathology** Marked changes in leukon. Demonstrate and culture organism from cerebrospinal fluid, joint fluid, pleural cavity, and myocardium.

**Lesions** Meningoencephalitis, hemorrhagic infarcts in brain, retinal hemorrhages,

*Continued*

pleuropneumonia, myocarditis. Vasculitis in infected tissue.

**Diagnostic confirmation** Culture, polymerase chain reaction (PCR).

**Treatment** Antimicrobials.

**Control** *H. somni* bacterin vaccines are available but unreliable; metaphylactic treatment with antimicrobials at time of placement in feedlot is frequently used.

## ETIOLOGY

*Histophilus somni* (formerly *Haemophilus somnus*) is a gram-negative, fastidious pleomorphic coccobacillus of the family Pasteurellaceae. Earlier investigations have shown that *H. somni*, *Haemophilus agni*, and *Histophilus ovis* represent the same species, and recent analysis of genes of strains supports the allocation of this species to a novel genus within the family Pasteurellaceae as *Histophilus somni*.<sup>1</sup> *H. somni* causes a variety of diseases in cattle, including septicemia, thrombotic meningoencephalitis (TME), pleuropneumonia, myocarditis, reproductive failure with abortion, polyarthritis, and, in sheep, mastitis, septicemia, and epididymitis.

## EPIDEMIOLOGY

### Prevalence of Infection

*H. somni* is an obligate inhabitant of mucosal surfaces of bovines, ovines, and related ruminants with worldwide occurrence. It is frequently found as an asymptomatic commensal in the male prepuce, the female vagina, and occasionally in the upper respiratory tract.<sup>1</sup> More than 50% of normal bulls, 8% to 10% of normal cows, and 10% of normal rams have *H. somni* in the reproductive tract. Among those that have had the disease and survived, the serologic reactor rate varies from 50% to 100%. Some surveys found more positive reactors in beef cattle and dairy cattle from infected herds than in dairy cattle from herds without clinical disease.

### Occurrence of Disease

*H. somni* is responsible for a variety of clinical syndromes in cattle, most of which occur in feedlot and dairy calves, although disease was also observed in grazing cattle.<sup>2</sup> Infection of cattle with *H. somni* may cause septicemia, thrombotic meningoencephalitis (TME), polysynovitis, pleuritis, suppurative bronchopneumonia, myocarditis, otitis media, mastitis, and reproductive tract diseases. When infection of cattle with the organism was first described in 1956, the primary form of the disease was TME. Since then, many different clinical forms of the infection have been described. Suppurative bronchopneumonia, fibrinous pleuritis, and myocarditis are now being recognized with increased frequency in feedlot cattle and are being attributed to *H. somni* infection. Based on necropsy examinations

over a 20-year period in a Saskatchewan diagnostic laboratory, there has been an increasing percentage of cattle with pneumonia and myocarditis associated with the organism and a decreasing percentage with TME. However, because of the practical difficulties in making a specific clinical, pathologic, and microbiological diagnosis in situations where the disease complex occurs, there is some uncertainty about the relative importance of the organism in causing certain diseases, such as pneumonia of feedlot cattle. For example, because of the variability of nature and extent of the lesions in bovine respiratory disease and the common occurrence of mixed infections, it is difficult to determine whether *H. somni* or *M. haemolytica* is the primary pathogen.

The disease occurs most commonly in **feedlot cattle** in North America after they have been commingled from different sources. The disease has also been recognized in the United Kingdom, Germany, Switzerland, and Israel. The organism has been found in the tonsillar tissues of American bison (*Bison bison*) and has been the cause of bronchopneumonia in bison.

The incidence rate of TME in a susceptible group of calves is low, averaging about 2%, but may be up to 10% in some outbreaks. The case-fatality rate, however, is 90% if affected animals are not identified and treated early in the course of the disease.

TME was historically a disease of feedlot cattle from 6 to 12 months of age with highest occurrence during the fall and winter months. In Canada TME occurred most commonly in cattle about 4 weeks after arrival in the feedlot, with a range of 1 week to 7 months. It also occurred in feedlot cattle in Argentina.

The disease complex that is encountered more commonly now is characterized by **pleuritis, pneumonia, and myocarditis** and can be the most significant cause of mortality in feedlot calves. Death from pneumonia attributable to the infection occurs mainly during the first 5 weeks in the feedlot; death from myocarditis, pleuritis, TME, septicemia, and euthanasia because of polysynovitis occurs mainly after the third week. This disease complex is occurring despite routine vaccination of calves on arrival in the feedlot. A history of respiratory tract disease preceding the outbreak is common, and in some cases TME had occurred in the same herd in the previous year.

*H. somni* also causes various forms of reproductive failure in cattle. The importation of infected young rams into a flock can have a deleterious effect on the percentage of ewes that lamb. Purchasing replacement animals and having cattle on the same farm were risk factors for infection in the flock. The possibility of interspecies transmission between cattle and sheep requires further study.

## Risk Factors

### Animal Risk Factors

Thrombotic meningoencephalitis, pleuropneumonia, and myocarditis occur most commonly in feedlot calves 6 to 12 months of age.

### Pathogen Risk Factors

The literature on the virulence factors of the organism has been reviewed.<sup>2,3</sup> Several virulence factors have been identified, including adherence, synthesis of lipooligosaccharide (LOS) and LOS phase variation, antigen variation of surface proteins, synthesis of immunoglobulin binding proteins, or the production of histamine and hemolysin.

**Adherence.** *H. somni* colonizes the surface of mucous membranes. In the asymptomatic carrier state the organism remains at the mucosal surface without invading cells; it attaches to nonepithelial cells, as has been documented in the example of bovine aortic endothelial cells. It is assumed that nonpilus adhesins are involved in the adherence of the organism to the cell surface.<sup>2</sup> *H. somni* attaches in large numbers to bovine vaginal epithelial cells, and attachment may be all that is necessary to produce infertility as a result of endometritis or degeneration of embryos during early gestation. The organism is able to persist in the lungs of calves for 6 to 10 weeks in the presence of specific antibody and in the absence of clinical abnormalities other than sporadic coughing.

### Lipooligosaccharides (LOS or Endotoxin).

Endotoxin produced by *H. somni* lacks the long, repeated polysaccharide chains that are characteristic for some gram-negative bacteria and is thus more appropriately designated as lipooligosaccharide (LOS) rather than lipopolysaccharide. The microorganism can vary the structure of the LOS by switching on and off specific genes encoding individual glycosyltransferases that are responsible for attaching individual glycoses to the oligosaccharide molecule, a phenomenon termed as **LOS phase variation**. The structure of the LOS outer core oligosaccharides of some strains mimics that of host glycosphingolipids, which may allow the organism to evade the host's immune system by camouflaging bacterial antigen.<sup>1</sup> LOS specifically triggers bovine platelet aggregation and may thereby contribute to adherence and colonization of respiratory epithelial cells and bovine endothelial cells. LOS was furthermore found to mediate apoptosis of bovine endothelial cells; the cytotoxic properties and the serum resistance of some strains have also been proposed to be associated with the production of LOS.<sup>4</sup>

### Antigen Variation of Surface Proteins.

Surface proteins or outer membrane proteins (OMPs) are important immunologic structures accessible for the host's immune system.

Strains of *H. somni* are diverse in molecular mass and antigenic reactivity. Although the precise role of OMPs in the pathogenesis of histophilosis is not yet understood, they may play an important role in the ability of the organism to evade the host's immune system and cause disease.<sup>2</sup>

**Immunoglobulin-Binding Proteins.** Immunoglobulin-binding proteins (IgBPs) are characterized by their affinity to IgG<sub>2</sub> immunoglobulin and are thought to enable *H. somni* to evade antibody defense. Although it is well accepted that IgBPs are important determinants of serum resistance of pathogenic *H. somni* strains, the underlying mechanism is not yet well explained.<sup>3</sup> Some isolates of the organism are indeed able to multiply *in vivo* because they are resistant to complement, and bovine leukocytes are incapable of destroying the organism in the absence of specific antibody.

**Transferrin-Binding Proteins.** *H. somni* is inherently dependent on the availability of iron and in absence of available iron produces transferrin-binding proteins (TBPs) that specifically bind bovine transferrin but not transferrin of other species.<sup>3</sup> This was proposed as one of the underlying causes for the host specificity of *H. somni*.

**Biofilm Synthesis.** *H. somni* was found to produce biofilm *in vitro* and *in vivo*, which is a virulence factor likely contributing to the pathogenesis of histophilosis. Strains of *H. somni* isolated from diseased tissue often have the greatest capacity to form a biofilm.<sup>5</sup> Furthermore, different strains were found to produce biofilm with different structures, and difference in biofilm architecture may correlate with resistance to the host's immune defense mechanisms.<sup>1</sup>

Some strains are serum resistant and others serum sensitive, which may explain the ability of certain strains to invade beyond mucous membrane surfaces. Virulence differences also exist between *H. somni* strains following intratracheal challenge of bovine lungs. Those strains isolated from encephalitic lesions, or from the prepuce, will not produce the same degree of experimental pneumonia as those strains isolated from lung lesions. Preputial and septicemic isolates of ovine *H. somni* are similar to bovine *H. somni* in pathogenicity and in surface antigens. Ovine isolates given by intracysternal inoculation to 2- to 3-month-old lambs caused fatal meningoencephalitis and myelitis.

In summary, many virulence factors are involved in several steps of pathogenesis. Adherence is likely to be important in colonization, complement resistance in survival in the circulation or inflammatory sites, and cytotoxicity in evading killing by phagocytes and in initiation of vasculitis, and invasion through the endothelium. The host damage

that occurs as a result may be further exacerbated by inflammatory mediators released by the host in response to *H. somni*.

### Methods of Transmission

The method of transmission and portal of entry are unclear. A feature of infections with this organism is its persistence at mucosal sites in both subclinical and diseased animals. The organism can be isolated from the respiratory and reproductive tracts of normal animals.

In bulls, the organism has been isolated from semen and the preputial orifice, preputial cavity, urinary bladder, accessory sex glands, ampulla of the ductus deferens, and the preputial washings of steers. Most bulls harbor the organism in the prepuce. Thus the potential exists for venereal transmission of *H. somni*, for lateral spread from the genital tract, and for environmental contamination by the organism.

The organism has also been isolated from the vagina, vestibular gland, cervix, uterus, and bladder of cows. The prevalence of infection in normal cows varies depending on the herd and geographic location, but 10% to 27% can harbor the organism. The organism can colonize the vagina of cows without causing disease, and it is thought to have a primary etiologic role in vaginitis and cervicitis in cows.

The organism has been isolated from the udder secretions of cattle with naturally occurring mastitis.

Urine is also a source of the organism. The young beef calf in a cow-calf herd can become infected as early as 1 month of age and become a nasal carrier of the organism without showing any signs of clinical disease. The mature cow is considered to be a major source of infection for the calf. The method of transmission is presumed to be by contact with infective respiratory and reproductive secretions or by aerosol transmission, especially in close-contact feedlots.

The organism can survive more than 70 days when it is mixed with cerebrospinal fluid, whole blood, blood plasma, vaginal mucus, or milk and frozen at -70°C (-94°F). At 23.5°C (73.5°F) it can survive beyond 70 days when mixed with whole blood and nasal mucus. The viability of the organism in urine at all temperatures is less than 24 hours and less than 15 minutes at 20°C (68°F) and 37°C (98°F). It survives for less than 1 day in milk at room temperature or when incubated at 37°C (98°F) and should be considered as a possible cause of mastitis in cases that are negative on routine bacteriologic culture.

### Immune Mechanisms

Serum antibody titers do not correlate with susceptibility to clinical disease. Naturally acquired humoral immunity does not influence the outcome of experimental intravenous inoculation of the organism. Also, the

role of naturally acquired antibody in protecting cattle from disease is uncertain. The levels of naturally occurring serum bactericidal activity to *H. somni* are low or absent in calves at 4 to 6 months of age, when they are most susceptible to TME. The levels increase with age and are high in mature cows; yearlings have intermediate levels.

Convalescent sera from calves with experimental *H. somni* pneumonia protect calves against acute *H. somni* pneumonia. Marked serum exudation characterizes the early stages of experimental pneumonia, and antibody should be involved in protection. The specificity of this protection is directed primarily against outer-membrane proteins (OMPs) of the organism. These antigens may also be useful in serologic diagnosis because convalescent calves have high IgG<sub>1</sub> and IgG<sub>2</sub> titers to *H. somni* for several weeks. The measurement of serum IgG<sub>1</sub> is a more reliable test to detect a current or recently active infection. Later, there is a sustained increase in IgG<sub>2</sub>. The development of a systemic IgG<sub>2</sub> antibody response is the basis for local immunologic protection in the bovine reproductive tract.<sup>3</sup>

The immune response in cattle to the major outer membrane proteins during infection is weak and directed to antigenically variable determinants in a strain specific manner that may have important implications in protective immunity. Vaccination of 1- to 2-month-old calves with commercial aluminum-hydroxide-adsorbed *H. somni* bacterins elicits an ELISA-detectable IgE response 14 days after injection, which may be associated with severe clinical disease associated with type I hypersensitivity.

### PATHOGENESIS

*H. somni* first establishes itself in the host by colonizing the surface of the mucous membranes. It is not known if strains harbored in the respiratory tract or the genital tract invade the circulatory system to cause septicemia with ensuing localization in many tissues and organs. Although respiratory disease preceding TME has been described, experimental intratracheal inoculation resulted in colonization of the upper and lower respiratory tract without concomitant septicemia.<sup>2</sup>

The ability of *H. somni* to survive in both mononuclear phagocytes and neutrophils may be important in the establishment of the chronic multisystemic infection characteristic of bovine histophilosis. With TME the sequence of events may be initiated by adhesion of the bacterium to vascular endothelial cells. The organism's LOS induces endothelial cell apoptosis and contraction and desquamation of cells, with exposure of subendothelial collagen; thrombosis and vasculitis is followed by ischemic necrosis of adjacent parenchyma. The common site of localization is the brain. Multifocal areas of hemorrhagic necrosis occur throughout the

brain, resulting in TME and causing the typical clinical findings of depression, paresis, and recumbency. Localization in synovia results in polysynovitis. Fibrin thrombi occur in the small vessels and capillaries of the liver, spleen, kidney, lung, heart, and brain, which suggests that **disseminated intravascular coagulation** may be a feature of the pathogenesis of *Histophilus* septicemia. Myocarditis has been recognized with increased frequency and is characterized by acute or chronic heart failure.<sup>6</sup>

The pathogenesis of *Histophilus* pneumonia is not clear. Although *H. somni* has been isolated from cattle with bronchopneumonia and fibrinous pneumonia in pure culture and in combination with *Pasteurella* spp., the lungs of cattle dying of TME are not usually affected with a fibrinous pneumonia. The pneumonia that is attributed to the organism is characteristically subacute or chronic, and it is probable that the portal of entry is via the upper respiratory tract. However, it is difficult to reproduce the disease by aerosol challenge with *H. somni*. The organism produces and secretes histamine, which may be enhanced by carbon dioxide concentrations that approximate those in the bronchial tree.

The microscopic lesions in the lungs of cattle with pneumonia from which *H. somni* is isolated consist of suppurative to necrotizing bronchiolitis, particularly in calves with subacute to chronic pneumonia. The experimental pneumonia is characterized by purulent to fibrinopurulent bronchiolitis accompanied by alveolar filling with fibrin, neutrophils, and macrophages. Laryngitis and polypoid tracheitis have also been attributed to *H. somni*, but the evidence for a cause and effect relationship is limited.

Hemorrhagic necrotic lesions also occur in the spinal cord, which contribute to the muscular weakness, recumbency, and paralysis encountered in some cases with or without brain lesions. Lesions in the esophagus, forestomachs, and intestines may account for the bloat and alimentary tract stasis that occurs in the experimental disease.

The septicemia usually causes marked leukopenia, neutropenia, and degenerative left shift.

Cattle dying of experimentally induced and naturally occurring disease have high levels of agglutinating *H. somni* antibody, but not of complement-fixing antibody. Because septicemia can occur even with high levels of serum antibody, it is hypothesized that the formation of antigen-antibody complexes may contribute to the development of vasculitis. It is possible that previous exposure to *H. somni* infection is necessary for typical TME to occur. Inoculation of colostrum-deprived calves with *H. somni* causes septicemia but does not produce lesions typical of TME. This suggests that the disease may be an example of a type III hypersensitivity reaction or serum sickness.

The organism can cause inflammatory disease in the genital tract of cows or may merely colonize the healthy genital mucosa. Vaginitis, cervicitis, and endometritis have been associated with infection by *H. somni*. Experimentally, the organism can be embryocidal, which indicates a possible role in early embryonic mortality. Sporadic abortions have been reported following septicemia and placentitis, the latter being characterized by thrombosis and vasculitis as observed with TME and *Histophilus* pneumonia.<sup>3</sup>

## CLINICAL FINDINGS

The range of clinical findings associated with *H. somni* infection in cattle has changed remarkably over the last decades. Historically, TME was the major form of the disease. However, fewer cases of this presentation are being diagnosed now, whereas many more cases of other forms of the disease are becoming prevalent.

### Thrombotic Meningoencephalitis (TME)

In the typical nervous form of the disease, thrombotic meningoencephalitis (TME), it is common for several animals to be affected within a few days or at one time, but single cases do occur. Some affected animals may be found dead without any premonitory signs, and often this may be the first sign of disease in the group.

In the more common acute form, in which there is usually neurologic involvement, cattle may be found in lateral or sternal recumbency and may or may not be able to stand. The temperature is usually elevated up to 41 to 42°C (105.8–107.6°F) but may be normal in some cases. Depression is common, the eyes are usually partially or fully closed, and unilateral or bilateral blindness may be present. Originally the disease was called the “**sleeping syndrome**” because the eyes were partially closed. Recumbent cattle that attempt to stand may have considerable difficulty and exhibit obvious ataxia and weakness. Others that are able to stand, when attempting to walk, knuckle over on the hind fetlocks, are grossly atactic, and usually fall after walking a short distance. In the recumbent position, opisthotonos, nystagmus, muscular tremors, hyperesthesia, and occasionally convulsions will occur, but the emphasis is on muscular weakness and paralysis rather than signs of irritation. Otitis media with concurrent meningitis may also occur.

TME is rapidly fatal in 8 to 12 hours if not treated when signs are first noticed. Affected cattle that are treated before becoming recumbent commonly recover in 6 to 12 hours, which is an important clinical characteristic of the disease. Once recumbent, particularly with obvious neurologic involvement, the affected animal will either die in spite of treatment or remain recumbent and

deteriorate over a period of several days. Secondary complications, such as pneumonia and decubitus ulcers, usually result.

The **ocular lesions** consist of foci of retinal hemorrhages and accumulations of exudate that appear like “cotton tufts.” Although these fundic lesions are not present in all cattle affected with *H. somni*, they are a valuable aid to the diagnosis. The organism has been isolated from the conjunctival sacs of feedlot cattle affected with conjunctivitis.

**Otitis in feedlot cattle** has also been attributed to the organism. The ears are commonly drooping, and affected animals appear depressed. A combination of otitis and meningitis in young cattle associated with the organism has been described.

The **synovitis** is characterized by distension of the joint capsules, usually the major movable joints such as the hock and stifle joints, but any joint may be involved. Pain and lameness are only mild; when treated early, the synovitis usually resolves in a few days. In a few cases there is marked lameness and a preference for recumbency associated with hemorrhages in muscle. The organism has been isolated from a calf with a urachal abscess.

### Respiratory Disease

The clinical findings of the respiratory form of the disease, which has been diagnosed with increased frequency in the last decades, have not been clearly described. It is unlikely that there are any distinctive clinical features. Most feedlot calves with pleuritis attributable to *H. somni* die in the pen without ever having been treated.

Epidemiologic surveys of weaned beef calf mortality attributable to pneumonia and pleuritis associated with *H. somni* suggest that death from pneumonia occurred during the first 5 weeks after arrival in the feedlot. The median fatal disease onset for pneumonia was day 12, and for myocarditis and pleuritis, day 22. It is suggested that pneumonia and pleuritis should be suspected in feedlot cattle that have been treated unsuccessfully for bovine respiratory disease in the previous several days. Laryngitis, tracheitis, pleuritis, and pneumonia can occur alone or in combination with the acute neurologic form of the disease. The laryngitis is characterized clinically by severe dyspnea, mouth-breathing, and stertor. Conjunctivitis similar to that seen in infectious bovine rhinotracheitis (IBR) may occur, and isolation of the organism from ocular swabs is necessary to make the definitive diagnosis. Chronic suppurative orchiepididymitis in a calf from which *H. somni* was isolated has been described.

### Myocarditis

In the myocardial form of the disease, affected animals may be found dead without any previous illness having been recorded or they may have been treated for respiratory

disease within the previous few weeks with a variable response. If seen early in the course of the myocarditis, the most common clinical findings are a fever and depression. With advanced stages of myocarditis, exercise intolerance, mouth-breathing, and protrusion of the tongue occur. Affected animals may collapse and die while being moved from their home pen to the hospital pen in the feedlot. Most animals with myocarditis have a previous history of being treated for an undifferentiated fever and depression within the previous 10 to 14 days. When returned to their home pens, they may be found dead or in severe respiratory distress.

**Chronic free-gas bloat** is a not uncommon finding in naturally occurring cases and occurs frequently in the experimental disease.

## CLINICAL PATHOLOGY

### Hematology

In most cases there are changes in the total and differential leukocyte count. Leukopenia and neutropenia may be present in severe cases, whereas in less severe cases a neutrophilia with a left shift is more common. In the cerebrospinal fluid, the total cell count is markedly increased, and neutrophils predominate. The Pandy globulin test on cerebrospinal fluid is usually strongly positive. In the synovial fluid the total cell count is also increased, and neutrophils predominate.

### Culture of Organism

The organism can be cultured from blood, cerebrospinal fluid, synovial fluid, urine, brain, kidney, and liver, less commonly from pleuritic fluid and tracheal washings. In vivo *H. somni* was isolated more often from bronchioalveolar lavage fluid than from nasopharyngeal swabs.<sup>3</sup> Culture of *H. somni* is poorly sensitive because the organism is fragile and fastidious. Collected samples must be shipped in a timely manner using special transport media and under refrigeration. Growth of *H. somni* is slow, requiring at least 48 to 72 hours on selective culture media and incubated on presence of 10% CO<sub>2</sub>. Previous antimicrobial therapy may further decrease the chances of successful recovery of the germ from an infected animal. The PCR technique is a more sensitive method for detection of the organism than bacterial culture and immunochemistry. The interpretation of a culture positive result is complicated by the common occurrence of asymptomatic carriers. Only large numbers of *H. somni*, ideally in pure culture obtained from a lesion, are considered confirmatory.<sup>3</sup>

### Serology

Cattle with experimental or naturally occurring disease have high levels of agglutinating anti-*H. somni* antibody. Recovered animals are positive to the complement fixation test (CFT) within 10 days following infection,

and titers begin to decline to low levels 30 days after infection.

A microagglutination test is available, but this test preferentially detects IgM antibody, an antibody class commonly cross-reacting with other members of the family Pasteurellaceae. Immunologic cross-reaction may explain why most cattle are positive on microagglutination in the absence of a history of *H. somni* disease or related clinical signs. ELISAs identifying the presence of IgG<sub>2</sub> are more specific; however, there is no significant difference in serum IgG<sub>2</sub> titers between culture-negative and culture-positive but asymptomatic animals. It was proposed that seroconversion could also occur in asymptotically infected carrier animals.<sup>3</sup>

An immunoblot test can detect an immune response after experimental abortion, experimental pneumonia, or vaccination with a killed vaccine. It is also able to distinguish between animals with an immune response as a result of disease or vaccination with the organism and those animals that are asymptomatic carriers, culture negative, or infected with closely related bacteria.

Paired serum samples obtained during acute and convalescence phase can be useful retrospectively.

## NECROPSY FINDINGS

The characteristic lesions of TME are hemorrhagic infarcts in any part of the brain and spinal cord. These are usually multiple and vary in color from bright red to brown and in diameter from 0.5 to 3 cm. Cerebral meningitis may be focal or diffuse, and the cerebrospinal fluid is usually cloudy and slightly yellow-tinged. Hemorrhages may also be present in the myocardium, skeletal muscles, kidneys, and serosal surfaces of the gastrointestinal tract.

There may be petechiation and edema of the synovial membranes of joints. There is an excessive quantity of synovial fluid, which is usually cloudy and may contain fibrinous flecks. The articular cartilage is usually not affected.

Pulmonary involvement is characterized by a fibrinopurulent bronchopneumonia, although the posterior aspects of the lung may be edematous and have a rubbery consistency. Histologically, there is fibrinosuppurative bronchiolitis accompanied by filling of the alveoli with fibrin, neutrophils, and macrophages. Peribronchiolar fibrosis and bronchiolitis obliterans, interlobular fibrosis and thrombosis of interlobular and pleural lymphatics develop in chronic cases. Fibrinous or serofibrinous inflammation of the peritoneum, pericardium, or pleura is found in more than 50% of cases. There may be focal ulceration and fibrinonecrotizing inflammation extending from the pharynx down into the trachea. Polypoid tracheitis has also been reported.

**Histologically, vasculitis and thrombosis** with or without infarctions and a cellular component composed almost entirely of neutrophils may be seen in all tissues where localization occurs, especially the heart but also the placenta in case of abortion.<sup>3</sup> Myocardial abscesses may develop and are most common in the left ventricular free wall, particularly in the papillary muscles.

## Samples for Confirmation of Diagnosis

- Bacteriology—culture swabs from brain/ meningeal and joint lesions; lung, spleen, heart (culture, PCR)
- Histology—formalin-fixed brain, lung, heart, kidney, synovial membrane (light microscopy, immunohistochemistry)

## DIFFERENTIAL DIAGNOSIS

### Thrombotic meningoencephalitis

attributable to *Histophilus somni* is characterized by sudden onset of weakness, ataxia, depression, fever, enlarged joints, and rapid death within 12 to 24 hours. There are marked changes in the cell count of the cerebrospinal fluid and the leukogram. There is a rapid response to treatment in the early stages.

In **polioencephalomalacia**, blindness, normal temperature, nystagmus, opisthotonos, and convulsions are common.

In **Listeria meningoencephalitis**, there is unilateral facial paralysis with deviation of the head and neck and a normal or slightly increased temperature. The cerebrospinal fluid in listeriosis usually contains an increased number of mononuclear cells.

**Mycoplasma bovis** infection can cause polyarthritis, otitis media in calves, and, in rare instances, meningoencephalitis.

**Hypovitaminosis A** in young cattle 6 to 12 months of age is characterized by sudden onset of short-term convulsions and syncope lasting 10 to 30 seconds, during which they may die but from which they more commonly recover to appear normal. Exercise such as walking from pasture to the farmstead will commonly precipitate the seizures. Eyesight may be slightly impaired, but the menace reflex is usually present.

**Pneumonia and pleuritis** associated with *H. somni* cannot be distinguished clinically from the other common causes of pneumonia in cattle, and the diagnosis is usually made at necropsy.

**Myocarditis** attributable to *H. somni* may cause sudden death or congestive heart failure, which will require a necropsy examination for a diagnosis.

## TREATMENT

Cattle with TME must be treated with antimicrobials as soon as clinical signs are obvious. Florfenicol, an analog of thiamphenicol, at a dose of 20 mg/kg BW intramuscularly and repeated 48 hours later, is effective for the treatment of acute undifferentiated fever in

feedlot calves and may be the antimicrobial of choice if *H. somni* infection is a major cause of mortality in feedlot calves. Oxytetracycline at 20 mg/kg BW intravenously daily for 3 days is effective when treatment is begun within a few hours after the onset of clinical signs. The prognosis in recumbent cattle is unfavorable, but treatment for 2 to 4 days may be attempted. A failure to respond after 3 days of treatment usually indicates the presence of irreversible lesions. The MICs of 33 antimicrobial agents for *H. somni* indicated high in vitro susceptibility to penicillin G, ampicillin, colistin, and novobiocin; oxytetracycline also revealed high activity. Once the disease has been recognized in a group, all in-contact animals should be observed closely for the next 7 to 10 days to detect new cases in the initial stages so that early treatment can be given. The treatment of pneumonia and pleuritis attributable to *H. somni* is the same as for acute undifferentiated bovine respiratory disease.

#### TREATMENT AND CONTROL

##### Treatment

Oxytetracycline (20 mg/kg IV every 24h for at least 3 days) (R-2)

Florfenicol (20 mg/kg IM every 48h) (R-2)

##### Control

*H. somni* bacterin vaccine

Florfenicol (40 mg/kg IM as single treatment)

Oxytetracycline (long acting formulation 20 mg/kg IM as single treatment)

#### CONTROL

Satisfactory control procedures are not available because the pathogenesis and epidemiology of the disease are not well understood. When an outbreak of the nervous form of the disease is encountered, the provision of constant surveillance and early treatment is probably the most economical and effective means of control.

#### Metaphylactic Antimicrobial Therapy

Postarrival metaphylactic treatment with antibiotics is widely used in feedlots to control undifferentiated bovine respiratory disease (UBRD) and was shown to reduce morbidity and mortality associated with this disease complex.<sup>7,8</sup> Evidence supporting the metaphylactic or prophylactic use of antimicrobials to reduce occurrence rate and mortality directly associated with *H. somni* infection is scant. Mass medication with long-acting oxytetracyclines did not reduce the risk of histophilosis mortality, but it reduced the risks of bovine respiratory disease morbidity and mortality by 14% and 71%, respectively.<sup>2</sup>

#### Vaccination

Vaccines have been available for use in North America and are mainly labeled

for protection from TME but not the other forms of histophilosis; their efficacy is uncertain.<sup>9</sup> One bacterin is immunogenic and will protect vaccinated cattle against the nervous form of the infection produced by intravenous and intracisternal inoculation of the organism. Two injections of the bacterin given subcutaneously 2 to 3 weeks apart are recommended. Controlled field trials indicate that the bacterin reduces the morbidity and mortality rates of nervous system disease in vaccinated cattle compared with nonvaccinated animals. However, the efficacy of the bacterin has been difficult to evaluate because the incidence of naturally occurring disease in nonvaccinated control animals is usually low and may not be significantly greater than in vaccinated animals.

The efficacy of a *H. somni* bacterin to reduce mortality was evaluated in auction-market-derived beef calves vaccinated immediately upon arrival at the feedlot. The vaccine had no significant effect on overall crude mortality but appeared to reduce the incidence rate of fatal disease during the first 2 months in the feedlot when the risk of fatal disease onset was highest. When mortalities unlikely to be associated with *H. somni* were removed from the analysis, the mortality rate in male calves was reduced by about 17% in the vaccinated group. A second vaccination 2 weeks after arrival did not reduce the mortality risk.

Vaccination of feedlot calves on arrival with a genetically attenuated leukotoxin of *M. haemolytica* combined with bacterial extracts of *H. somni* increased serum antibody titers to both organisms and reduced acute undifferentiated bovine respiratory disease. However, it is not known what proportion of the respiratory disease was attributable to *H. somni*.

Vaccinating calves twice with a killed whole-cell bacterin reduced the clinical and pathologic effects of experimentally induced *H. somni* pneumonia. Calves vaccinated once were incompletely protected.

There is no published evidence to indicate that vaccination of feedlot calves before or after entry into the feedlot with any of the available *H. somni* vaccines will provide protection against the various forms of clinical disease, particularly the respiratory and myocardial types described earlier.<sup>9</sup> The disease complex is occurring in feedlot calves in spite of vaccination. A rational vaccination program would consist of vaccinating calves at least twice, 2 to 4 weeks apart, with the second vaccination occurring at least 2 weeks before entry into the feedlot.

### SEPTICEMIA AND THROMBOTIC MENINGOENCEPHALITIS IN SHEEP ASSOCIATED WITH *HISTOPHILUS SOMNI*

#### SYNOPSIS

**Etiology** *Histophilus somni* (formerly *Haemophilus agni*, *Histophilus ovis*)

**Epidemiology** Worldwide occurrence but not a common disease. In affected flocks, cases occur over several weeks to result in a significant population mortality.

**Clinical findings** Acute disease and affected sheep commonly found dead. Septicemia, polyarthritis, and occasionally meningitis primarily in lambs 4 to 7 months of age.

**Necropsy findings** Multiple hemorrhages throughout the carcass. Focal hepatic necrosis. Polyarthritis, meningoencephalitis.

**Diagnostic confirmation** Isolation of the organism.

**Treatment and control** Oxytetracycline.

#### ETIOLOGY

*Histophilus somni* falls within the family Pasteurellaceae. This organism, previously known as *Haemophilus agni* and *Histophilus ovis*, has been isolated from sheep, bighorn sheep, and bison with a number of different pyogenic conditions, including septicemia, polyarthritis, thrombotic meningoencephalitis, general pyemia, metritis, mastitis, abortion, neonatal mortality, and epididymitis.<sup>1</sup>

#### EPIDEMIOLOGY

Disease associated with *H. somni* in sheep has worldwide occurrence but is not common.

The most common presentation is lameness and septicemia in lambs aged 4 to 7 months, but infection with this organism can

also result in polyarthritis in lambs 1 to 4 weeks of age. The morbidity rate varies between outbreaks, but the case-fatality rate is likely to be 100% unless treatment is undertaken, and the population mortality rate can approach 10%. Outbreaks may last several weeks; within a flock, cases of the disease occur sporadically but over a long period.

In some outbreaks, both in lambs and adult sheep, meningoencephalitis is the primary presentation, and the clinical and pathologic findings are similar to those of thromboembolic meningoencephalitis in cattle. The method of transmission is unknown, but the disease does not appear to spread by pen contact and cannot be produced by oral, nasal, or conjunctival exposure to the organism. Environmental or other stress may be a predisposing factor. *H. somni* has been isolated from the genital mucosa of goats that are in contact with sheep flocks, but their role in transmission of this organism is not clear.<sup>2</sup>

### PATHOGENESIS

The organism colonizes the respiratory and reproductive tract mucosa and invades to produce septicemia and disseminated bacterial thrombosis, leading to a severe focal vasculitis.

### CLINICAL FINDINGS

Affected sheep are often found dead. Depression, high fever (42°C [107°F]), disinclination to move, and collapse with movement are the obvious clinical signs, and affected lambs may die within 12 hours of becoming ill. Lambs that survive more than 24 hours develop a severe arthritis with a palpable increase in joint fluid and heat in the joints. They are usually recumbent, and those with meningoencephalitis show hypersalivation, convulsions, and opisthotonos. The clinical course is short.

### CLINICAL PATHOLOGY

Hematology and blood chemistry are not commonly conducted because of the acute nature of the disease and the availability of carcasses for postmortem. Initially there is leukopenia and neutropenia, with neutrophilia and left shift in more prolonged cases. Total cell count is elevated in cerebrospinal fluid and joint fluid, and these also can be cultured for the organism. Antibody detected by complement fixation persists for about 3 months in animals that survive.

### NECROPSY FINDINGS

At necropsy the most striking feature is the presence of multiple hemorrhages throughout the carcass. Focal hepatic necrosis surrounded by a zone of hemorrhage is also a constant finding. Lambs that die in the early stages of the disease show minimal joint changes, but those that survive for more than 24 hours develop fibrinopurulent arthritis.

Histologically, the disease is a disseminated bacterial thrombosis leading to a severe focal vasculitis. This change is most apparent in the liver and skeletal muscles. More protracted cases can have hemorrhages in the leptomeninges and foci of liquefactive necrosis at the gray-white junction of cerebral hemispheres, basal gray nuclei, and thalamus. Microscopically, these foci exhibit suppurative necrosis and vascular thrombosis, with bacterial colonies inside the abscesses.<sup>3</sup>

### Samples for Confirmation of Diagnosis

- Bacteriology—swabs from joint fluid, liver, meningeal fluid for culture and PCR
- Histology—formalin-fixed liver and brain for histology and immunochemistry

### DIFFERENTIAL DIAGNOSIS

Because of the acute nature of the clinical disease, the disease is likely to be confused with acute septicemia associated with *E. coli* or *P. trehalosi*, and with enterotoxemia. The characteristic hepatic lesions and histology serve to identify the disease, and final diagnosis depends on isolation of the organism.

### TREATMENT AND CONTROL

Antimicrobials, such as tetracyclines or tilmicosin,<sup>4</sup> need to be given very early in the course of the disease if they are to be effective. Because of the acute nature of the disease, vaccination is likely to be the only satisfactory method of control. Although there is no label, vaccine immunity after a field attack seems to be solid. Mass treatment of the group of sheep at risk with long-acting tetracyclines is a possible strategy to reduce the occurrence of further cases.

## TICK PYEMIA OF LAMBS (ENZOOTIC STAPHYLOCOCCOSIS OF LAMBS)

### SYNOPSIS

**Etiology** Infection with *Staphylococcus aureus* predisposed by infection with *Anaplasma* (formerly *Ehrlichia*) *phagocytophila*.

**Epidemiology** Disease of young lambs that occurs in areas that are habitats for *Ixodes ricinus*.

**Clinical and necropsy findings** Septicemia and subsequent abscessation in internal organs.

**Diagnostic confirmation** Isolation of organism.

**Treatment** Long-acting antimicrobials.

**Control** Tick control.

### ETIOLOGY

The disease has a complex causality and results from a septicemia produced by *Staphylococcus aureus* predisposed by infection with *Anaplasma* (formerly *Ehrlichia*) *phagocytophila*, which is transmitted by *Ixodes ricinus*.

### EPIDEMIOLOGY

Enzootic disease has been recorded only in the United Kingdom and occurs only in the hill areas that are habitats for the tick *I. ricinus*. The disease occurs in the spring and early summer. The annual incidence varies with the year and between farms. On average, 5% of lambs at risk are affected, but on some farms the incidence may be as high as 29% in certain years.

In enzootic areas the disease has considerable economic importance and has been stated to affect as many as 300,000 lambs every year, the majority of which die or fail to be profitable.

### PATHOGENESIS

Experimental and epidemiologic studies have established a clear relationship between infection with *A. phagocytophila*, the agent of tick-borne fever, and susceptibility to infection with *S. aureus*. The role of the tick is in the transmission of *A. phagocytophila*, which produces waves of bacteremia detectable by quantitative PCR as early as 1 day following experimental infection.<sup>1</sup>

Infection with *A. phagocytophila* produces a significant lymphocytopenia that develops 6 days after infection and affects all subsets of T- and B-lymphocytes, and also a prolonged neutropenia lasting for 2 to 3 weeks combined with a thrombocytopenia. Up to 70% of the neutrophils are parasitized from the onset of the parasitemia and have impaired function, and lambs with tick-borne fever have a much higher susceptibility to experimental infection with *S. aureus* than noninfected lambs. The ticks are not thought to necessarily provide portals of entry for, nor to be the primary carriers of, the infection with *S. aureus*, although they are important in this respect. *S. aureus* can gain entry through a variety of sources, and in affected flocks there is a high incidence of lambs carrying the same infection on their nasal mucosa.

## CLINICAL AND NECROPSY FINDINGS

Lambs aged 2 to 10 weeks are affected. They may die quickly of septicemia or show signs of localization of infection. Clinically, this is most evident by infections that localize in joints or the meninges to manifest as arthritis or meningitis, but on postmortem examination abscesses can be found in any organ, including the skin, muscles, tendon sheaths, joints, viscera, and brain.

## TREATMENT AND CONTROL

Treatment of the established disease has limited value, and efforts should be directed at prevention or mitigation of early infection during the bacteremic phase.

The strategic use of long-acting antibiotics has shown success in this respect. On farms with enzootic disease, benzathine penicillin administered at 3 weeks of life has been shown to result in a marked decrease in the incidence of subsequent clinical disease. The use of long-acting tetracyclines has the additional advantage of protecting against infection with the agent of tick-borne fever and *S. aureus* infection; two treatments of lambs, the first between 1 and 3 weeks of age and the second between 5 and 7 weeks, has been shown to result in a significant reduction in morbidity and mortality. In addition, the treatment has been accompanied by increased weight gain.

Tick control by dipping lambs or using a pour-on insecticide significantly reduces the incidence of clinical disease and increases weight gain of clinically normal lambs. Separation of the lambs for dipping has not been associated with problems of mis-mothering. A combination of antibiotic and acaricide treatment may be the most effective and in one trial reduced losses from 10.3% to 0.6%. Dipping the whole flock in an acaricide in spring, although it will not completely eradicate tick infestation, will reduce the incidence of tick pyemia.

Pyemic infection with *S. aureus* is also recorded in association with tick infestation in camels in Saudi Arabia.

## SEPTICEMIC PASTEURELLOSIS OF CATTLE (HEMORRHAGIC SEPTICEMIA)

### ETIOLOGY

Hemorrhagic septicemia (HS) is mainly associated with two specific serotypes of *P. multocida*, a gram-negative, aerobic coccobacillus of the family Pasteurellaceae. The Asian serotype is designated B:2 and the

African serotype is E:2 by the Carter-Heddestone system, corresponding to 6:B and 6:E by the newer Namioka-Carter system. The letter denotes the capsular antigen and the cipher the somatic antigen. Other serotypes—namely, A:1, A:1,3, A:3, A:4, B:1, B:2,5, and others—have occasionally been isolated from HS outbreaks.<sup>1</sup> Serotype E:2 has thus far only been retrieved in Africa, whereas serotype B:2 was isolated from cases on other continents but also from Egypt and Sudan.

Although *P. multocida* does not readily survive in the environment, it is thought that it can survive for hours and probably days in moist soil and water.

## EPIDEMIOLOGY

### Occurrence

Hemorrhagic septicemia is a highly fatal acute septicemic disease predominantly affecting **water buffaloes and cattle**. Occasional outbreaks among pigs and less frequently among sheep, goats and bison have been reported. Incidental cases have been reported in horses, donkeys, elephants, yaks and camels.<sup>2</sup>

HS is considered economically important in Asia, Africa, and the Middle East, with highest incidences in Southeast Asia. Cases have also been reported from countries in southern Europe and the United States, where outbreaks among bison were reported. In regions where the disease is endemic it causes heavy death losses and has emerged as the economically most important bacterial disease following the successful eradication of rinderpest and the continued low mortality of food-and-mouth disease.<sup>1</sup> HS is listed on list B of the World Organization for Animal Health (OIE), which includes “transmissible diseases that are considered to be of socioeconomic and/or public health importance within countries, and that are significant in the international trade of animals and animal products.”<sup>3</sup>

Both morbidity and case-fatality rates vary between 50% and 100%, and animals that recover require a long convalescence. Morbidity will depend on the immune status of the herd, either acquired naturally or induced by vaccination. The greater the percentage of immune to nonimmune animals, the lower will be the morbidity. In endemic areas, adult animals develop a naturally acquired immunity, and large outbreaks no longer occur in these areas. The incidence of disease is reduced significantly in areas where the vaccine is used.

### Risk Factors

#### Animal Risk Factors

The disease predominantly affects water buffaloes and cattle, but buffaloes are considered to be more susceptible to clinical disease. These species also present the most important host reservoir for the pathogen. It is estimated that in endemic areas up to 5%

of water buffaloes and cattle are carriers and thus potential shedders of the pathogens.<sup>1</sup>

All age groups are susceptible to infection, but in endemic regions, older animals previously exposed to the pathogen may have antibodies providing some protection. In these regions the most susceptible age group is 6 months to 2 years of age. Colostral immunity of calves from cows vaccinated against hemorrhagic septicemia peaks at 8 to 16 weeks of age and then declines. There is no difference in susceptibility between breeds.

The immune status and health of the individual animal and the herd are considered important factors in the epidemiology of HS. Stress resulting from inadequate feed supply, disease, or exhaustion is considered an important predisposing factor for clinical disease.<sup>2</sup>

### Pathogen Risk Factors

*P. multocida* possesses a number of virulence factors, which include the capsule, fimbriae, and adhesins; outer membrane proteins (OMPs); endotoxin (lipopolysaccharide [LPS]); siderophores; and a number of extracellular enzymes.<sup>1</sup> Endotoxin appears to be the most important virulence factor responsible for clinical disease. LPS of serogroups B and E were found to be identical, and intravenous inoculation with LPS from these strains allowed for reproduction of clinical disease and death within hours, consistent with severe endotoxemia in water buffaloes.<sup>1</sup> Synthesis of the extracellular enzyme hyaluronidase appears to be a specific feature of serotype B:2, but the significance of the enzyme for the virulence of the pathogen is not known.<sup>1</sup>

### Environmental Risk Factors

Although clinical disease can occur at any time of the year, close herding and wet conditions clearly contribute to the spread of the disease. Outbreaks of the disease are often associated with wet, humid weather during the rainy season.

Stressors such as inadequate feed supply or exhaustion are considered important predisposing factors that not only increase the susceptibility to clinical disease, but also stimulate shedding of the bacterium from subclinically infected animals.

During intervening periods the causative organism persists on the tonsillar and nasopharyngeal mucosae of carrier animals.

### Transmission

Transmission of *P. multocida* occurs either through oral ingestion or inhalation, either during direct contact between infected and susceptible individuals or via fomites such as contaminated feed or water. The saliva of affected animals contains large numbers of *Pasteurella* during the early stages of the disease. Although infection occurs by ingestion, the organism does not

survive on pasture for more than 24 hours. Biting insects do not seem to be significant vectors.<sup>2</sup>

### **PATHOGENESIS**

The portal of entry of infection is thought to be the tonsils. A fulminating septicemia occurs, which is associated with the capsular material of the organism and its endotoxin. In acute and peracute cases death ensues within 8 to 24 hours of appearance of the first clinical signs. The effects of the septicemia are most severe in the respiratory tract, heart, and gastrointestinal tract. In cattle and buffalo there is rapid translocation of bacteria from the respiratory tract to the blood, liver, and spleen, suggesting that the bacteria are able to invade via the mucosal epithelial layers.

### **CLINICAL FINDINGS**

The disease is an acute septicemia and is clinically characterized by a sudden onset of fever (41 to 42°C [106–107°F]), followed by profuse salivation, submucosal petechiation, severe depression, and death in about 24 hours. On range lands, animals may be found dead without any clinical signs having been observed. Localization may occur in subcutaneous tissue, resulting in the development of warm, painful swellings about the throat, dewlap, brisket, or perineum, and severe dyspnea may occur if the respiration is obstructed. In the later stages of an outbreak, some affected animals develop signs of pulmonary or alimentary involvement. *P. multocida* may be isolated from the saliva and the bloodstream. The disease in pigs is identical to that in cattle.

### **CLINICAL PATHOLOGY**

#### **Culture and Detection of Bacteria**

Laboratory diagnosis is by isolation and identification of the causative agent. The organism can be cultured from blood or a nasal swab from an animal within a few hours of death. Blood or a nasal swab during the clinical phase of the disease is not reliable because the septicemia is a terminal event.<sup>2</sup> From older carcasses, a long bone is used for culture from the bone marrow. Biochemical and serologic tests are used for identification and serotyping of *P. multocida*. Serotyping can be done by rapid slide agglutination, indirect hemagglutination, agar gel immunodiffusion, and counterimmunoelectrophoresis.<sup>4</sup> DNA fingerprinting and other molecular techniques are suitable for epidemiologic studies to trace an outbreak back to its origin.

#### **Serology**

Serology is not normally used for diagnosis because of the peracute and highly fatal course of disease; however, high titers (1:160 or higher) by indirect hemagglutination (IHA) in surviving in-contact animals are suggestive of disease.<sup>2</sup>

### **NECROPSY FINDINGS**

At necropsy, the gross findings are usually limited to generalized petechial hemorrhages, particularly under the serosae, and edema of the lungs and lymph nodes. Subcutaneous infiltrations of gelatinous fluid may be present, and in a few animals there are lesions of early pneumonia and a hemorrhagic gastroenteritis. Varying degrees of lung involvement range from generalized congestion to patchy or extensive consolidation. Thickening of the interlobular septa may be prominent. Lymph nodes in the thoracic region are enlarged and hemorrhagic. Isolation of the causative bacteria is best attempted from heart, blood, and spleen samples.

### **DIFFERENTIAL DIAGNOSIS**

The differential diagnoses for hemorrhagic septicemia include many other conditions causing peracute death, sometimes without specific clinical signs:

- Blackleg
- Anthrax
- Rinderpest
- Lightning strike
- Acute salmonellosis

More protracted cases with signs of respiratory distress:

- Pneumonic pasteurellosis (shipping fever, enzootic calf pneumonia)
- Atypical interstitial pneumonia
- Mycoplasmosis

### **TREATMENT**

Treatment is of little use once clinical signs have become apparent because of the acute/peracute course of disease.<sup>2</sup> Various antimicrobials have been used to treat HS in cattle and other species, including tetracyclines, penicillin, and sulfonamides, but monitoring of antimicrobial susceptibility of *P. multocida* strains associated with HS revealed a gradual development of in vitro resistance, particularly against sulfonamides.<sup>1</sup> Treatments described in the section on pneumonic pasteurellosis of cattle should also be effective in this disease. Whatever antimicrobial is chosen, an initial intravenous loading dose is required to reach bactericidal concentrations in blood as fast as possible.

### **TREATMENT AND CONTROL**

#### **Antimicrobial therapy**

Penicillin G sodium/potassium (22,000 IU/kg initial IV then IM every 12h) (R-2)

Procaine penicillin (22,000 IU/kg IM every 12h or 44,000 IU/kg IM every 24h after initial IV loading dose of penicillin G sodium/potassium) (R-2)

Oxytetracycline (10 mg/kg initial IV then IM every 24 for 4 days) (R-2)

Trimethoprim ([2.66 mg/kg] + sulfadoxine [13.33 mg/kg] initial IV then IM every 12h) (R-2)

Enrofloxacin\* (2.5–5 mg/kg SC q24h)

Ceftiofur sodium\* (1.2–2.2 mg/kg IV every 24h)

Ceftiofur hydrochloride\* (2.2 mg/kg SC every 24 after initial IV loading dose of ceftiofur sodium)

#### **Metaphylaxis**

Tulathromycin (2.5 mg/kg SC as single dose)

Florfenicol (40 mg/kg SC as single dose)

Tilmicosin (10 mg/kg SC as single dose)

Gamithromycin (6 mg/kg SC/IM as single dose)

Oxytetracycline long-acting formulation (20 mg/kg IM as a single dose)

Enrofloxacin\* (7.5–12.5 mg/kg SC/IM as single dose) (R-3)

Danofloxacin\* (8 mg/kg SC as single dose) (R-3)

Ceftiofur\* crystalline acid free (6.6 mg/kg SC posterior pinna as single treatment) (R-3)

#### **Vaccination**

Vaccination with inactivated HS vaccine (R-1)\*\*

Vaccination with modified live vaccine (intranasal) (R-1)\*\*

\*Classified as critically important antimicrobials in human and veterinary medicine. Use as first-line treatment is discouraged.<sup>5</sup>

\*\*Colostrum antibody interferes with vaccine efficacy in calves.

### **CONTROL**

Hemorrhagic septicemia can be eradicated from nonendemic areas by animal movement control, quarantines, tracing of contacts, culling of infected and exposed animals, and disinfection of the premise. Although treatment may be successful when initiated early in the course of the disease, up to 20% of surviving animals are estimated to become clinically unapparent shedders, thereby creating a host reservoir.<sup>2</sup>

In endemic areas the condition is mainly controlled by vaccination. Removing identified carrier animals, avoiding stress by providing adequate feed supply, and avoiding overcrowding, particularly during the rainy season, can further reduce the risk of clinical disease and transmission of the infection.

Treatment of animals that were in contact with clinical herd mates may be suitable to limit morbidity and mortality rates during an outbreak.<sup>2</sup>

#### **Antimicrobial Metaphylaxis**

Although the metaphylactic use of antimicrobials as disease control is debatable from the point of view of prudent antimicrobial use, the treatment of clinically still healthy in-contact animals during an outbreak may

be indicated and justified by the high case-fatality rate that is largely attributable to the peracute course of disease.<sup>2</sup>

### Vaccines

Vaccines against HS are widely used in endemic areas and are the only practical approach to prevent HS.<sup>1</sup> Initially, inactivated vaccines based on plain bacterins of *P. multocida* were used, to which various adjuvants were added later to enhance immune response. The commonly used vaccines are alum precipitated vaccines, aluminium hydroxide gel vaccines, oil-adjuvant vaccines (OAVs), and multiemulsion vaccines (MEVs), which vary considerably in the duration of immunity induced and in side effects. Alum-precipitated vaccines are widely used. Plain broth bacterins, or alum-precipitated and aluminum hydroxide gel vaccines, are administered twice a year because these vaccines offer immunity of 4 to 6 months. OAVs give both a higher degree and a longer duration of immunity, up to 1 year, but have not been popular because they are difficult to inject and because of local tissue reactions and abscess formation at the site of injection. To overcome this issue, an (MEV of a thinner viscosity has been developed that provide immunity parallel to the OAV.

Generally, inactivated vaccines are widely used in endemic areas and are effective in reducing the disease incidence. Disadvantages of these vaccines are the short duration of immunity they provide and the high costs of production.<sup>2</sup>

A fallow deer strain aerosol vaccine (strain B:3,4) developed in Myanmar is currently the only available modified live (MLV) HS vaccine. The safety, efficacy, and cross-protectivity of this vaccine has been tested in young cattle and buffaloes in Myanmar, where more than 1.5 million animals were inoculated with the vaccine between 1989 and 1999. A recommended dose of  $2 \times 10^7$  viable organisms was used for the efficacy test. The administration of 100 times the recommended dose to 50 cattle and 39 buffalo calves was innocuous. Three out of three buffaloes were protected 7 months after they were vaccinated, and 12 months after they were vaccinated, 3 out of 4 buffaloes were protected against a subcutaneous challenge with serotype B:2, which killed 3 of 3 unvaccinated buffaloes; 12 months after they were vaccinated, 8 out of 8 cattle survived a serotype B:2 challenge that killed 4 out of 4 unvaccinated controls. The vaccinated cattle had developed serum antibodies detectable by the passive mouse protection test. Indirect hemagglutination tests on sera taken from cattle 10 days and 5 weeks after they were vaccinated showed high titers on antibodies. The serum of vaccinated cattle cross-protected passively immunized mice against infection with *P. multocida* serotypes E:2, F:3,4, and A:3,4. The intranasal aerosol

vaccination is safe, even at very high dose levels, and does not induce anaphylactic shock even after repeated vaccinations. The freeze-dried live vaccine is stable for at least 3 years at room temperatures of 30 to 36°C (86 to 97°F), and thus a “cold chain,” which is impracticable for many hemorrhagic-septicemia-endemic areas, is not necessary for the storage and transport of the vaccine.

The Food and Agriculture Organization (FAO) of the United Nations has reviewed development and use of this MLV vaccine in Myanmar and has commended the intranasal use of live B:3,4 vaccine as safe and potent and has suggested that the technology be transferred to other countries. Nevertheless, no other country is currently using the MLV vaccine.<sup>2</sup>

## PASTEURELLOSIS OF SHEEP AND GOATS

*Mannheimia* (*Pasteurella*) *haemolytica* and *Bibersteinia trehalosi* are the main causes of pasteurellosis in sheep and goats. Under the old classification system, *M. haemolytica* was classified into two biotypes, A and T, which were then subdivided into serotypes based on antigenic differences in capsular polysaccharide.

- The serotypes within biotype A are now classified as *Mannheimia haemolytica* with the exception of serotype A11, which is a separate species, *Mannheimia glucosida*.
- The most common manifestation of *M. haemolytica* in sheep is pneumonic pasteurellosis, which occurs in all ages.
- M. haemolytica* is a secondary invader, and a cause of death, in chronic enzootic pneumonia in sheep and goats that is initiated by *Mycoplasma ovipneumoniae*.

- M. haemolytica* infections in sheep also cause septicemic pasteurellosis in young suckling lambs, which often occurs in association with pneumonic pasteurellosis in the same flocks, and mastitis in ewes.<sup>1,2</sup>
- Palpable lesions in the testicles of rams have also been associated with heavy pure growth of organisms from the *Pasteurella* cluster.<sup>3</sup> Lesions include epididymitis, spermatic granulomas, testicular atrophy, and adhesions between the vaginal tunic and scrotum.
- M. glucosida* comprises a heterogeneous group of organisms that cause opportunistic infections of sheep, especially mastitis.<sup>1,2</sup>
- Biotype T of *M. haemolytica* contains four serotypes and is now classified as *Bibersteinia trehalosi*. Isolates of *B. trehalosi* that are leukotoxin A (LkTA) positive are associated with septicemic disease in weaned sheep.
- Genetic analyses show that bovine and ovine strains of *M. haemolytica* represent genetically distinct subpopulations that are specifically adapted to, and elicit disease in, either cattle or sheep.
- These analyses also demonstrate that traditional classification based upon metabolic characteristics lack the resolution and accuracy to reliably classify isolates. Consequently, for reliable epidemiologic investigations they should be augmented by molecular techniques such as 16s rRNA and LkTA screening using PCR assays.<sup>4</sup>
- P. multocida* is an uncommon respiratory pathogen in sheep in temperate areas but may be of greater importance in tropical areas.

## SEPTICEMIC PASTEURELLOSIS OF SUCKLING LAMBS

Septicemic pasteurellosis is a disease of young lambs typically associated with *M. haemolytica* biotype A. It occurs in lambs from 2 days to 2 months of age but presents most commonly at 2 to 3 weeks of age. The young lamb is highly susceptible to biotype A infections, which progress rapidly from the tonsils and lungs to a fatal septicemia. The organism is also a primary pathogen in goat kids. Septicemic pasteurellosis in suckling lambs may occur as an isolated disease but more commonly occurs in conjunction with pneumonic pasteurellosis, with younger lambs succumbing to the former and ewes and older lambs to the latter. This disease probably does not warrant a separate classification but is kept separate because some outbreaks are manifest only by septicemia in lambs.

There is a significant difference in the incidence of death from septicemic pasteurellosis in lambs between flocks that are

infested with *Ixodes ricinus* and flocks that are *Ixodes* free. It is thought that immune suppression from tick-borne fever caused by *A. phagocytophilum* can predispose to septicemic pasteurellosis. Lambs that die are usually 4 to 8 weeks of age. *B. trehalosi* can also cause of this condition.<sup>5</sup>

A single subcutaneous injection of 10 mg/kg tilmicosin or intramuscular injection of 20 mg/kg oxytetracycline is effective in preventing disease. Tulathromycin (2.5 mg/kg, SC), a semisynthetic macrolide, may also be an effective treatment.<sup>6</sup>

*P. multocida* is a rare cause of septicemic disease in neonatal lambs but can occur with a high morbidity and high case-fatality rate. Clinically, it presents with a syndrome resembling watery mouth with marked salivation, abdominal distension, and a short clinical course. On postmortem examination, there is excess peritoneal and pleural pericardial fluid. Prophylactic long-acting tetracycline at a dose of 100 mg per lamb has prevented further cases.

### MANNHEIMIA MASTITIS IN SHEEP

*M. haemolytica*, *M. glucosida*, and *M. ruminantis* have been isolated from cases of peracute, gangrenous acute mastitis in sheep.<sup>1</sup> *M. haemolytica* is the most common cause of mastitis in meat-producing flocks. It occurs in the Canada, United States, Australia, New Zealand, and Europe in ewes kept under systems of husbandry that vary from open pasture to enclosed barns, and is a major cause of mastitis in ewes in Britain. A variety of typed and untyped strains within biotype A are isolated, with serotype A2 most common from cases of acute mastitis. Mastitis is most common in ewes suckling large lambs up to 3 months old. There is a high diversity among *Mannheimia* isolates. Horizontal transmission by lamb suckling probably occurs, supported by the observation that the prevalence of mastitis associated with this organism is less in dairy sheep than in meat flocks.<sup>7</sup>

### PNEUMONIC PASTEURELLOSIS AFFECTING WILDLIFE

*Pasteurella* and *Mannheimia* spp. have been isolated from a number of different species of wildlife, but there has been particular concern with outbreaks of acute fatal pneumonic pasteurellosis that have occurred in Rocky Mountain and desert bighorn sheep (*Ovis canadensis*) following commingling with domestic sheep or feral goats. This appears to be a complex polymicrobial disease, with *M. ovipneumoniae*, *M. haemolytica*, LktA-positive *B. trehalosi*, *P. multocida*, respiratory syncytial virus, and parainfluenza-3 virus isolated from natural cases, and some argument over which agent is the primary cause.<sup>8</sup> Experimental challenge with *M. haemolytica* will induce disease, and bighorn sheep are particularly

susceptible to pathogenic (LktA positive) biotype A strains acquired from commingling with domestic sheep. This, coupled with the stress of high densities and food shortage, was thought to be important in the epidemiology of this disease. However, bighorn sheep are not naturally infected with *M. ovipneumoniae*, and spread of this agent from domestic sheep to susceptible populations of bighorn sheep, which then increases their susceptibility to *M. haemolytica*, has been proposed as an alternative explanation.<sup>8</sup> If this is the case, vaccinating domestic sheep against *M. ovipneumoniae* may be an effective way to reduce exposure and disease in bighorn sheep.

Nevertheless, whereas previous vaccines were not effective, repeated doses of an experimental multivalent vaccine containing *M. haemolytica* serotypes A1 and A2 and *B. trehalosi* serotype 10 did protect bighorn sheep against experimental challenge with a pathogenic *M. haemolytica*.<sup>9</sup> A commercial multivalent killed vaccine (OviPast Plus™) with five strains of *M. haemolytica* (A1, 2, 6, 7, 9) and four strains of *B. trehalosi* (T3, 4, 10, 15) is available in the United Kingdom for the reduction of mortalities as a result of pneumonic pasteurellosis in sheep. However, this vaccine did not increase weight gain or reduce lung scores in a study in seven flocks in New Zealand.<sup>10</sup> A primary virulence factor of *Mannheimia* spp. isolates is leukotoxin A (LktA), which are toxic to ruminant leukocytes and probably have an important role in immunity to disease caused by *Mannheimia* spp. A comparison of the similarity of the LktA of *Mannheimia* spp. isolated from clinical cases of mastitis found that the LktA from *M. glucosida* may be a more suitable candidate for a monovalent vaccine than the LktA from *M. haemolytica*.<sup>11</sup>

### PASTEURELLOSIS OF SWINE

*Pasteurella multocida* (PM) is an important pathogen of pigs. Toxigenic strains, in conjunction with *Bordetella bronchiseptica*, are recognized as the etiologic agents of atrophic rhinitis described under that heading. Pneumonic pasteurellosis and septicemic pasteurellosis are also manifestations of infection with *P. multocida* in pigs. *P. multocida* capsular type A can cause pneumonia in growing

pigs but also septicemia and arthritis. It has been consistently isolated from skin lesions in sporadic cases of porcine dermatitis and nephropathy syndrome. Strains from pigs may be found in nasal passages of pig workers, and pig strains have been found in bronchopneumonia in humans. There is therefore the possibility of occupational exposure. Some forms are very similar to pleuropneumonia, with dyspnea, cyanosis, and sudden death.

### PNEUMONIC PASTEURELLOSIS

#### Etiology

*P. multocida* is commonly isolated from the lungs of pigs with chronic pneumonia, purulent bronchopneumonia, and pleurisy. Isolates are predominantly capsular serotype A strains with some serotype D strains. It is possible to serotype *P. multocida* and of the 16 serotypes, serotypes 3 and 5 are the predominant isolates.<sup>1</sup> In most herds, there is a single isolate, and this is usually A3. In one study, 88% of the lung strains were type A (OMP strains 1:1, 2:1, 3:1, 5:1, and type 6:1). It may be a primary pathogen with a relatively high degree of virulence and a considerable transfer of capsular biosynthesis and *tox*A genes between strains of both type A and type D. Virulence genotypes have also been studied.<sup>2</sup> It may be that most *P. multocida* strains have the *tox*A gene, which suggests widespread genetic diversity in the capsular type A strains<sup>3</sup> and that a single clone might be more predominant in a particular pig population. For many years it was thought that toxigenic strains were not found in the lung, but in three surveys, 25% to 90% of the pneumonic strains were toxigenic. A study looked at 230 isolates from 250 pigs and found that 200 (88%) were A, 4% were D, and 9% were untypeable. The *tox*A gene was found in 13%, of which 11% belonged to A, 1% to D, and 1% could not be typed. Serotype D strains were specifically associated with abscesses in the lung. A wide diversity is found in the lung.

*P. multocida* is a common secondary infection in the lungs of pigs with enzootic pneumonia associated with *M. hyopneumoniae*. The pneumonic lesions from dual infections are more severe than those from *M. hyopneumoniae* alone. The organism is also commonly associated with *A. pleuropneumoniae*.

#### Epidemiology

In the microbiome of the soft palate of swine it was found that members of the Pasteurellaceae predominate.

Although found in other species, it is generally assumed that there is little interspecies transfer. The tonsils of the pig are an important site of colonization of many pathogenic and commensal organisms. In a study of the microbiome of the tonsils in 12 healthy pigs from two herds, it was found that Pasteurellaceae dominated the tonsillar

biome of all the pigs, comprising 60% of the total.

It is generally considered that *P. multocida* is not a primary pathogen of the lower respiratory tract and that its involvement in pneumonia is secondary to infection with other respiratory pathogens. A large-scale survey in Germany of 6560 postmortem examinations found that pneumonia was present in 24.4% of cases. In 49.3% of these *P. multocida* was found, and with increasing age there was an increasing rate of recovery of *P. multocida*. Most of the lung cultures (54.2%) showed multiple infections. Pneumonic pasteurellosis cannot be reproduced by the intranasal or intratracheal challenge of healthy pigs with *P. multocida* but can be reproduced by challenge to pigs whose pulmonary clearance mechanisms have been compromised by infections with *M. hyopneumoniae*, pseudorabies virus, or by anesthesia and other stresses, and also lungworms. Although atmospheric ammonia may predispose to nasal attachment of *P. multocida* type D, it seems unlikely that this applies to pulmonary infection. The organism is carried in the nasal cavity and tonsils of pigs, and carriage rates are higher in herds with a history of chronic respiratory disease.

Transmission is by aerosol and more probably by direct nose-to-nose contact and thence by inhalation or ingestion. The bacterium has a short-term survival in aerosols, particularly of low humidity (less than 1 hour), but it survives for longer at high humidity and lower temperature. Heating to 60°C (140°F) will kill it, but it can survive for up to 14 days in water, 6 days in slurry, and up to 7 weeks in nasal washings at room temperature. There is always the feeling that the condition is most common under conditions where mycoplasmosis is common and where there is poor husbandry, notable overcrowding, and poor hygiene and where environmental stress is high. As a result, it is often seen after transport, mixing, or moving groups of pigs.

### Pathogenesis

Pneumonic pasteurellosis results from the colonization of existing lung lesions by inhaled organisms, often from reservoirs in the nasopharynx and tonsil, and the major virulence mechanisms are unknown. It is suspected that they may attach particularly to the alveoli by means of fimbriae or pili. Serotype A strains are resistant to phagocytosis, which has been attributed to the presence of capsular hyaluronic acid and might allow their colonization of lung lesions. Isolates from lung lesions are not invariably toxigenic. A recent study has shown that there is a change in the functional capabilities of the blood cells, with oxygen radical formation and phagocytosing neutrophils elevated after infection. The disease is difficult to produce experimentally, and large

volumes of inoculum must be used in the trachea together with other infectious agents or their toxins to produce pathology. It has been reproduced when nontoxigenic strains are given repeatedly by intrabronchial injection following *A. pleuropneumoniae* or *M. hyopneumoniae* infections. Strains vary in their ability to produce secondary pneumonia and pleuritis in these experimental models, suggesting the existence of specific pneumotropic and pleurotropic strains, which is supported by epidemiologic studies that have found that a single strain predominates in problem herds.

### Clinical Findings

There is a possibility of a hyperacute condition in which the only sign is sudden death.

Pneumonic pasteurellosis is a common cause of sporadic cases of acute bronchopneumonia in grower-finisher pigs. Affected pigs have fever of up to 41°C (106°F), are anorectic and disinclined to move (lethargic), and show significant respiratory distress with labored respiration and increased lung sounds, often breathing through the mouth. Cyanosis may occur. Without treatment, death is common after a clinical course of 4 to 7 days. There is a marked tendency for the disease to become chronic, resulting in reduced weight gain and frequent relapses, and real recovery seldom occurs. It can occur as an outbreak, spreading to affect several pigs within a group. The first indication of disease within a group and of an impending outbreak may be the finding of a pig dead with a peracute infection. In an intermediate stage there may be fever, coughing, and poor growth rate for about 3 to 5 weeks before recovery. The disease may also exist in a chronic form as part of the porcine respiratory disease complex, with little evidence of overt clinical disease but with an adverse effect on growth rate and food-conversion efficiency.

### Necropsy Findings

At necropsy the lesions are considered to be typical of what is normally called enzootic pneumonia—a chronic bronchopneumonia with abscessation. Pleuritis is common, and there may also be pericarditis. In some instances, there may be carcass congestion, and the trachea may be full of frothy fluid. Experimental infections have caused between 15.5% and 39.4% of lung tissue to be affected with pneumonia. Histologically, the airways are filled with degenerate leukocytes, but the overall lung pathology is often complicated by other pathogens. Peracute fatalities show an acute necrotizing and fibrinous bronchopneumonia reminiscent of bovine pneumonic pasteurellosis. There is edema, congestion, and hemorrhage with bronchiolar exudation containing bacteria, neutrophils, and macrophages, which are also

present in the alveoli. Small bronchi and bronchioles may be completely occluded by the exudates.

### Diagnosis

Diagnosis is through the clinical signs (fever, dyspnea, cyanosis, sudden death), lesions at gross postmortem, histopathology, and isolation of *P. multocida*. Aerobic culture from these cases usually produces a pure culture of the organism.

### DIFFERENTIAL DIAGNOSIS

The disease must be differentiated from other causes of respiratory disease in pigs.

**Enzootic pneumonia** of pigs, unless accompanied by pasteurellosis, is not manifested by a marked systemic or pulmonary involvement.

Dyspnea is a prominent sign in **Glässer's disease**, but there is obvious arthritis; at necropsy the disease is characterized by arthritis, a general Serositis, and meningitis.

**Pleuropneumonia associated with *A. pleuropneumoniae*** causes a severe pneumonia with rapid death, and differentiation from pasteurellosis is necessary at necropsy.

The septicemic and acute enteric forms of salmonellosis in pigs are often accompanied by pulmonary involvement, but these are usually overshadowed by signs of septicemia or enteritis. Chronic pasteurellosis has to be differentiated from lungworm infestations and ascariasis.

### Treatment

The animals are usually severely ill, and therefore treatment is first by parenteral injection and then by water medication; once they start to eat, medication should continue with in-feed antibiotics.

Treatment is with antibiotics, commonly with tetracyclines. There is also a case for using ceftiofur, penicillin, streptomycin, trimethoprim/sulfonamides, ampicillin, spiramycin, and spectinomycin for 3 to 5 days. Tilmicosin and telithromycin would also be suitable antibiotics. There is significant variation in the antibiotic sensitivity of isolates, and the choice of antibiotic should be based on a sensitivity established for the organism for that farm. In a recent survey in the United Kingdom, 15% of *P. multocida* isolates were resistant to tetracyclines, and it was also reported that resistance to trimethoprim/sulfonamides, Apramycin, and neomycin was found in some isolates. A German survey showed that 55% were resistant to sulfonamides.

### Control

Vaccination is ineffective, although autogenous vaccines have been produced that are effective (need to be certain that you have the

strain causing the problem). Control depends on management of the risk factors, which are described under enzootic pneumonia of swine because pasteurellosis is often secondary to that condition. In particular, all-in, all-out management with vaccination for enzootic pneumonia is essential. Tiamulin at 40 ppm in the feed has also been used strategically at the time of stress, for example, over mixing and moving.

### SEPTICEMIC PASTEURELLOSIS

Septicemic disease with death occurring within 12 hours and without signs of pneumonia is occasionally observed in neonatal pigs. They are associated with *M. haemolytica* infection (occasionally *P. trehalosi* that is untypeable), and in many cases there is an association with sheep. Septicemic disease is also recorded in India in association with infection with capsular serotype B. The disease occurs in all ages of pigs, including adults, and is manifest with fever, dyspnea, and edema of the throat and lower jaw. A population mortality of 40% in a group of pigs is recorded. Clinical signs are rarely seen. Acute septicemic disease in grower pigs aged 14 to 22 weeks and associated with serotype D has been recorded in Australia. Cases can be confused with those caused by taxon 15 of APP.

An outbreak of hemorrhagic septicemia was reported from Australia associated with *P. multocida* subsp. *gallicida* in a large pig herd. Affected pigs were found dead, with swelling of the pharyngeal region and blue discoloration of the ventral abdomen and ears. On gross postmortem there was hemorrhage and congestion on serosal surfaces. The postmortem picture is reported to resemble that seen in *A. suis* infection with a superimposed pneumonic pasteurellosis. Histologic examination of the viscera showed widespread vascular damage with thrombus formation and intravascular colonies of bacteria.

### Samples for Confirmation of Diagnosis

- Bacteriology—lung, bronchial node (plus liver, spleen, kidney for septicemic form). Culture produces large mucoid colonies 3 mm to 5 mm in diameter on blood agar. In the past the recovered organisms were rarely toxigenic. Some isolates did have fimbriae. On a smear gram-negative coccobacilli may be seen. In early cases aerobic cultures of heart blood and lung lesions will give a pure culture. Anaerobic cultures often yield *Bacteroides* spp. as well, and if *Haemophilus* cultures will also often prove positive. Further identification using electrophoretic typing may be necessary, as in the case of secondary infection in sporadic cases of porcine dermatitis and nephropathy syndrome.

Here a high proportion had a single electrophoretic type (01) isolated from a range of tissues. In the septicemic form the organism was readily cultured from the liver, spleen, and lymph nodes.

- Histology—formalin-fixed lung (variety of organs for septicemic form) (light microscopy)

## STREPTOCOCCUS SUI S INFECTION OF YOUNG PIGS

There are three organisms that infect the neonatal pig quite commonly—*Haemophilus parasuis*, *S. suis*, and *Actinobacillus suis*, which have been dubbed the “suis-cides.” *S. suis* (SS) is therefore one of the early colonizers of the pig; by the end of the nursery period, most pigs are infected. Virulence may be an attribute of strains that colonize the young pig poorly but infect older animals more easily, in the absence of maternal antibody. They also have public health importance.

### SYNOPSIS

**Etiology** *Streptococcus suis*; 35 capsular serotypes exist if you include 1/2. Worldwide, type 2 is probably the most common, and types 1 through 9 are more frequent than types 10 to 34.

**Epidemiology** - Occurs principally in piglets under 12 weeks of age

**Signs** Septicemia, arthritis, meningitis, pericarditis, endocarditis, polyserositis, and pneumonia.

**Clinical pathology** Culture organism.

**Lesions** Fibrinous polyserositis, purulent meningitis, myocarditis, vegetative endocarditis, fibrinous arthritis, or fibrinous or hemorrhagic pneumonia may be a secondary problem.

**Diagnostic confirmation** Culture organism from body tissues and blood.

**Differential diagnosis** Arthritis as a result of the following:

*Mycoplasma hyorhinis*

Erysipelas

Glässer's disease

Meningitis as a result of the following:

*Escherichia coli*

*Trueperella pyogenes*

*Pasteurella multocida*

**Treatment** Antimicrobials based on culture and sensitivity.

**Control** Provision of optimum environment (temperature and relative humidity). Avoid overcrowding in nursery pens. Age spread of pigs in pens should not exceed 2 weeks. Use all-in, all-out pig flow. Control of other common infectious diseases. Avoid nutritional deficiencies. Consider mass medication of feed with antimicrobials. Possible use of autogenous vaccines.

### ETIOLOGY

The streptococci are gram-positive, encapsulated, facultative anaerobes; are coccoid or ovoid; and occur singly or in pairs or in chains. *S. suis* (SS) type 1 (SS1) and *S. suis* type 2 (SS2) were the original capsular types of the organism, which appeared to account for most epidemics of the disease. SS types are related to Lancefield's group D. The Lancefield's groups R, S, RS, and T are no longer used.<sup>1</sup> There are now 35 known SS capsular types. Even now, new species of *Streptococcus*, such as *S. ferus*, are being isolated from pigs. The important species of *Streptococcus* that have been isolated in the pig are shown in Table 21-2.<sup>2,3</sup>

At least 40% of the genome of SS is distinct from the other species of *Streptococcus*.<sup>4,5</sup> The strains within each capsular serotype are also very diverse genetically.<sup>6-8</sup>

### EPIDEMIOLOGY

The epidemiology of SS is very complex. The isolation of different strains within the same herd and the predominance of particular strains within some herds are evidence that infection by SS is a dynamic process and reinforce the idea that the epidemiology is complex.

The distribution of the serotypes varies widely across the world. In general, SS1-9 is the most commonly found type and likely to cause disease.<sup>9,10</sup> SS9-34 will colonize, but this type is less likely to cause disease. There may be one, two, or even more serotypes in a single pig. In some countries one serotype is more important (e.g., SS14 in Scotland or SS7 in Scandinavia).<sup>11</sup> The position is complicated because a certain serotype in one

**Table 21-2** Species of streptococci isolated from the pig with principal locations

Intestine	Tonsils	Oral cavity	Vagina
<i>hyointestinalis</i>	<i>suis</i>	<i>orisuis</i>	<i>hyovaginalis</i>
<i>suis</i>	<i>porcinus</i>	<i>mutans</i> -like	<i>thoraltensis</i>
<i>alactolyticus</i>	<i>dysgalactiae</i> ssp. <i>equisimilis</i>		
<i>bovis</i>			

country is not necessarily of the same virulence and importance in another because the genetic makeup of the strains varies geographically. It is further complicated in that, following culture, the strains may lose their capsules and become untypeable.<sup>9,10</sup> Again, in general, in Eurasia, SS2 is the most common,<sup>12</sup> and in North America it is SS2 and SS3, but SS2 is not necessarily the most prevalent.<sup>9,10</sup> There are considerable differences between the SS2 in Europe and the SS2 in North America.

### Occurrence

Diseases associated with SS occur worldwide, generally affecting pigs 2 weeks to 22 weeks of age but capable of causing disease in any age of susceptible pig. Most cases occur just after weaning and are associated with weaning stressors such as moving, mixing, overcrowding, and inadequate ventilation. SS2 causes outbreaks of meningitis in young pigs 10 to 14 days after weaning. The disease occurs most commonly in intensive systems of high population density, such as flat-deck rooms and early (grower) finishing pens. Sporadic cases occur in older pigs, including adults, depending on immunity.

The organism has also been isolated from cattle, sheep, goats, a horse with meningitis, fallow deer, and cats and increasingly from other species. It has also been isolated from wild boar.<sup>13</sup>

### Prevalence of Infection

SS2 is the most prevalent serotype. Types 3, 4, 7, 8, and 14 have been isolated from affected pigs in the United Kingdom. In Australia, SS2 was detected in 58% of the palatine tonsils, in 66% of the pneumonic lungs, and in 28% of the healthy lungs. Overall, the carrier rate in piggeries was 60%. The organism was also present in the blood of 3% of apparently normal pigs at slaughter. It could also be cultured from many other tissues, including the vagina of sows, and it is possible that piglets are infected during birth. Specific pathogen-free herds are free of the organism, and hysterectomy-derived piglets are born SS free.

The rate of infection of the environment of the pigs can also be very high. In Canada, all 35 serotypes have been isolated, with SS2 being the most prevalent of all isolates. The other capsular types in decreasing order were 3, 7, 1/2, 8, 23, and 4. Over a period of several years, more than 60% of isolates belong to capsular types 2, 1/2, 3, 4, 7, and 8. In a survey of clinically healthy piglets 4 to 8 weeks of age in Quebec, the organism could be isolated from 94% of piglets and 98% of farms. The typeable isolates of the organism are more frequently recovered from pigs between 5 and 10 weeks of age, whereas untypeable isolates are most frequently found in animals more than 24 weeks old. In the United States, serotype 3 was most prevalent (26.1%), followed by serotypes 8 (17.4%),

2, 4, and 7 (15.2%). There were no significant differences in the epidemiologic features, clinical signs, or lesions in pigs infected with multiple serotypes compared with a single serotype of SS.

Only some Scandinavian countries reported a higher incidence of type 7 over type 2. In Denmark, SS2 accounted for 29% of the isolates; SS7 for 17%; and 3, 4, and 8 for a further 9% to 10%. SS7 was isolated more frequently than reported in other countries, causing septicemia, arthritis, and meningitis. In Finland, the most common types isolated from dead pigs were 7, 3, and 2, respectively, and they were most frequently isolated from cases of pneumonia. In the Netherlands, SS2 was most frequently isolated from pigs with meningitis. SS9 and SS2 have been isolated as the cause of septicemia and meningitis in weaned pigs in Australia.

### Morbidity and Case Fatality

The incidence of clinical disease ranges from 0% to 15%. In a 3-year survey of a breeding herd, the combined morbidity and mortality rates attributable to meningitis from SS2 were 3%, 8%, and 9.1%, respectively.

### Methods of Transmission

The organism is usually transmitted by healthy carriers. The organism is carried in the tonsils and occasionally in the nose of healthy pigs<sup>14,15</sup> of all ages, and transmission to uninfected pigs can occur within 5 days of mixing. In a herd where there are no clinical signs there is usually a low carriage of SS. There is a higher carriage in herds where there is clinical disease.<sup>16</sup> The introduction of breeding gilts from infected herds results in disease appearing subsequently in weanlings and growing pigs in the recipient herds. The detectable carrier rates in different groups of pigs can vary from 0% to 80% and are highest in weaned pigs aged 4 to 10 weeks. Over 80% of the sows in an individual herd may be subclinical carriers. They do not normally carry the organism in the nasal cavity but in the vagina. Based on the results of sampling of sows and piglets at parturition, and being able to culture multiple serotypes of the organism from the sow's vaginal secretions and oropharyngeal samples of piglets, it is highly probable that the newborn piglet is infected during birth by the organism, which is transferred from the sow's vagina to the dorsal surface and oral cavity of the piglet. However, even though most pigs are colonized by weaning age, colonization by the virulent strains of SS2 takes longer and usually does not occur before 15 days of age. This could constitute a risk factor for developing disease later when maternal immunity has waned.

Weaned carrier pigs transmit the infection to previously uninfected pigs after mixing following weaning. The organism can persist in the tonsils of carrier pigs for more than 1 year, and in the presence of circulating

opsonic and binding antibodies, and in pigs receiving penicillin-medicated feed. Thus the organism can be endemic in some herds without causing recognizable clinical disease. House flies can carry the organism for at least 5 days and can contaminate feed for at least 4 days.

The carrier rate in some surveys of slaughter pigs ranges from 32% to 50% of pigs 4 to 6 months of age. Sporadic cases of SS2 have also been found in pigs with bronchopneumonia (secondary to enzootic pneumonia), pleuropneumonia, arthritis, vaginitis, and aborted fetuses and in neonatal piglets 1 to 2 days of age affected with fatal septicemia. It appears that the organism is found in the lungs of pigs affected with pneumonia more frequently in North America than in other countries. Although airborne infection of type 2 has been described, it is thought that indirect transmission is a much better way to infect piglets because it is easily transmitted via fomites. It can survive in feces for 104 days at 0°C (32°F) and for 10 days at 9°C (48°F) and in dust for 54 days at 0°C and 25 days at 9°C. Experimentally, pure cultures of the organism placed on rubber and plastic surfaces, especially when protected by swine manure, are viable up to 55°C (131°F) and can survive if kept frozen for up to 10 days. In the summer, at a temperature in the middle range, it may survive for about 8 days. The organism is readily destroyed by disinfectants. It can be spread by contaminated pig nose snares and needles used for blood sampling. SS can also be transmitted by flies.

### Risk Factors

#### Animal Risk Factors

The host factors that render pigs susceptible to clinical disease are uncertain. Over 30 different gram-positive bacterial organisms may occur in the nasal cavities and tonsils of unweaned pigs between 2 weeks and 6 weeks of age. It is suggested that strains of SS2 vary in pathogenicity and that the occurrence of disease is dependent on both exposure to a pathogenic strain and undetermined secondary factors. The peak incidence of SS from 5 to 10 weeks of age suggests that the stressors of weaning may render pigs susceptible to clinical disease and certainly to the horizontal spread of the infection. At this point any infected pig may be shedding large numbers of organisms. Most weaned pigs carry SS, but few appear to carry virulent strains.<sup>16</sup> In an outbreak, one strain of SS usually predominates. The presence of other infectious diseases, such as porcine reproductive and respiratory syndrome (PRRS) and *Actinobacillus pleuropneumoniae*, may be associated with a higher-than-average prevalence of infection with SS. PRRS certainly increases susceptibility to SS infection experimentally. In utero infection with PRRS makes pigs more susceptible to subsequent neonatal SS infections. Infection of specific-pathogen-free pigs with PRRS virus may be

a risk factor for infection and disease associated with SS. Similarly, the pseudorabies virus may enhance clinical disease associated with SS. In addition, faulty teeth clipping may be associated with the condition in young pigs.

### Environmental and Management Factors

The incidence of clinical disease appears to depend on environmental factors (which may be important in the spread of SS), such as inadequate ventilation, high population density, and other stressors. Several environmental and management risk factors have been associated with a high prevalence of pigs harboring SS in swine herds. Excessive environmental temperature fluctuation in the nursery pig facilities was the most common factor. Nursery pig environmental temperatures should not fluctuate more than 1.1° to 1.7°C (34° to 35° F) over a 24-hour period to prevent chilling of pigs. Fluctuations in temperature are caused by drafts, inadequate heaters, or poorly insulated buildings. Excessive relative humidity was also a factor; the recommended range for nursery pigs is 55% to 70%. The third and fourth most common factors were age spread of more than 2 weeks for pigs in the same room and crowding (both increasing SS transmission rates). The fifth most common factor was the use of continuous flow facilities, which allows for build-up of dust and manure (and therefore SS) and increased infection pressure. An unusual case where SS was isolated from the lumen of the small intestine occurred when a feed was formulated with no salt and 58.5 kg instead of 3.5 kg of vitamin premix. Once the ration was corrected, the problem disappeared.

SS2 can survive in feces for 104 days at 0°C (32°F), up to 10 days at 9°C (48°F), and up to 8 days at 22 to 25°C (71 to 77°F). It can survive in dust for up to 25 days at 9°C (48°F) but could not be isolated from dust stored at room temperature for 24 hours. The organism is rapidly inactivated by disinfectants commonly used on farms. Liquid soap inactivates SS2 in less than 1 minute at a dilution in water of 1 in 500. The organism can survive in pig carcasses at 40°C (104°F) for 6 weeks and may therefore be an important source of the organisms for infection in humans.

### Pathogen Risk Factors

Most studies of virulence have been associated with studies on SS2. Some have proved to be virulent, others not so.<sup>11</sup> New factors are being discovered all the time. For example, a new virulence gene *virA* was discovered that only occurs in virulent strains.<sup>17</sup> Many other secreted substances, important as virulence factors, are probably awaiting discovery.

Colonization of piglets occurs very early in life, with most pigs being colonized by

weaning age; virulent strains of SS2 may not colonize until later. Early colonization reduces the subsequent clinical signs. Despite the association of bacteria with disease, they may also be recovered from the nasal cavities and tonsils of healthy pigs. High numbers of organisms were isolated from the cerebrospinal fluid of clinically normal pigs. A study also showed that a persistent epidemic strain of SS was consistently isolated from the brains of pigs over a 2-year period.

There are differences in pathogenicity between serotypes and between strains of the same serotype. In the United Kingdom there are differences in pathogenicity between types 1 and 2; type 1 causes less severe disease in piglets, whereas type 2 causes a more severe and acute disease in older and growing pigs. Highly virulent and completely avirulent type 2 strains exist. Different strains of SS2 vary in their ability to cause meningitis. Streptococci require manganese but not iron as a growth factor, which affects the activity of superoxide dismutase in cell cultures.

### Capsules

One of the main virulence factors is the presence of the capsules, which are powerfully antiphagocytic. The organism is classified into serotypes on the antigenic specificity of its capsular polysaccharide. The capsule, certainly for SS2, plays an important role in pathogenesis. It is an important antiphagocytic factor.<sup>18</sup> Because many nonpathogenic strains are capsulated, there are probably many other interrelating factors.

There are also modifications of the cell wall, such as lipoteichoic acids and peptidoglycans.<sup>11,19,20-22</sup>

### Proteins

The virulence markers of the organism include the structural proteins muramidase-related protein (MRP) and extracellular factor (EF). There are virulence differences between strains of the same serotype based on the presence or absence of muramidase-released proteins. It has also been reported that some of these proteins are not essential for virulence; on the other hand, there is sometimes a strong association between proteins and strain virulence.<sup>12,23</sup> Most Canadian field isolates of SS2 do not produce these virulence-related proteins.

Fibronectin and fibrinogen-binding protein played a role in the colonization of specific organisms involved in a SS infection.<sup>24</sup> An IgG binding protein in the 60-kDa range has been shown to bind IgG in a non-immune way. A 44-kDa protein has been isolated as a virulence marker of SS2, and the presence of antibodies against this protein appears to be necessary to obtain complete protection against the disease.

Recently, 36 environmentally regulated genes have been identified. Strains of SS2 from Europe are genotypically different from

those of North America. A serum opacity-like factor has also been identified as a novel virulence determinant.<sup>11</sup>

### Suilyisin

Suilyisin, an extracellular protein with hemolytic properties, has been described, and it is cytotoxic.<sup>25</sup> In one study most SS2 field strains from four different European countries produced this hemolysin. Between 58% to 90% of strains from the Netherlands, Denmark, France, England, and Italy produced the suilyisin but only 1% of Canadian strains. A total of 164 field isolates from diseased pigs in four countries were serotyped and tested for suilyisin. SS2 was the most prevalent type isolated from all four countries. After SS2, SS9 was most prevalent in the Netherlands and France and SS7 in Denmark. All the English isolates were SS2. No nonvirulent suilyisin-producing SS2 strains have been reported.

### Hemolysin

The hemolysin gene was found in over 80% of the strains that were associated with meningitis, septicemia, and arthritis but in only 44% of pneumonia isolates.

### Other Properties

The organism bears fimbriae and pili, and the capsular materials from different serotypes have distinct morphologies. Certain strains possess hemagglutinating properties.

Glutamine synthetase is required for the full expression of virulence in SS2.<sup>26</sup> Recently glutamate dehydrogenase, glyceraldehyde 3-phosphate dehydrogenase, and a secreted nuclease have been suggested as aiding the virulence of SS2.<sup>27</sup>

### Adhesion

There are also adhesins.<sup>5,21,28</sup> SS2 isolates possess a factor that allows them to adhere to porcine lung. Australian isolates of SS are genetically very diverse, which suggests that serotyping is not a reliable technique for identifying specific strains and not a good predictor of the genetic background of a given isolate.

### Zoonotic Implications

Splenectomized humans are particularly at risk from certain infections, including streptococci, and should not handle or come into contact with pigs in particular. Death is not common in humans in North America but does occur in Europe and is much more common in Asia,<sup>29</sup> which may be a feature of greater contact with SS2. It has been identified as an important emerging zoonotic agent,<sup>30</sup> particularly in the East.

Infections with SS2 are the most common infections in humans (from pigs or raw pork). The Chinese outbreaks may be associated with undercooked or raw pork.<sup>28,31</sup> A high percentage of pork in Asian markets is contaminated with SS.<sup>32</sup> It is possible that

many human cases are misdiagnosed, such as in those that were described in Southeast Asia, where 5 of 8 cases of SS were described as *S. viridans*. SS in humans is associated with the nasopharynx<sup>33</sup> and the gastrointestinal tract; diarrhea is often a prominent feature,<sup>34</sup> but SS can produce very variable clinical signs in humans. The clinical manifestations in humans include meningitis and septicemia, which may be accompanied by arthritis, endophthalmitis, and disseminated intravascular coagulation. Endocarditis and acute gastroenteritis have also been reported. Deafness occurred in 50% to 60% of cases and is a result of cochlear sepsis following invasion of the organism from the subarachnoid space into the perilymph of the inner ear. Vertigo and ataxia occurred in 30% and arthritis in 53% of patients. There was a case-fatality rate of 13%. The organism invades the cerebrospinal fluid within monocytes, an example of the “Trojan horse” mechanism of entry.

A truck driver has recently been described with septic shock. It is thought that SS25 has evolved to become the highly pathogenic SS1, which has in turn evolved to become epidemic strain SS7, which in turn stimulates the production of large amounts of proinflammatory cytokines, leading to streptococcal shock syndrome.<sup>35</sup>

In the United Kingdom, the highest incidence of meningitis attributable to SS2 is in butchers and abattoir workers; transmission is thought to be mainly via minor skin abrasions, and often there is no visible point of entry. Subclinical infection in pigs sent to slaughter represents a potential source of infection for abattoir workers; eviscerators who remove the larynx and lungs have a significantly higher risk of exposure to the organism than other abattoir workers.

Within infected herds in New Zealand, up to 100% of pigs are carriers, and SS2 infection may be one of the most infectious potentially zoonotic pathogens present in New Zealand, although very rarely resulting in clinical disease. The annual incidence of subclinical infection and seroconversion in pig farmers in New Zealand is close to 28%.

## **PATHOGENESIS**

Streptococci exist in extremely different phenotypes with regard to adhesion, invasion, and cytotoxicity. These features depend on the state of encapsulation and environmental growth conditions.

The crypts of the tonsils are a site of persistence, multiplication, and portal of entry of a variety of pathogens, including SS. Invasive disease occurs in a minority of infected pigs. It is not clearly known how SS travels from the mucosal surfaces to the blood and produces a bacteremia, then septicemia, and finally meningitis. Most bacteria remain extracellular, with fewer than 2% of monocytes containing bacteria.<sup>36,37</sup> Persistent

bacteremia is an important phase in the pathogenesis of SS2 meningitis. There is a high level of adhesion of bacteria to phagocytic cells. SS adheres to brain microvascular endothelial cells, and suilysin can damage these. It has been shown that SS capsular strains stimulate tumor necrosis factor alpha (TNF- $\alpha$ ) and interleukin (IL)-6, but the suilysin and the extracellular protein do not do so on their own. It is likely that the enhanced production of inflammatory cytokines contributes to the more severe signs and an early death.<sup>38,39</sup> A terminal acute fatal septicemia is the common outcome in young animals, but in older animals localization can occur in synovial cavities, endocardium, eyes, and meninges. Virulent isolates of SS2 possess capsules and are relatively resistant to phagocytosis. Isogenic mutants defective in capsule production were not virulent. SS is able to adhere to but not to invade epithelial cells, and the adhesins are partially blocked by the capsule and are part of the cell wall. The highly virulent isolates possessed the suilysin, muramidase-releasing protein, and extracellular protein factor phenotype.<sup>40</sup> SS are able to survive and replicate within macrophages, and the bacteria enter the cerebrospinal fluid space in association with migrating monocytes, which move through choroid plexuses. They therefore enter the cerebrospinal fluid by a “Trojan horse” mechanism similar to that used by some viral pathogens of the central nervous system (CNS). The predominant lesions are suppurative or fibrinopurulent inflammation in brain, heart, lungs, and serosae. SS9 may produce a different distribution of lesions compared with SS2. The disease has been reproduced experimentally in pigs and laboratory animals by intravenous, intranasal, and subarachnoid routes. Certain strains of streptococci can cause vascular lesions, with the development of fibrinohemorrhagic pneumonia and septal necrosis. Of importance in the pathogenesis of SS infections is the predisposing role of PRRS. This effect of PRRS has still only been experimentally demonstrated with SS.

## **CLINICAL FINDINGS**

Multiple *Streptococcus* spp. are implicated in lameness and CNS signs in piglets and sows. There is significant variation of carrier states and clinical signs with the individual serotypes. Although morbidity is usually less than 5% in an endemic infection, the case-mortality rate may be as high as 20%. The earliest clinical sign is often a raised temperature, followed by reduced appetite, depression, shifting lameness. In a new infection on a premises, only sudden death may be seen at first. It does occur as hyperacute, acute, subacute, and chronic pictures, with the basic difference being the time scale of events.

Arthritis and meningitis may occur alone or together and are most common in the

2- to 6-week age group. More commonly several piglets within a litter are affected. Meningitis is particularly associated with serotypes 1, 2, 1/2, 3, 4, 8, 9, 14, and 16; septicemia with 2; arthritis with 7 and 14; abscesses with 2; bronchopneumonia with 2, 3, 7, 10, 15, and 27; and reproductive damage with 2, 13, and 22; 14 can be associated with any clinical condition.

An experimental infection with SS9 in SPF pigs produced meningitis, arthritis, and serositis.<sup>41</sup>

The arthritis is characterized by enlarged and distended joint capsules, lameness, and pain on palpation of the affected joints. Fever, depression, reluctance to move, and inactivity are common.

Meningitis is characterized by fever, anorexia, and depression. The gait is stiff, the piglets stand on their toes, and there is swaying of the hindquarters. The ears are often retracted against the head. Blindness and gross muscular tremor develop, followed by inability to maintain balance, lateral recumbency, violent paddling, and death. In many cases there is little clinical evidence of omphalophlebitis.

In epidemics of meningitis attributable to SS2, sudden death in one or more pigs may be the first sign. The eyes may stare. Affected pigs found alive are uncoordinated and rapidly become recumbent. There is opisthotonos, paddling, and convulsions and death in less than 4 hours. A fever of up to 41°C (105°F) is common. In the United Kingdom, meningitis of recently weaned pigs is the most striking feature of SS2 infection.

Otitis interna is a common sequela to many cases of SS meningitis. Arthritis is common in younger pigs.

In endocarditis, which is a relatively rare clinical sign (except in North America), and in septicemia the piglets are usually found comatose or dead without premonitory signs having been observed.

Valvular endocarditis attributable to SS2 has also been reported in a 13-week-old finishing pig in a breeding herd that had a long history of SS meningitis. Occasionally, the infection results in conjunctivitis, rhinitis abortion, and vaginitis.

## **CLINICAL PATHOLOGY**

### **Culture or Detection of Organism**

The organism can be cultured from joint fluid, cerebrospinal fluid, blood, and the brain at necropsy. Often the lungs will yield SS, but the role of SS in primary lung disease is not understood. The tonsils of live pigs may be swabbed and cultured for the organism. Improved and selective media are available for the isolation and serotyping of the organism. An indirect fluorescent antibody test can be used to identify the organism on tonsillar swabs of live pigs. Because of multiple antimicrobial resistance among strains of the organism, drug sensitivity testing on a

routine basis is recommended. Highly virulent strains of SS2 and SS1 were detected in tonsillar specimens using a PCR. Rapid serotype-specific PCR assays have been developed. A multiplex PCR for identifying four capsular types and four associated virulence markers was described.<sup>23</sup>

### Serology

The specific serotype of SS should be determined. A simplified laboratory method is available for the identification of SS strains associated with different animal hosts or located in different body regions. An ELISA using monoclonal antibodies directed against virulence markers of SS can distinguish between virulent and avirulent strains of the organism. A rapid and specific double-sandwich ELISA is available for the detection and capsular typing of the organism, with a specificity of 97.6% and sensitivity of 62.5%. However, many laboratories are not readily equipped to identify the numerous serotypes of the organism.

### NECROPSY FINDINGS

In pigs dying from SS2 infection, the gross and microscopic findings are usually found in the brain, heart, and joints and include one or more of fibrinopurulent polyserositis, fibrinous polyarthritis, fibrinous or hemorrhagic bronchopneumonia, suppurative meningitis, hemorrhagic necrotizing myocarditis, and vegetative valvular endocarditis. Gross myocardial lesions cannot be distinguished from those of mulberry heart disease. In cases with meningitis, there is turbidity of the cerebrospinal fluid, congestion of meningeal vessels, and variable amounts of white exudate in the subarachnoid space. The brain may be so swollen that the cerebellum herniates into the foramen magnum. Suppuration is usually most evident along the ventral aspect of the brain, and the meninges may appear grayish as a result of neutrophilic inflammation.

The typical histologic picture is one of acute inflammation—neutrophils and fibrin dominate the response. There is a choroiditis, encephalitis, and meningitis. Other changes that may be observed in SS infections of the central nervous system include internal hydrocephalus, foci of liquefaction necrosis, subacute (mononuclear cell-rich) meningoencephalitis, or meningoencephalomyelitis with bilateral subacute optic perineuritis and Gasserian ganglioneuritis. In the tonsils, SS organisms can be seen in the subepithelial lymphoid tissue and in the crypt lumen and crypt epithelium. SS9 is more prone to cause bronchopneumonia than the spectrum of lesions typical of SS.

### Samples for Confirmation of Diagnosis

- Bacteriology—spleen; culture swabs from serosal surfaces, joints, and meninges are best. The significance of

SS-positive lungs is not yet resolved. Biochemical tests can be used (Amylase and Vosges-Proskauer tests are positive for SS). Cerebrospinal fluid is the material for the best diagnosis. Bacterial culture is difficult if the animals have been treated, and this is so even when they receive growth-promoting antibiotics. Immunomagnetic isolation of SS2 and SS1/2 from swine tonsils has been described, and it is better than the standard procedure.

- PCRs have been used in human medicine but not in veterinary medicine.<sup>1</sup>
- Histology—formalin-fixed samples of a variety of organs, including lung, brain, heart, liver (light microscopy) are best. Immunohistochemistry 42 and in situ hybridization have been described for use on formalin-fixed tissue and are able to detect single infected cells. Using immunohistochemistry (IHC) the bacteria can be seen in the cytoplasm of the neutrophils and macrophages, and the IHC may be positive even though culture is negative following antibiotic or growth promotant administration.

**Note the zoonotic potential of this organism when handling the carcass and submitting specimens.**

### DIAGNOSIS

Diagnosis is often possible based on clinical signs, gross pathology, histopathology, and culture if the carcasses are fresh and the correct sites are examined. A colloidal gold-based immunodiagnostic assay has been described for SS2 and SS1/2.<sup>43</sup> Serotyping by coagglutination will enable the SS strain to be identified. The genetic diversity within and between strains is increasing.<sup>6</sup> The same SS isolated from different geographic regions may be genetically and phenotypically very different.<sup>42</sup>

Serologic tests are generally not very useful because of the diversity of the strains involved, but an ELISA has been developed for human exposure.<sup>33</sup>

### DIFFERENTIAL DIAGNOSIS

In pigs, there may be sporadic cases of arthritis attributable to staphylococci but the streptococcal infection is the common one. Arthritis attributable to *M. hyorhinis* is less suppurative but may require cultural differentiation. Glässer's disease occurs usually in older pigs and is accompanied by pleurisy, pericarditis, and peritonitis. Erysipelas in very young pigs is usually manifested by septicemia. Nervous disease of piglets may resemble arthritis on cursory examination, but there is an absence of joint enlargement and lameness. However, the meningitic form of the streptococcal infection can easily be confused with viral encephalitis. Meningitis

in young pigs may also be associated with *P. multocida* and *E. coli*. Polyarthritis in calves, lambs, and piglets may also be associated with infection with *T. pyogenes* and *F. necrophorum*. SS2 can also be the cause of meningitis in older pigs of 10 to 14 weeks of age.

### TREATMENT

#### Antimicrobials

In summary, there has been an increasing level of resistance to tetracyclines and erythromycin and a variable resistance to ciprofloxacin and penicillin.<sup>43</sup> Most SS are resistant to tetracyclines.<sup>44</sup> If treatment is based on serotyping and sensitivity testing, then there is much less chance of treating or creating resistant organisms.

In Denmark, over the last 15 years there has been an increase in resistance of SS isolates to the two most commonly used antibiotics, tylosin and tetracyclines. The strains show a varying pattern of resistance dependent on to which of the 21 ribotype profiles they belong. For example, strains causing meningitis were more resistant to sulfamethoxazole, but those causing pneumonia were more resistant to tetracyclines. Tilmicosin has been used successfully to remove clinical signs of streptococcal meningitis from a herd.

Penicillin has been the treatment of choice, but penicillin-resistant isolates have emerged. Penicillin sensitivity can no longer be assumed for all strains of SS, and the routine use of penicillin must be reevaluated. In one study, more than 50% of isolates of SS were not susceptible to penicillin. Penicillin did not eliminate the organism from the tonsils of carrier pigs treated daily for several days. In some surveys, the antimicrobial sensitivity of SS indicates a high degree of sensitivity to ampicillin, cephalothin, and trimethoprim-sulfamethoxazole, and resistance to the aminoglycosides gentamicin and streptomycin. It is recommended that trimethoprim-sulfamethoxazole be used for the treatment of affected pigs and be given daily for 3 days. An occasional strain may be resistant to trimethoprim-sulfamethoxazole.

None of the resistant strains produced beta-lactamase. Conjugation of antibiotic resistance in SS has been reported, which may explain the multiple antimicrobial resistance. The genes responsible for resistance appear to be homologous to genes found in many other species of bacteria. Treatment of pigs affected with meningitis attributable to SS2 with either trimethoprim-sulfadiazine or penicillin reduced the case-fatality rate from 55% to 21%. Cefquinome has been shown to improve cure rates (67%) compared with ampicillin (55%) and to reduce mortality from 35% with ampicillin to 24% with cefquinome.

Passive immunization against SS2 has been described.

### CONTROL

At the present time there are no known specific methods for the prevention of the disease complex associated with SS2. The recommendations are based on empirical field observations. Regular isolation of the agent from any clinical cases will confirm the continuation of a strain or the arrival of a new strain and hopefully differentiate virulent from nonvirulent.<sup>15</sup>

It has been suggested that ceftiofur administered by injection for 3 consecutive days following SS challenge is the most effective regimen for minimizing disease associated with PRRS virus and SS infection. The use of potassium penicillin G in drinking water for several days was reported as being successful<sup>45</sup> and will reduce mortality. A combination of medication and vaccination was seen to remove SS from the tonsils of carrier sows.<sup>47</sup>

### Environment and Management

Good management and hygiene techniques should be emphasized. Based on observations of the effects of management practices on SS carrier rate in nursery pigs, excessive temperature fluctuations, high relative humidity, crowding, and an age spread exceeding 2 weeks of pigs in the same room were associated with a higher-than-average percentage of carrier pigs.

Nursery pig environmental temperature should not fluctuate more than 1.1° to 1.7° C (34° to 35° F) over a 24-hour period.

Excessive relative humidity must be avoided; the recommended range of relative humidity for nursery pigs is 55% to 70%.

The age spread between pigs in the same room should not exceed 2 weeks. Young, potentially naive piglets raised in the same air space as older animals may be exposed to high concentrations of the organism.

Adequate space to avoid crowding is also necessary. Crowding occurs when less than 0.18 m<sup>2</sup> is provided for each 22.7 kg of pig. The use of an all-in, all-out production system is recommended, compared with a continuous flow system, which allows for a build-up of pathogens. The control of the most commonly encountered infectious diseases is also important. A well-fortified nutritional program may also aid in the control of SS infection and the carrier state in a swine herd.

Segregated early weaning programs have been used in an attempt to control the disease but appear to be unsuccessful in reducing the carrier state. Pigs are weaned at an early age and moved to a separate site in an effort to separate the piglets from the sows, which are the primary source of the organism. Carrier pigs readily transmit the infection to uninfected pigs, and the main method of spread between herds is the movement of infected

breeding stock or weaner pigs. In herds that are free of the infection, it is necessary to avoid the importation of infected pigs. Eradication of SS2 infection can be attempted by depopulation of suspected carrier sows and replacement with noninfected breeding stock.

### Mass Medication of Feed

Mass medication of individual pigs or medication of the feed during periods of high risk may control the incidence of clinical disease. Outbreaks in sucking piglets have been controlled by a single injection of benethamine penicillin to all piglets given 5 days before the average age of onset of clinical signs. The feeding of oxytetracycline (400 g/ton) for 14 days immediately before the usual onset may control the occurrence of the disease at a low level in weaned pigs, although there is increasing evidence of resistance. The use of a medicated feed containing trimethoprim-sulfadiazine (1:5) at a rate of 500 g/ton for the first 6 weeks after weaning did not significantly reduce the incidence of disease. Oral prophylactic medication with either procaine penicillin G or a mixture of chlortetracycline, sulfadimidine, and procaine penicillin G reduced the incidence of meningitis. Penicillin V administered orally provided higher plasma concentrations of drug. The inclusion of penicillin V potassium (10%), at a rate of 2 kg/ton of feed, significantly reduced the incidence of streptococcal meningitis when fed to the pigs for a total of 6 weeks from 4 to 10 weeks of age.

Tiamulin in the drinking water at 180 mg/L of water for 5 days significantly reduced the effects of experimentally induced SS infections.

### Vaccination

Most vaccination studies have been carried out with piglets.<sup>46</sup> Either commercial or autogenous bacterins are available. Autogenous vaccines need to use strains from systemic sites such as the meninges, spleen, liver, and joints, nasal cavity, or tonsils, but not the lungs because they are more likely to be the nonvirulent SS. A study showed that SS9 bacterin produced a much lower level of efficacy than a SS2 vaccine.<sup>47</sup> Homologous protection is always more successful than for heterologous strains, which is why it is essential to continually monitor the strains in an endemically affected herd. A commercial vaccine reduced mortality from 17% to 2.6%. What constitutes an effective antigen is still a matter of conjecture. High levels of antibody against MRP and EF proteins did not confer protection.<sup>48</sup>

Studies are being conducted on the use of vaccines containing the immunogenic polysaccharide from SS2. However, the protection provided by whole-cell vaccines is probably type specific, which suggests that such vaccines should contain many

serotypes if broad protection is desired. A trial minimizing variation in weaning age to achieve a uniform size with a combination of an autogenous vaccine and ceftiofur sodium has been reported. The protective levels of antibody did not prevent the survival of the organism in either tonsils or joints. An ELISA can be used to evaluate the antibody response in pigs vaccinated with SS2.

Different components of the organism are being examined to identify possible fractions for the preparation of a subunit vaccine. A subunit vaccine containing both MRP and EF, formulated with an oil/water adjuvant, that protected pigs against challenge with a virulent SS2 has been proposed. Vaccination of sows with 2 mL of bacterin prevented neurologic signs but not lameness, bacteriuria, or mortality in their progeny from challenge at 13 to 21 days of age. Immunization of experimental mice with a live avirulent strain of SS2 provided protection, which may be extrapolated for consideration in pigs. A vaccine containing purified suilysin protected mice against a lethal homologous challenge and induced protection against clinical signs in pigs after homologous challenge. Pigs vaccinated with a vaccine containing purified suilysin were protected from challenge with the homologous strain of the organism, whereas pigs vaccinated with a vaccine containing most of the extracellular antigens, and the placebo pigs, developed clinical disease. Suilysin is produced by most of the field strains tested and could be an important cross-protection factor.

Medicated early weaning does not produce eradication. The establishment of a new herd by hysterectomy and artificial rearing will allow this, and freedom can only be maintained by intense 24/7 biosecurity. Complete degreasing, cleaning, disinfection, and drying and letting a building rest before repopulating with SS-free stock from a known SS-free pyramid is the only way to get rid of a persistent infection.

## STREPTOCOCCAL LYMPHADENITIS OF SWINE (JOWL ABSCESES, CERVICAL ABSCESES)

Cervical or "jowl" abscess of pigs is observed mainly at slaughter. Clinically, there is obvious enlargement of the lymph nodes of the throat region, particularly the mandibular and the retropharyngeal. It is of considerable importance because of the losses resulting from rejection of infected carcasses at meat inspection.

The condemnation rate of pig heads at slaughter was as high as 78% to 94% in some herds in the 1960s. However, since then, the incidence of jowl abscesses in pigs has declined steadily. This may be a result of changes in management of pig herds and the use of antibiotic feeding.

Most jowl abscesses in swine are associated with beta-hemolytic streptococci of Lancefield's group E type IV, although *P. multocida*, *E. coli*, and *T. pyogenes* may also be present. Some additional serotypes have been isolated. Jowl abscessation occurs primarily in postweaning and finishing pigs. Piglets under 28 days of age are relatively resistant, and even colostrum-deprived piglets are resistant to clinical disease following experimental infection.

The disease has been produced by feeding or the intranasal or intrapharyngeal instillation of streptococci, and they are thought to be the cause, with infection occurring through the tonsil or pharyngeal mucosa from contaminated food and water. The contamination occurs from abscess material

leaking into food or water. In herds where cervical abscess is a problem, streptococci can commonly be isolated from the vaginas of pregnant sows and the pharynges of normal young pigs. The persistence of the infection in herds is thought to depend on the presence of carrier animals. Transmission occurs via feed and drinking water. After infection has occurred, bacteremia develops, and abscesses are initiated in the cervical lymph nodes in a high proportion of pigs. Infrequently, abscesses occur in atypical sites other than the head and neck. Pigs that have recovered from the natural disease are immune to experimental challenge. A microtitration agglutination test is available to detect infections associated with type IV streptococci.

Vaccination of pregnant sows with an autogenous or commercial bacterin containing streptococci and staphylococci is thought to be of value in protecting the litters of the vaccinated sows. Vaccination of young pigs with a whole-culture bacterin has provided some protection. The use of an oral vaccine prepared from an avirulent strain of group E streptococci and sprayed into the oropharynx is highly effective as a preventive measure. None of these vaccines is widely used because the condition is very sporadic. A number of prophylactic regimens based on the feeding of antibiotics have been proposed and generally give good results. Chlortetracycline fed to young pigs at the rate of 220 g/ton for 1 month is an example. Treatment of breeding pigs at the same time is likely to have a beneficial effect in reducing the severity of exposure of the young pigs to infection. A similar advantage can be gained by keeping the treated groups isolated from untreated groups of older pigs. Because piglets under 28 days of age are relatively resistant to clinical disease, the weaning and isolation from older pigs is a successful control program.

## ERYSIPELAS IN SWINE

Erysipelas of pigs is the major disease of animals associated with *Erysipelothrix rhusiopathiae*, and it can occur in all stages of pig production. The condition is seen as sudden death; as an acute disease, possibly with diamond-shaped skin lesions; and also as a chronic disease with arthritis and vegetative endocarditis and reproductive failure in adults. In many minimal-disease herds they have tended not to vaccinate, and then the epizootics have occurred as a result of an increasing lack of immunity. It is zoonotic, most commonly causing erysipeloid in the fingers.

### SYNOPSIS

**Etiology** *Erysipelothrix rhusiopathiae*.

**Epidemiology** Pigs worldwide. Common in unvaccinated pigs raised outdoors. High

case-fatality rate if not treated. Organism in environment and transmitted by carrier pigs. Important zoonosis.

**Clinical signs** Hyperacute sudden death. Sudden onset of acute disease, fever, anorexia, typical diamond-shaped skin lesions. Arthritis, endocarditis in chronic form.

**Clinical pathology** Organism in blood. Hemogram and serology.

**Necropsy findings** Skin lesions, widespread ecchymotic hemorrhages (kidney, pleura, peritoneum), venous infarction of stomach. Nonsuppurative proliferative arthritis. Vegetative endocarditis.

**Diagnosis** Culture and isolate organism from blood in acute case and then tissues.

**Differential diagnosis** Other septicemias of pigs:

- Septicemic salmonellosis
- Hog cholera and African swine fever
- Streptococcal septicemia and arthritis
- Streptococcal endocarditis

Other arthritides of pigs:

- Glässer's disease
- Mycoplasma synoviae and hyorhinis arthritis
- Ricketts and chronic zinc poisoning
- Foot rot of pigs
- Leg weakness

**Treatment** Penicillin.

**Control** Vaccination, with at most 6 month-interval until new and improved vaccines appear.

## ETIOLOGY

*Erysipelothrix rhusiopathiae* (formerly insidiosa) (ER) is the causative bacterium, and the disease can be produced in hyperacute, acute, and subacute septicemic and chronic forms by the injection of cultures of the organism. The organism occurs as rough and smooth strains; the smooth are more virulent. At least 29 antigenic types have been identified, and usually types 1 and 2 are isolated from the septicemic forms.<sup>1</sup> The species has recently been divided into two species on the basis of the DNA tests that reflect biochemical and serologic characteristics. Many of the serotypes have been regrouped and called *Erysipelothrix tonsillarum* (ER), which is nonpathogenic.<sup>2</sup> This is found in the tonsil and is morphologically and biochemically similar to ER but has a very distinctive genetic profile. However, some species identified as ET on serology have been shown to be ER on multilocus enzyme electrophoresis. In addition, the restriction fragment length polymorphism (RFLP) typing using the PCR products of the Spa A gene have been used to subdivide the serotypes.<sup>3</sup> Recently, a new classification has been put forward based on Spa genes.<sup>4,5</sup> These are proteins, and at least three genes are known (Spa1, Spa2 and Spa3).<sup>6,7</sup>

*Erysipelas rhusiopathiae* now contains the former serotypes 1, 2, 4, 5, 6, 8, 9, 11, 12, 15, 16, 17, 19, 21, and N.

*Erysipelas tonsillarum* now contains serotypes 3, 7, 10, 14, 20, 22, and 23. Serotypes 13 and 18 are intermediate and called *Erysipelas* species strains 1 and 2 (also contains a few 9 and 10), respectively, and strain 3, which contains some strains of 7 and is as yet untypeable.<sup>3</sup> The identification and characterization of *E. inopinata* has not yet been determined.<sup>8</sup>

## EPIDEMIOLOGY

### Occurrence

Erysipelas in pigs occurs worldwide and causes serious economic loss, substantially as a result of deaths, morbidity and devaluation of pig carcasses because of arthritis. However, because the indoor confinement of swine and no contact with contaminated soil has followed, the occurrence of the disease has decreased markedly. The exception to this would be outdoor units where no regular vaccination is practiced. The other major exceptions are those parts of the world where the backyard or enthusiast's pigs are still found and where hygiene and biosecurity are usually nonexistent. Historically, the disease occurred most commonly in unvaccinated growing pigs over 3 months of age and adults. This is primarily because the maternal antibody is thought to last up to 3 months. The infection, usually with serotypes 1a or 2, has also been demonstrated in wild boars, so these should not be forgotten as a reservoir. Perhaps more important, these strains were resistant to oxytetracycline and/or dihydrostreptomycin.

### Prevalence of Infection

The prevalence of infection with ER in carrier pigs ranges from 3% to 98%, with most surveys indicating that 20% to 50% of pigs are carriers, particularly in the tonsils. Carriers occur among vaccinated and unvaccinated pigs. The organism has been isolated from 10% of apparently healthy slaughter pigs and may explain its wide prevalence. In addition, the organism has been isolated from over 30 species of wild birds and 50 species of wild animals.

### Morbidity and Case Fatality

Morbidity and case-fatality rates in pigs vary considerably from area to area, largely because of variations in virulence of the particular strain of the organism involved. On individual farms or in particular areas the disease may occur as a chronic arthritis in finishing pigs or as extensive outbreaks of the acute septicemia, or both forms may occur together. In unvaccinated pigs, the morbidity in the acute form will vary from 10% to 30%; the case-fatality rate may be as high as 75%.

### Methods of Transmission

Soil contamination occurs through the feces of affected or carrier pigs. Other sources of

infection include infected animals of other species, mouse contamination, open muck heaps and effluent on the soil, and birds. Straw-based systems are often highly contaminated. The clinically normal carrier pig is the most important source of infection, with the tonsils being the predilection site for the organism. Young pigs in contact with carrier sows rapidly acquire the status of carriers and shedders. Because the organism can pass through the stomach without loss of viability, carrier animals may reinfect the soil continuously, and this appears to be the main cause of environmental contamination. The organism can survive in feces for several months. All effluent contains species of *Erysipelothrix* but not necessarily ER. However, its persistence in soil is variable and may be governed by many factors including temperature, pH, and the presence of other bacteria. The organism can be isolated from the effluent of commercial piggeries and from the soil and pasture of effluent disposal sites for up to 2 weeks after application of the effluent containing the organism. Although the environment is considered to be secondary to animals as a reservoir of infection, the survival of the organism in the environment could create an infection hazard. Flies are known to transmit the disease, and a lowered prevalence has been attributed to the use of insecticides.

Under natural conditions, skin abrasions and the alimentary tract mucosa are considered to be the probable portals of entry, and transmission is by ingestion of contaminated feed. Occasional outbreaks occur after the use of virulent and incomplete avirulent cultures as vaccines. Abortion storms in late pregnant sows with septicemic death in sucklers may be the first indication of the disease in specific-pathogen-free herds.

Spread of the infection can also occur to most other species. The organism has been recovered from sylvatic mammals in northwestern Canada. It has been isolated from a horse affected with vegetative endocarditis. It has, at times, been found in fish meal, but this is now less used in pig diets. It is possible that other species, such as cattle, may harbor strains that are pathogenic for swine.

### Risk Factors

It may be that some serotypes are resident in a single farm, and an outbreak may represent the arrival of a new serotype on that farm.

There is considerable variation in the ease with which the disease can be reproduced and in its severity. Many factors, such as age, health and intercurrent disease, exposure, and heredity, influence both natural and artificial transmission. Stress may predispose to the condition, but virulence of the strain is probably the most important factor. Smooth strains can be used successfully to produce the disease experimentally, but rough strains appear to be nonpathogenic. This variation

in virulence between strains of the organism has been utilized in the production of living, avirulent vaccines.

### Animal Risk Factors

Infected pigs probably shed the agent in feces and oronasal secretions and also in urine, and direct contact is probably the most usual method.

Pigs of all ages are susceptible. Recently farrowed sows seem to be particularly susceptible. This suggests that fatigue may be a factor. Sudden diet changes have also predisposed, as have heat and cold stress. When the strain is virulent, pigs of all ages, even sucklers a few weeks old, develop the disease. Almost entire litters under 2 weeks of age may be affected. Piglets from an immune sow may get sufficient antibodies in the colostrum to give them immunity for some weeks. It is likely that the animals are immune to the strains that are normally found in their particular environment. Possibly the arrival of new serotypes through new pig arrivals or the turning over of previously contaminated land together with an increase in stress are the main factors. It is known that ER from bovine tonsils is pathogenic for mice and pigs and possibly pathogenic for other animals and humans.

### Pathogen Risk Factors

At least 32 serotypes are known to exist and many strains; however, 15 probably commonly affect pigs. Serotypes 1 and 2 are the most common types isolated from swine affected with clinical erysipelas and are generally thought to be the only serotypes that cause the acute disease. The other serotypes are relatively uncommon, and none of them has yet been a cause of acute epidemics, but some have been isolated from lesions of chronic erysipelas. Serotypes 1a, 3, 5, 6, 8, 11, 21, and type N have been isolated from pigs with chronic erysipelas, mainly arthritis and lymphadenitis.

Not all serotypes isolated from pigs are virulent. In a survey in Japan, the organism was found in 10% of the tonsils of healthy slaughter pigs: 54% were serotype 7, 32% serotype 2, 9.5% serotype 6, and 1.6% each of serotypes 11, 12, and 16. All serotype 2 isolates were highly virulent for pigs, whereas the other serotypes were only weakly virulent. Members of the other nonvirulent or weakly virulent group, mainly serotype 7 strains, are considered to be resident in porcine tonsils. Serotypes 1a or 2 were found most commonly in pigs in Australia, less commonly in sheep, and infrequently in other animals. Serotypes 1a and 1b accounted for 79% of the isolates from diseased pigs. The genetic diversity of Australian field isolates of ER and ET indicates widespread diversity. Those recovered from sheep or birds were more diverse than those isolated from pigs, and isolates of serovar 1 were more diverse than those of serovar 2. The

diversity indicated that serotyping of ER is unreliable as an epidemiologic tool.

The serotype antigens of ER are immunologically distinct, and commercial bacterins prepared from the common serotypes will not provide protection against other pathogenic serotypes. This may be an explanation for the epidemics that may occur in vaccinated pigs. The 64 to 66 kDa protein appears to be most immunogenic. Also, a variety of serotypes may be recovered from pigs affected with the septicemic and arthritic forms of the disease.

The organism is resistant to most environmental influences, and to heat (15 minutes at 60°C [14°F]), and can survive in animal tissues at 40°C (105°F) and frozen tissues and is not readily destroyed by chemical disinfection, including 0.2% phenol and by drying agents. It can survive for 60 months in frozen or refrigerated media, 4 months in flesh, and 90 days in highly alkaline soil and is resistant to drying. It will also resist salt preparations and other food preservatives.

### Zoonotic Implications

Because of human susceptibility, swine erysipelas has some public health significance. Veterinarians in particular are exposed to infection when vaccinating with virulent cultures. It commonly contaminates pig products and therefore is quite a common infection in abattoir workers or butchers or those employed in similar trades. It usually produces a swollen finger and is known as erysipeloid. In this context, there have been recent advances in slide agglutination and latex agglutination tests for rapid diagnosis, which have a good correlation with each other and subsequent culture. Now a PCR identifying four species has been described, principally for use in the abattoir. Recently a case of endocarditis and presumptive osteomyelitis has been described, so care is needed. Type 21 is recorded as having produced a septicemia in humans.<sup>1</sup>

### PATHOGENESIS

The invasion of the susceptible pig by ER can occur under particular circumstances, for example, if weather conditions are hot and humid or in particular fields or buildings. Experimentally, it is often easier to infect the pig through scarified wounds than through intravenous infusions, through the gut, or through intravenous injections. There are marked differences in virulence between strains.

There is the presence in the pathogenic serotypes of a capsule that resists phagocytosis. Some virulent strains also produce a phosphorylcholine which resists phagocytosis. Some others may produce a neuraminidase, which may cleave the mucopolysaccharides in cell walls and cause vascular damage leading to hemorrhage and thrombosis. The surface protective antigen, a protein, Spa is also important in

pathogenesis. There is also the possibility of novel adhesins called RspA and RspB. Apparently, avirulent strains do not have these four important features. Invasion of the bloodstream occurs in all infected animals in the first instance. Septicemia results within 1 to 7 days. The subsequent development of either an acute septicemia or a bacteremia with localization in organs and joints is dependent on undetermined factors. Virulence of the particular strain may be important, and this may depend on the number of recent pig passages experienced. Coagulase activity is a possible virulence factor. Concurrent viral infection, especially hog cholera, may increase susceptibility of the host.

Localization in the chronic form is commonly in the skin, joints, and other heart valves, with probable subsequent bacteremic episodes, and it may start from as early as 4 days after initial infection, although the cartilage lesions may be delayed until about 8 months, and they can then continue to progress for at least 2 years. Selective adherence of some strains of ER to heart valves may be a factor in the pathogenesis of endocarditis. In joints, the initial lesion is an increase in synovial fluid and hyperemia of the synovial membrane, followed in several weeks by the proliferation of synovial villi (really a synovitis), thickening of the joint capsule, and enlargement of the local lymph nodes. Diskspondylitis also occurs in association with chronic polyarthritis attributable to erysipelas. Amyloidosis may occur in pigs with chronic erysipelas polyarthritis. The heart lesions may begin with early inflammatory changes associated with emboli.

There has been some controversy over whether the arthrodial lesions result from primary infection or whether they result from hypersensitivity to the *Erysipelothrix* or other antigens. Current opinion suggests that the former is the case but that the lesions are enhanced by immunologic mechanisms to persistent antigen at the site. There are increased levels of immunoglobulins IgG and IgM in the synovial fluids of pigs with polyarthritis attributable to ER, and the levels are considered to be only partly a result of serum and increased permeability. The presence of antibody does not remove the organism from the joints.

Abortion is thought to occur as a result of high fever, but the organism has been isolated from the fetus. Congenital erysipelas has also been recorded. In these cases, the organism can be recovered from the anterior vagina.

### CLINICAL FINDINGS

There are several forms of disease. These include hyperacute, acute, subacute, and chronic.

#### Hyperacute Form

Quite often the disease is seen for the first time in pigs approaching market weight. The

animal is usually found dead or is dull, is depressed, has a temperature of 42°C (106–109°F), and dies quickly; it usually occurs in finishing pigs and is uncommon in sows.

#### Acute and Subacute Forms

This form is uncommon in adults. The signs vary with age and immune status. The acute usually die within 12 to 48 hours of the onset of signs. After an incubation period of 1 to 7 days, there is a sudden onset of high fever (up to 42°C [108°F]), which is followed some time later by severe prostration, complete anorexia, thirst, and occasional vomiting. Initially, affected pigs may be quite active and continue to eat even though their temperatures are high. However, generally in an outbreak one is initially presented with one or two dead or severely affected pigs showing marked red (scarlet flush) to purple discoloration of the skin of the jowl and ventral surface (may even be whole-body cyanosis), with others in the group showing high fever, reluctance to rise, and some incoordination while walking. Dyspnea is a common feature. Conjunctivitis with ocular discharge may be present.

Skin lesions are almost pathognomonic but may not always be apparent. These may take the form of the classical diamond-shaped, red, urticarial plaques about 2.5 by 5 cm square that occur within the 24 to 48 hours of the onset of clinical signs, or a more diffuse edematous eruption with the same appearance. These lesions can also be palpated as raised patches. In the early stages the lesions are often palpable before they are visible. The lesions are most common on the belly, inside the thighs, and on the throat, neck, and ears, and usually appear about 24 hours after the initial signs of illness. Sometimes they can be felt rather than seen. After a course of 2 to 4 days the pig recovers or dies, with diarrhea, dyspnea, and cyanosis evident terminally. The mortality rate may reach 75%, but wide variation occurs. Pregnant animals may abort, and it is thought that this is a result of the fever, but it may be that there is a direct fetal action because congenital infections and isolations of the organism from the fetus have occurred. There may occasionally be waves of returns to service and abortion storms. Infected boars recover but may be infertile for 6 to 8 weeks.

The so-called “skin” form is usually the acute form with more prominent skin localization but less severe signs of septicemia and with a low mortality. The skin lesions disappear in about 10 days without residual effects. In the more serious cases the plaques spread and coalesce, often over the back, to form a continuous deep-purple area extending over a greater part of the skin surface. The affected skin becomes black and hard, and the edges curl up and separate from an underlying, raw surface. The dry skin may hang on for a considerable time and rattle while the pig walks, or it may slough off.

### Chronic Form

Many of the chronic cases require euthanasia because they deteriorate rapidly.

Signs are vague and indistinct except for the joint lesions characteristic of this form of the disease. Bacteria may localize in the joints. There may be alopecia, sloughing of the tail and tips of the ears, and dermatitis in the form of hyperkeratosis of the skin of the back, shoulders, and legs; growth may be retarded. Joint lesions are most common in the elbow, hip, hock, stifle, and knee joints and cause lameness and stiffness. The joints are obviously enlarged and are usually hot and painful at first but in 2 to 3 weeks are quite firm and without heat. This is especially the case when the arthritis has been present for some time, allowing healing and ankylosis to develop. Paraplegia may occur when intervertebral joints are involved or when there is gross distortion of limb joints.

A subclinical form of synovitis may occur that affects feed intake and results in a reduced rate of growth.

Endocarditis also occurs as a chronic form of the disease with or without arthritis. Suggestive clinical signs are often absent, with the animals dying suddenly without previous illness, especially at times of exertion, such as mating, or movement between pens. In others there is progressive emaciation and inability to perform exercise. With forced-exercise dyspnea, cyanosis and even sudden death may occur. The cardiac impulse is usually markedly increased, the heart rate is faster, and a loud murmur is audible on auscultation if the valves are badly damaged. Cyanosis, tachycardia and tachypnea, and heart murmurs may feature in these cases.

In Switzerland, chronic swine erysipelas is suspected where there is vegetative endocarditis, arthritis, and the culture of ER from vulval discharges. These signs are also accompanied by poor fertility and increased prevalence of abortions, stillbirths, and small litter size. Vaccine was used to control an outbreak of purulent periparturient vulval discharge in which ER was the only organism isolated. In one study anterior vaginal samples from 64 sows all yielded ER.

### CLINICAL PATHOLOGY

#### Detection of Organism

In the acute form, examination of blood smears may reveal the presence of the bacteria, particularly in the leukocytes, but blood culture is likely to be more successful as a method of diagnosis. Repeated examinations in the chronic forms of the disease may by chance give a positive result during a bacteremic phase. Final identification of the organism necessitates mouse or pigeon inoculation tests and protection tests in these animals using antierysipelas serum.

### Hematology

In the early stages of the acute form there is first leukocytosis, followed by leukopenia

and monocytosis. The leukopenia is of moderate degree (40% reduction in total leukocyte count at most) compared with that occurring in hog cholera. The monocytosis is quite marked, varying from a 5-fold to a 10-fold increase (2.5% to 4.5% normal levels rise to 25%).

### Serology

The efficiency of agglutination tests for ER is not clear. They appear to be satisfactory for herd diagnosis but not sufficiently accurate for identification of individual affected pigs, particularly clinically normal carrier animals. A more accurate and reliable complement fixation test is available, but an enzyme immunoassay test is much quicker, easier, and more economical to perform. An ELISA test has been used.

### NECROPSY FINDINGS

Experimentally the disease can be produced by oral dosing; by intradermal, intravenous, and intraarticular injection; and by application to scarified skin, conjunctiva, and nasal mucosa. The arthritic form of the disease can be reproduced by multiple intravenous inoculations of ER.

The microscopic lesions include vasculitis in capillaries and venules in many sites, including glomeruli, pulmonary capillaries, and the skin. Sometimes, it is possible to see emboli of bacteria without specific stains to demonstrate bacteria.

### Acute and Subacute Forms

In the hyperacute cases, all that may be seen is a congested carcass with discoloration of the skin. The degree of skin discoloration may provide a clue to prognosis, in that it is said that if the skin lesions are pink to light purple, then resolution will often occur within 4 to 7 days, but the dark angry black/purple lesions have a grave prognosis.

Classic “diamond skin” lesions may be present. They are almost pathognomonic. However, the diffuse, purplish discoloration of the belly and cyanosis of the extremities common to other septicemic diseases of pigs is a more reliable finding. Internally, petechial and ecchymotic hemorrhage occurs, mainly on the pleura and peritoneum and beneath the renal capsule but also on the heart, kidney, pleura, liver, and spleen. Venous infarction of the stomach is accompanied by swollen, hemorrhagic mesenteric lymph nodes, and there is congestion of the lungs and liver. Infarcts may be present in the spleen and kidney and the former much enlarged. Histologic changes in all tissues are those of toxemia and thrombosis. Large numbers of intravascular organisms are often visible. There are no specific histologic changes.

### Chronic Form

There may be necrotic skin lesions and embolic lesions in organs and the enlarged joints,

A nonsuppurative proliferative arthritis involving limb and intervertebral joints is characteristic. Synovitis, with a serous or serofibrinous amber-colored intraarticular effusion, occurs first; degenerative changes in the subendochondral bone, cartilage, and ligaments follow. When the synovial changes predominate, the joint capsule and villi are thickened. There are enlarged, dark-red pedunculations or patches of vascular granulation tissue, which spread as a pannus onto the articular surface. When bony changes predominate, the articular cartilage is detached from the underlying bone, causing abnormal mobility of the joint. Ulceration of the articular cartilage may also be present. Local lymph node enlargement is usual. With time, the joint lesions often repair by fibrosis and ankylosis sufficiently to permit use of the limb.

Endocardial lesions, when present, are large, friable vegetations on the valves, often of sufficient size to block the valvular orifice. Occasionally, endocarditis may be the only lesion seen, but this is a rare occurrence. Erysipelas is often said to rank below *S. suis* as a cause of endocarditis in growing pigs, but ER was the most frequent isolate from cases of endocarditis seen in slaughtered pigs. Infarcts occur in the kidney, and these may also yield pure cultures of the organism. Chronic joint lesions are often sterile, but bacteriologic culture should nevertheless be attempted. The probability of positive isolation increases with the number of joints sampled, and isolations are more frequent from the smaller, distal joints.

### DIAGNOSIS

Clinical signs (fever, lameness, and skin lesions) and the absence of respiratory signs and anorexia are suggestive and confirmed by isolation of the agent from blood in the acute stages. Diagnosis from joints in chronic stages is more difficult. Postmortem examination of the acute case cases will usually allow culture from the heart, blood, spleen, and bone marrow, particularly the long bones.

### Samples for Confirmation of Diagnosis

With acute cases, the tests are more successful. Bacteriologic examination of subacute cases is less successful, and chronic cases often not successful.

- Bacteriology—culture swabs from joints; synovial membranes in culture media; heart valve masses, spleen, kidney, skin and bone marrow, particularly from a long bone. Smears of heart blood are particularly useful in the first 1 to 2 days of the acute diseases. The organism is a slender, facultative anaerobe and gram-positive rod that produces a 1-mm gray colony after 24 hours of incubation on blood agar. It may be observed singly, in short chains, or as a palisade.

There are a variety of short gram-positive rods that can be confused with *Erysipelas* organisms.<sup>9</sup> Different morphologic types (rough and smooth colonies), exist and the rough are considered less virulent. Enrichment techniques and the use of selective media will also increase the frequency of isolation.<sup>9</sup>

- Florescent techniques have been developed to show antigen in joints. New PCR techniques have also been used.
- Histology—formalin-fixed synovial membranes, heart valve masses, spleen, kidney, and skin lesions (light microscopy) are useful. There may be granulation tissue on the heart valves. The synovial lesions are characterized by macrophages and lymphocytes with synovocyte proliferation. The vasculitis is extensive, and thrombi and bacterial colonies may be seen. Immunohistochemistry aids in the differential diagnosis from the other bacteria (*Mycoplasma*, *S. suis*, and *H. parasuis*).<sup>10</sup>

Antigen detection has helped greatly in detection. PCR and RT-PCR have been developed. A multiplex PCR has been developed to differentiate ER and ET11, and strain 2 was then added.<sup>11</sup> A qRT-PCR has been described for ER and ET13 and for differentiating vaccine strains from field strains.<sup>12</sup>

Note the zoonotic potential of this organism when handling the carcass and submitting specimens.

### DIFFERENTIAL DIAGNOSIS

Erysipelas in pigs is not ordinarily difficult to diagnose because of the characteristic clinical and necropsy findings. In the occasional situation in which anthrax may have occurred in the past, it is worth testing a smear of edema fluid taken by a needle from the jowl or ear region for this pathogen before opening of the carcass. The acute disease may be confused with the other septicemia affecting pigs, but pigs with erysipelas usually show the characteristic skin lesions and are less depressed than pigs with hog cholera or salmonellosis. Rarely, *A. pleuropneumoniae* and *H. parasuis* may also appear similar.

Other septicemias of pigs:

- Septicemic salmonellosis is characterized by gross bluish-purple discoloration of the skin, especially the ears, some evidence of enteritis, and polypnea and dyspnea.
- Hog cholera is characterized by large numbers of pigs affected quickly, weakness, fever, muscle tremors, skin discoloration and rapid death; convulsions are also common.
- Streptococcal septicemia and arthritis are almost entirely confined to suckling pigs in the first few weeks of life as is septicemia associated with *Actinobacillus suis*.

- Streptococcal endocarditis has a similar age distribution to erysipelas endocarditis and bacteriologic examination is necessary to differentiate them.

Other arthritides of pigs:

The chronic disease characterized by joint disease occurs in pigs of all ages but less commonly in adults and must be differentiated from the following conditions:

- Glässer's disease in pigs is accompanied by a severe painful dyspnea. At necropsy there is serositis and meningitis
- *Mycoplasma hyorhinis* arthritis generally affects pigs less than 10 weeks of age and produces a polyserositis and polyarthritis. However, *Mycoplasma hyosynoviae* can produce simple polyarthritis in growing pigs. In general, the periarticular, synovial, and cartilaginous changes are less severe in these infections compared with erysipelas; however, cultural differentiation is frequently necessary.
- Rickets and chronic zinc poisoning produce lameness in pigs, but they occur under special circumstances and are not associated with fever, and rickets is accompanied by abnormalities of posture and gait that are not seen in erysipelas.
- Foot rot of pigs is easily differentiated by the swelling of the hoof and the development of discharging sinuses at the coronet.

Leg weakness. In recent years there has been a marked increase in chronic osteoarthritis and various forms of "leg weakness" in growing swine, probably related to the increased growth rate resulting from modern feeding and management practices.

### TREATMENT

#### Antimicrobial Therapy

Penicillin and antierysipelas serum (available only in some countries) comprise the standard treatment, often administered together by dissolving the penicillin in the serum. The antiserum lasts about 2 weeks. Penicillin alone is usually adequate when the strain is mildly virulent. Standard dose rates give a good response in the field, but experimental studies suggest that 50,000 IU/kg BW of procaine penicillin intramuscularly for 3 days and preferably 5 days is required for complete chemotherapeutic effect. Most animals are significantly improved within 2 days. Oxytetracycline is also useful, but in a Japanese study, over 70% of the strains were resistant. Chronic cases do not respond well to either treatment because of the structural damage that occurs to the joints and the inaccessibility of the organism in the endocardial lesions. Most strains are susceptible to ampicillin, cloxacillin, benzylpenicillin, ceftiofur, tylosin, enrofloxacin, and danofloxacin. Most strains are resistant to apramycin, neomycin, streptomycin, and spectinomycin and also to sulfonamides and polymyxins.

### CONTROL

Successful control depends on good hygiene (cleaning, disinfection, and separation from feces and contaminated fields); biosecurity (other pigs and other species); reduction of stress, an effective 6-month vaccination policy, preferably two doses, for all animals over 3 months of age, including boars; and rapid diagnosis, quarantine, and treatment. The organism is inactivated by most disinfectants but is never completely eliminated. Effective bird and rodent control is important, especially if they are near feed such as in outdoor herds. Where there are scrape-through systems, there is never complete control. Do not forget that sheep and turkeys may also be a source of infection.

### Eradication

Eradication is virtually impossible because of the ubiquitous nature of the organism and its survival in suitable environments. Complete removal of all pigs and leaving the pens unstocked is seldom satisfactory. Eradication by slaughter of reactors to the agglutination test is not recommended because of the uncertain status of the test.

General hygienic precautions should be adopted. Clinically affected animals should be disposed of quickly, and all introductions should be isolated and examined for signs of arthritis and endocarditis. This procedure will not prevent the introduction of clinically normal carrier animals. All animals dying of the disease should be properly incinerated to avoid contamination of the environment. Although thorough cleaning of the premises and the use of very strong disinfectant solutions is advisable, these measures are unlikely to be completely effective. The organism is susceptible to all the usual disinfectants, particularly caustic soda and hypochlorites. Whenever practicable, contaminated feedlots or paddocks should be cultivated for a spell before repopulating.

Specific-pathogen-free piggeries established on virgin soil may remain clinically free of erysipelas for several years. However, because of the high risk of introduction of the organism, it is advisable to vaccinate routinely.

### Immunization

Because of the difficulty of eradication, biological prophylactic methods are in common use. Immunizing agents available include hyperimmune serum and vaccines.

#### Antierisipelas Serum

The parenteral administration of 5 to 20 mL of serum, with the amount depending on age, will protect in-contact pigs for a minimum of 1 to 2 weeks, possibly up to 6 weeks, during an outbreak. Suckling pigs in herds where the disease is endemic should receive 10 mL during the first week of life and at monthly intervals until they are actively vaccinated, which can be done as

early as 6 weeks, provided the sows have not been vaccinated. Repeated administration of the serum may cause anaphylaxis because of its equine origin. For this reason, it has been withdrawn from sale in many countries.

### Vaccination

There is no fully satisfactory vaccine available for erysipelas because of the strain variation and short duration of immunity, but vaccines have reduced the occurrence of clinical disease. Regular administration at 6-month intervals overcomes this to some extent, but there is always the possibility of a new strain appearing. Most vaccines are formalized whole cultures. Most bacterins are serotype 215, and most of the attenuated live vaccines (only available in some countries, such as the United States and Japan) contain 1a. Vaccines containing serotypes 2 and 10 protect against both *Erysipelothrix* species. Serum-simultaneous vaccination has been largely replaced by the use of bacterins, for which lysate and absorbate preparations are available, or by the use of attenuated or avirulent live-culture vaccines, which are administered orally or by injection. The use of live-culture vaccines is prohibited in many countries because of the risk of variation in virulence of the strains used and the possibility of spreading infection.

None of these vaccines gives lifelong protection from a single vaccination, and the actual duration of protection achieved following vaccination varies considerably. It should not be assumed that protection lasts longer than 6 months. The recent identification of the region responsible for protective immunity should improve these vaccines in future. Most of the commercially available vaccines are formalin-treated whole cultures with an adjuvant.

There is considerable difficulty in the experimental evaluation of the efficacy of erysipelas vaccines. Strain differences in immunogenicity and variation in host response to vaccination attributable to innate and acquired factors influence this evaluation, as does variation in virulence of the challenge strain and the method of challenge. A recent experiment has shown that an antigen of serotype 1a will elicit a protective response to a challenge with serotypes 1a and 2b. Similar factors are involved in the variations seen in field response to the use of these vaccines. Cross-protection of mice and pigs given a live-organism vaccine against 10 serovars of ER has been demonstrated. The use of culture filtrate from a broth culture of an attenuated strain of the organism has been evaluated to produce cross-protective antibody.

Vaccination will reduce the incidence of polyarthritis attributable to erysipelas, but not mild cases of arthritis. Passively acquired maternal immunity may significantly affect the immune response to vaccination in the young piglet. Also, the immunity

engendered by standard vaccines is not uniformly effective against all strains. Vaccine breakdown occurs when the vaccine type is very different from that occurring on the farm. For example, a vaccine made from serotypes 1 and 2 will protect against serotype 10 (ET), but it is not certain that it will protect against serotype 20. Under certain conditions, some unusual serotypes have the potential for causing disease in animals vaccinated with vaccines containing the common serotypes. This possibility cannot be ignored and must be considered when vaccination failures occur. Nevertheless, these vaccines are valuable immunizing agents in field situations.

### Vaccination Program

Following a single vaccination at 6 to 10 weeks of age, significant protection is provided to market age. However, a second "booster" vaccination given 2 to 4 weeks later is advisable. In herds where sows are routinely vaccinated before farrowing, a persisting maternal passive immunity (6 to 9 weeks) may require that piglet vaccination be delayed until 10 to 12 weeks of age for effective active immunity.

Replacement gilts and adults should also be vaccinated. Bacterins are effective, and field evidence suggests that vaccination provides immunity for approximately 6 months. Sows should be vaccinated twice yearly, preferably 3 to 6 weeks before farrowing, because this will also provide significant protection against the septicemic form in young sucklers. If possible, a closed herd should be maintained. Abortion may occur sporadically following the use of live vaccines.

Vaccination is subcutaneous in the skin behind the ear or at the axilla and the flank. Reactions at the site of injection are not uncommon. Swelling with subsequent nodule formation and occasional abscessation may occur following the injection of bacterins, and modified live vaccines may produce hemorrhage in the skin at the injection site. Granulomatous lesions may occur following the use of oil-based vaccines. There is little evidence that vaccination increases the incidence of arthritis. It has been suggested by a very limited study that maternal antibody does not appear to interfere with the vaccination. These vaccines were also used in pigs with PRRS and found to be safe and effective. In those cases where the vaccine has not worked, it may be that the correct serotype was not in the vaccine or the administration and storage instructions were not followed.

## ACTINOBACILLUS SEPTICEMIA IN PIGLETS

*Actinobacillus suis* and *Actinobacillus equuli* sometimes cause a fatal septicemia in piglets of 1 to 6 weeks of age. Occasionally in older animals there may be skin lesions or necrotizing pneumonia. It is probably underdiagnosed because most cases are possibly assumed to be *S. suis*.

### ETIOLOGY

It is gram negative and produces small translucent colonies on blood agar. In Canada, two groups appear, one associated with healthy pigs and the other with severely diseased pigs. The organism also produces the Apx toxins I and II. The organism should be distinguished from APP biotype II.

### EPIDEMIOLOGY

It is probably widespread. In one study 94% of the tested herds were positive,<sup>1</sup> but no clinical cases were reported. It is reported infrequently. The introduction of carrier animals may be the cause of infections. Maternal antibodies are usually present in colostrum. Active antibodies are produced at 6 to 8 weeks of age.

### PATHOGENESIS

The organism is probably carried in the nasal cavity and under stress or in the absence of immunity becomes septicemic. It may die at this point or may develop as endocarditis or arthritis. The virulence factors of *A. suis* are unknown, but outer membrane proteins are thought to be important.<sup>2</sup>

### CLINICAL SIGNS

Sudden death may occur and may be attributed to hypoglycemia, starvation, or crushing and not investigated.

Piglets may be pyrexic and have dyspnea, cough, lameness, wasting, abscesses, neurologic components, and cyanosis, with congestion and hemorrhages on the skin and possibly swollen joints. Recovered animals have poor growth. Older animals are not often affected but can be if the bacteria are entering a susceptible herd for the first time. Finishers may also die suddenly, and in the older animals, the condition may resemble swine erysipelas.

### NECROPSY FINDINGS

Animals may have petechiae on the lung; microabscesses throughout the body, particularly the lungs; and skin discoloration. Chronic cases may have endocarditis, pericarditis, pneumonia, or

polyarthritis. Histologically, the lesions are often microabscesses with central necrosis surrounded by neutrophils with bacterial thromboemboli.

## DIAGNOSIS

The clinical signs and pathology are not diagnostic. The infection can be confirmed by pure culture from the liver, kidney, or heart blood and from lesions. Quite often, the organism can be recovered from tonsils of young pigs, vaginas of sows, and the preputial diverticulum of boars. Because there is production of Apx I and II, PCR testing may be useful, but it should be remembered that the level of toxin production is much lower in *A. suis*.

A real-time TaqMan PCR assay for the detection of *A. suis* has been described.<sup>3</sup> It was highly specific, sensitive, and reproducible and gave results within 3 hours.

## TREATMENT

A wide range of antibiotics have proved useful, and most infections clear up in 2 to 5 days. Ceftiofur, gentamicin, and trimethoprim/sulfadiazine seem to be the drugs of choice. Resistance to amoxicillin, ampicillin, and tetracyclines has been recorded.

## KLEBSIELLA PNEUMONIAE SEPTICEMIA IN PIGS

*Klebsiella pneumoniae* subspecies *pneumoniae* (KPSP) is an opportunist pathogen causing mastitis in sows but has recently been recognized in the United Kingdom as a cause of septicemia in preweaned pigs in outdoor herds. The organism is commensal in the healthy porcine alimentary tract and is present in the environment in soil and water. It can cause infections in humans, but it is not a recognized zoonosis and is more likely to occur in immunocompromised patients in hospitals. Pigs are found dead, with lesions consistent with septicemia and pure/predominant growth of KPSP isolated from internal sites.

The condition has been seen in preweaned pigs 17 to 28 days of age, in good bodily condition, and occasionally they are found in extremis, recumbent, with cyanosis and mouth breathing, with death within 30 minutes. All the cases occurred in outdoor commercial units in the summer (June through September). The mortality is estimated to be 1% to 4%, with one or a whole litter succumbing. The outbreak lasts from a period as short as 7 to 10 weeks to others lasting for more than 12 weeks.

The lesions can only be described as non-specific, with the most common finding being the presence of fibrin strands in the abdominal cavity. Other findings include ventral skin reddening, serosal hemorrhages, pleural effusions, and reddened lymph nodes. Standard bacteriologic methods recover KPSP from several visceral sites.

The bacteria recovered have an innate resistance to ampicillin. Once weaned, the piglets do not appear to suffer from the condition.

## CHLAMYDIAL INFECTION IN THE PIG

*Chlamydia* spp. infection in the pig has been known in pigs since 1955. These organisms may cause conjunctivitis, pneumonia, pleurisy, pericarditis, polyarthritis, orchitis, infertility, abortion, and the birth of weak piglets. They are also thought to be a cause of enteritis. Many infections are inapparent. Diagnostic laboratories may also not routinely test for *Chlamydia*, and therefore the diagnoses of such infections may be greatly underestimated.

The transmission of *C. abortus* from pigs to humans has not been proven but cannot be excluded. *Parachlamydiae* are probably not involved in abortion, and their potential as a zoonotic agent is also unknown.

## ETIOLOGY

The Chlamydiaceae family includes the genus *Chlamydia*, with nine species. *Chlamydophila* and *Chlamydia* both occur in the pig, as do *Chlamydia*-like *Parachlamydiae* spp. and *Waddlia* spp.<sup>1</sup>

The several species occurring in the pig have been identified by PCR, gene sequencing, DNA probes, and immunohistochemistry.

*Chlamydia suis* has been particularly associated with growing pigs with or without diarrhea and finishing pigs with conjunctivitis.<sup>2,3</sup> Infection is sporadic in pigs, but evidence for infection has been found in boar semen, fetuses, intestinal samples, reproductive tissues, and lungs from pigs in Germany, Switzerland, and Estonia.<sup>4</sup> Although it is considered that the intestine is the natural reservoir for this species, it may also cause lung function disorders, together with pleurisy, pericarditis, polyarthritis, and polyserositis, and reproductive problems. *C. suis* was formerly known as the porcine serovar of *C. trachomatis*, and the only known host is the pig. There is a high genetic diversity in the pig.

*Chlamydia pecorum* is associated with enteritis.

*Chlamydia psittaci* has been associated with respiratory and reproductive problems in pigs.

*Chlamydia abortus* has been associated with aborted material.<sup>5</sup> *Chlamydia trachomatis* has been isolated from the uteri of sows with conception failure.

## EPIDEMIOLOGY

They have been found in pigs in all continents, but particularly North America, Europe, and Asia. Recently, studies have described them in Poland, Italy, Austria, Germany, Scotland, Switzerland, and Belgium. Pigs of all ages may be affected. The presence of antibodies is widespread in the pig population. They have also been found in wild boar; for example, a study of wild boar in Thuringia in Germany found three species: *abortus*, *psittaci*, and *suis*.

They can be spread by aerosol, direct contact, and ingestion of contaminated feed. Venereal transmission may be particularly important. *Chlamydiae* may survive for a long time in the environment, especially if there is a moist organic base. *Chlamydia* have been found to survive up to 30 days in feces and bedding.

Vertical transmission can occur if infections are contracted in utero. Flies and dust are also thought to transmit the organism. There is a suspicion that they may be transmitted by birds. In the United Kingdom, an outbreak of suspected brucellosis subsequently turned out to be chlamydiosis associated with the arrival of thousands of gulls at the morning feeding time of sow rolls to the sows held in outside paddocks. In experimental infections with *C. suis*, it has been found that the diarrhea was dose dependent. In a study of pigs with intestinal lesions, using PCR and immunohistochemistry, it was found that although *C. suis* was identified, there was no correlation with isolation of the organism and clinical signs.<sup>6</sup>

There is no doubt that the occurrence of the agent may be associated with the immunosuppressive disorders that affect the pig (PRRS, PCV2, and SIV). A large pig production unit in Estonia with a problem of post-weaning multisystemic wasting syndrome (PMWS) and PCV2 infection and *Chlamydia* was studied.<sup>7</sup> It was found that chlamydial disease occurred 3 days after the introduction of Swedish boars and PMWS 11 days after the introduction.

## PATHOGENESIS

The development of lesions may depend on different factors, such as the virulence of the strain, infectious dose, route of infection, age of the animal, and immunologic status of the host.

Experimental infection of the respiratory tract results in acute exudative or interstitial pneumonia within 4 to 8 days of infection.

The organism is an obligate intracellular parasite characterized by a unique developmental cycle. Elementary bodies (EBs) attach to the host cell by endocytosis and differentiate into noninfectious metabolically active reticulate bodies (RBs). These multiply by binary fission, resulting in mature chlamydial intracytoplasmic inclusion bodies approximately 48 to 72 hours after infection. The

RBs reorganize to form infective EBs, which are released by rupture of host cells and can initiate new cycles. There are also intermediate bodies between EBs and RBs.<sup>8</sup> There are also mostly enlarged RB-like structures called aberrant bodies, and these may allow the persistence of Chlamydiaceae. These aberrant bodies may occur when there are dual infections with other agents.<sup>9</sup> The organism lives in the mucosal epithelial cells, placental trophoblastic epithelium, and monocytes and macrophages.

*C. suis* enteritis may develop within 4 to 5 days following infection and may last for up to 8 days. Villus atrophy develops, and antibodies occur within 2 weeks.

Chlamydial replication was particularly marked at 2 to 4 days following infection and primarily located in the small intestinal epithelium.<sup>10</sup> Further sites of replication included large intestinal enterocytes, lamina propria, and tunica submucosa and mesenteric lymph nodes.

### CLINICAL SIGNS

The clinical signs may vary considerably because of the early development of immunity. They are also variable depending on the presence of concurrent infections, such as PRRS, PCV2, and SIV, and in some cases there appears to be an association with *Lawsonia* and *Brachyspira* infections. In general, most infections are inapparent, but respiratory and systemic infections may result in inappetence and pyrexia (39–41°C, [103–106°F]). Dyspnea, conjunctivitis, and pneumonia may occur and last 4 to 8 days, accompanied by pleurisy and pericarditis with occasional lameness. Clinical signs following experimental infection included moderate to severe diarrhea, slight and transient anorexia, weakness, and body-weight loss.

Pigs experimentally infected with an aerosol challenge of *C. suis* resulted in severe acid-base disturbance characterized by respiratory acidosis and strong ion metabolic acidosis secondary to anaerobic metabolism and hyperlactatemia. Maximal changes were seen at 3 days following inoculation, when severe clinical signs of respiratory dysfunction were evident.<sup>14</sup>

### NECROPSY FINDINGS

The pathologic role of the organism has yet to be clearly defined. However, confirmed cases may show consolidation in the lungs (particularly the caudal lobes), pericarditis, pleurisy, splenic enlargement, synovitis, orchitis, and dead fetuses and mummified piglets. The enteritis is typified by watery contents, undigested food in the stomach, villus atrophy, multifocal necrosis of the villi of the distal jejunum in particular and the ileum, and membranous colitis in the large intestine. Histologically, the villus atrophy can be severe, with villus tip erosions, necrosis of the villi, inflammatory changes, and

lymphangitis. Chlamydial antigens can be demonstrated in the enterocytes.<sup>10</sup>

### DIAGNOSIS

The clinical signs may be suggestive. Bear in mind that most laboratories do not routinely test for *Chlamydia*.

Preparations of intestine, lungs, and other suspect tissues can be stained by Koster's method or by MZN stains, but the acid-fast result is not specific for *Chlamydia* (*Brucella* and *Coxiella* are also acid fast).

Recently, species-specific nucleic acid amplification tests have been developed. These, including PCRs and DNA probes, can identify strains and species. A multiplex PCR has been developed for the usual four species.<sup>11</sup> These PCR techniques target the *omp A* gene, the 16S–23S RNA, or the *inc A* gene.<sup>12</sup> Immunofluorescence and immunoperoxide methods have been developed for frozen and fixed tissues.

Serology using CF tests (limited use in pigs) or ELISAs can confirm infection, particularly if rising titers can be seen on paired samples. The kits do not allow identification of species and strains, have a high cost, and lack sensitivity and specificity.

### TREATMENT

Tetracyclines are the drug of choice, but resistant strains are not unknown. There is now thought to be a stable tetracycline-resistant phenotype.<sup>13</sup> Second-choice treatments are quinolones or macrolides.

A recent study showed that short-term antimicrobial treatment at dosages recommended for treatment for other bacterial infections in the pig was not effective in the treatment of *Chlamydiosis*. Such treatment did not eradicate subclinical infections.<sup>14</sup> However, it is most important that treatment should last at least 21 days at therapeutic levels to achieve effective eradication.

### CONTROL

Proper cleaning and disinfection in indoor units with effective rodent and bird control is essential. Disinfection with a 1:1000 dilution of a quaternary ammonium compound will work, as will a solution of 7% isopropyl alcohol, 1% Lysol, 1:100 bleach, or chlorophenols. Outside pig production requires the same techniques but is infinitely more difficult to achieve. In some cases in the United Kingdom, one of the most effective techniques is to get all outside sows fed at the same time because this spreads the descending gull population over several outdoor sites.

Probiotic strains of *E. faecium* have been used to reduce carry-over infections from sows to piglets.

## Multi-Organ Diseases Due to Viral Infection

### FOOT-AND-MOUTH DISEASE (APHTHOUS FEVER)

#### SYNOPSIS

**Etiology** Foot-and-mouth disease virus, an aphthovirus.

**Epidemiology** Affects ruminants and pigs. Highly contagious, usually low mortality but great economic impact worldwide.

**Clinical signs** Fever, profuse salivation, vesicles in mouth and feet, sudden death in young animals.

#### Clinical pathology/diagnostic confirmation

Virus isolation, serology and reverse-transcription polymerase chain reaction (RT-PCR) detection. Typing confirmed in a reference laboratory.

**Lesions** Vesicular, erosive/ulcerative stomatitis and esophagitis, vesicular/ulcerative dermatitis (feet and teats); in neonates, interstitial mononuclear and necrotic myocarditis.

#### Differential diagnostic list

Vesicular stomatitis  
Vesicular exanthema  
Swine vesicular disease  
Rinderpest  
Bovine viral diarrhea

**Treatment** None except symptomatically.

**Control** Mass vaccination with killed vaccines in endemic areas, eradication by slaughter when feasible, and strict quarantine during outbreaks.

### ETIOLOGY

Foot-and-mouth disease (FMD) is a highly contagious disease of cloven-footed animals and is caused by the foot-and-mouth disease virus (FMDV), a small, nonenveloped virus that belongs to the genus of *Aphthovirus*, family Picornaviridae. The picornaviruses include the human rhinovirus causing the common cold and poliovirus causing polio. FMDV occurs as seven major distinct serotypes: A, O, C, Southern African Territories (SAT) 1, SAT 2, SAT 3, and Asia 1. Each serotype has multiple subtypes with varying antigenicity and degrees of virulence, especially within the A and O types. Because there is no

cross-immunity between serotypes, immunity to one type does not confer protection against the others. This presents difficulties for vaccination programs. Furthermore, there can be great changes in antigenicity between developing serotypes; virulence may also change dramatically. There are also biotypical strains that become adapted to particular animal species and then infect other species only with difficulty. There are strains that are much more virulent for pigs (so-called porcophilic strains), some for buffalo, and some even for tropical breeds of cattle, which generally react only mildly to endemic strains. Newer techniques for identifying subtypes involve enzyme-linked immunosorbent assay (ELISA), reverse-transcriptase polymerase chain reaction (RT-PCR) and nucleotide sequence analysis.

## EPIDEMIOLOGY

### Occurrence

FMD affects all cloven-footed animals, and outbreaks are reported from Africa and Asia and less frequently from South America and parts of Europe. The disease can occur in any country or continent, but New Zealand and Australia have always been disease-free, and North America has been so for about 60 years. In nonendemic countries, FMD often occurs as devastating epidemics resulting in great economic losses from the control measures that must be instituted to regain disease-free status. Worldwide, countries have been classified into categories with respect to FMD occurrence as follows<sup>1</sup>:

- Endemic, as in most of sub-Saharan Africa and Asia
- Intermediate, sporadic, as in Eastern Europe and parts of Asia
- Free with vaccination or multizone, as in most of South America
- Free with virus in game parks, as in South Africa
- Free, as in North America, Western Europe, and Australia

By 2009, 70 countries in the world were officially recognized by the OIE as free from FMD with or without vaccination, whereas more than 100 countries were considered as either endemically or sporadically infected with the disease.<sup>2</sup> Three examples of recent major outbreaks since the turn of this century are as follows:

1. An outbreak in Great Britain in 2001 spread to Ireland, France, and the Netherlands before it was eventually contained. The outbreak was traced to illegal import to the United Kingdom of infected meat products. Spread within the country and to other countries was mostly through the movement of livestock not showing obvious clinical signs. Over 10 million animals were culled or died.
2. An outbreak occurred in the Republic of Korea in 2010/2011, during which more than 3 million animals were destroyed.<sup>3</sup>

3. An outbreak in Japan in 2010 involved cattle and pigs. Nearly 300,000 animals were culled, but the epidemic was contained within a localized area and was eradicated within 3 months.<sup>4</sup>

As for North America, the last outbreak in the United States was in 1929, Canada in 1951 to 1952, and Mexico in 1946 to 1954. During the outbreaks, movement of cattle and cattle products between the United States and either Canada or Mexico was brought to a standstill. The importance of the Darien Gap in maintaining the disease-free status of North America is well known. This tract of impassable territory between Colombia and Panama prevents any chance of direct contact between cattle populations in North and South America.

### Prevalence

There are no reliable figures for the prevalence of FMD in different countries. Cases in endemic countries may go unreported unless they occur as outbreaks in previously uninfected regions or herds. Worldwide, the cumulative incidence of FMD serotypes show that six of the seven serotypes (O, A, C, SAT-1, SAT-2, SAT-3) have occurred in Africa, Asia contends with four (O, A, C, Asia-1), South America with only three (O, A, C), and the Middle East periodically has incursions of types SAT-1 and SAT-2 from Africa.<sup>5</sup> Thus, the serotypes and strains are distributed into several major virus ecological reservoirs, each containing distinct regional viral strains from which new variants may emerge.<sup>2</sup> These regional differences are more attributable to the pattern of the meat trade and livestock movements than to any inherent properties of the serotypes. Overall, outbreaks of types O and A occur more frequently than the others, and recently, outbreaks of type C have become uncommon. Whereas the disease in endemic countries may not be clinically apparent and therefore not be promptly reported, it usually occurs as outbreaks in nonendemic countries and rapidly spreads from herd to herd, making international news, before it is controlled.

### Morbidity and Case-Fatality Rate

The morbidity rate in outbreaks of FMD in susceptible animals can rapidly approach 100%, but some strains are limited in their infectivity to particular species, mostly cattle and pigs. However, the case fatality is generally very low, about 2% in adults and 20% in young stock. Nonetheless, severe outbreaks of a more violent form sometimes occur, as in the 1997 Taiwan outbreak in pigs, where case fatality was 18% and reached 100% in piglets, and the outbreak in calves of exotic dairy animals in Nigeria in the 1970s. During outbreaks in nonendemic countries, most deaths are attributable to a slaughter policy that usually involves all susceptible animals and herds in

contact with, or within a certain radius of, the infected herd.

### Methods of Transmission

FMD is transmitted by a variety of methods between herds, countries, and continents, but spread from one animal to another is by inhalation or by ingestion. In endemic areas, the most important method of spread is probably by direct contact between animals moving across state and national boundaries as trade or nomadic cattle. In nonendemic areas such as Europe, the first introduction to a new area is often via pigs that contract infection by ingestion of infected meat scraps. Spread from these pigs to cattle is via movement of people, abattoir waste, or animals. Further spread between cattle is more likely to be by airborne means. The virus can persist in aerosol form for long periods in temperate or subtropical climates but not in hot and dry climates. The speed and direction of the wind are important factors in determining the rate of airborne spread. Humidity is also important, but rain as such appears not to be. In the most favorable circumstances, it is now estimated that sufficient virus to initiate an infection can be windborne as far as 250 km (156 miles). There are peaks of spread at dawn and dusk. Animals in the United Kingdom are thought to be vulnerable to airborne transmission of the virus from the European mainland. It has been shown that pigs are the most potent excretors of airborne virus and cattle the most susceptible to airborne infections. During the 2001 outbreak in England, there was no indication of airborne spread to the mainland, perhaps because ruminants rather than pigs were mostly affected.

The risk of airborne infection varies with the FMD serotype and animal species. In a study involving serotypes A, O, and Asia 1, it was found that each serotype demonstrated distinct transmission characteristics and required different exposure times to achieve successful contact transmission.<sup>6</sup> In that study, serotype A required less time of exposure (4 hours) for contact transmission, had the highest levels of viral shedding in saliva and nasal swabs, and also had the highest virus levels in room air compared with serotypes O and Asia 1. Furthermore, under experimental conditions in which virus from affected pigs was given via the intranasal route to cattle, sheep, and pigs, cattle were found to require the least amount of virus to cause infection and give rise to lesions, followed by sheep, whereas pigs were not readily infected by the intranasal route.<sup>7</sup>

In cattle, the first site of virus infection and subsequent rapid multiplication is the pharynx, and the virus is first detectable in the oropharyngeal fluid. The onset of clinical signs is associated with high levels of virus in the blood, oropharyngeal fluid, and nasal fluid.<sup>8</sup> Following a few days of viremia, the virus appears in milk and saliva for up to 24

hours before vesicles appear in the mouth. All other excretions, including urine, feces, and semen, may be similarly infective before the animal is clinically ill and for a short period after signs have disappeared. However, the period of maximum infectivity is when vesicles are discharging because vesicular fluid contains the virus in maximum concentration. Although it is generally conceded that affected animals are seldom infective for more than 4 days after the rupture of vesicles, except insofar as the virus may persist on the skin or hair, some animals may remain as **carriers** and are important in the epidemiology of the disease in the field. In cattle, carriers may develop during convalescence from the natural disease or, more important, in vaccinated animals that are exposed to infection. Up to 50% of cattle, sheep, and goats may become carriers, but pigs do not.

The nasopharynx is the main site for persistence of the FMDV, and erratic low-level excretion may occur for up to 2 years. Using molecular techniques, intact, nonreplicating virus was found in the germinal centers of lymph nodes in the oropharyngeal region for up to 38 days.<sup>9</sup> The virus may also persist in mammary tissue for 3 to 7 weeks. Wild fauna may serve as the FMDV reservoir, and in southern, central, and eastern Africa, the African buffalo (*Syncerus caffer*) is a significant reservoir. Similarly, viral persistence may be a common outcome in the farmed Indian buffaloes (*Bubalis bubalis*) following FMDV Asia 1 infection.<sup>10</sup>

Humans are often a vehicle for transmission of the virus. It has been recovered from the nasal mucosa of persons working with infected cattle for up to 28 hours after contact. Nose-blowing did not eliminate it, nor did cotton face masks prevent infection. In a more recent study, the virus could not be detected in nasal secretions 12 hours after contact, and contaminated personnel could not transmit the disease to susceptible pigs and sheep after they had showered and changed into clean outer wear.

The disease is **spread from herd to herd** either directly by the movement of infected animals or indirectly by the transportation of FMDV on inanimate objects, including farm equipment, uncooked and unprocessed meat products, and other animal products, including milk. The pH and temperature of milk significantly affect survival, which may be as long as 18 hours. Flash pasteurization procedures, as distinct from the holding method, do not inactivate the virus in milk—neither does evaporation to milk powder or processing into butter, cheese, or casein products. The risk of spreading FMDV through importation of vaccinated cattle, sheep, and pigs is extremely small, and the risk from products derived from vaccinated animals is even smaller, provided appropriate risk mitigation measures are applied.<sup>11</sup>

Introduction of FMD into a herd or country as a result of the use of infected

cattle semen for artificial insemination is possible. The virus can also be detected in the semen of infected boars, but this has not been a means of transmitting it. Similarly, it is not transmitted through the transfer of embryos from viremic donor cows.

Epidemics in free areas occur intermittently and from a number of sources. In England it was estimated that outbreaks arose in the following manner:

- Meat products used as pig food—40%
- Completely obscure causes—28%
- Transportation by birds—16%
- Contact with meat and bones other than swill—9%
- Unknown causes (probably swill)—7%

The greatest danger appears to be from uncooked meat scraps fed to pigs. A common pattern is the importation of the virus in sheep meat from sheep that showed no illness, an initial infection in pigs, and then spread to cattle. However, more unusual methods of introduction must not be disregarded. With modern methods of transport, farm workers can carry the virus long distances in their clothing. In Tanzania, where the disease is endemic, roads played a dominant role in epidemic situations between 2001 and 2006, and FMD occurrence was more related to animal movement and human activity via communication networks than transboundary movements or contact with wildlife.<sup>12</sup> Human activity was also the main factor in the spread of the FMD epidemic in South Korea in 2010/2011.<sup>3</sup> However, movement restrictions during the 2010 FMD outbreak in Japan proved insufficient to prevent spread of the disease for about 3 months.<sup>13</sup>

## Risk Factors

### Host Factors

The disease is most important in cattle and pigs, but goats, sheep, and buffaloes in India and llama in South America are also affected. Some strains of the virus are limited in their infectivity to particular species. Although cattle, sheep, and goats can be carriers, they are not regular sources of infection, and early studies in Kenya showed that goats were infrequent carriers, and sheep not at all. Immature animals and those in good condition are relatively more susceptible, and hereditary differences in susceptibility have also been observed. Horses are not susceptible to the disease. Old World camels (dromedaries) are also not susceptible, but New World (Bactrian) camels can contract the disease.<sup>14-15</sup>

A variety of **wildlife species**, such as the deer in England, the water buffalo (*Bubalus bubalis*) in Brazil, and wild ungulates in Africa, become infected periodically but are thought to play little or no role as reservoirs of infection for domestic animals. A notable exception is the **African buffalo** (*Syncerus caffer*), probably the natural host of the SAT types of the virus and the major source of

infection for cattle in southern Africa. The disease in buffalo populations is mild, but the infection rate is often high and can be persistent. On the other hand, the domesticated **Asian buffalo** shows typical clinical disease and spread from buffalo to other species. Small rodents and hedgehogs in Europe and capybaras in South America may also act as reservoirs. **Yaks** that live in high altitudes in China (*Bos grunniens* yaks) are susceptible and can keep carrier status for at least 8 months.<sup>16</sup> In Bulgaria, infection in **wild boar** was found to be a short-lived event that failed to develop into a large-scale epidemic.<sup>17</sup> Feral swine in the United States are susceptible, they can transmit the disease to domestic swine, and FMD viral RNA can persist in their tonsils up to 36 days following infection, by which time virus isolation is negative.<sup>18</sup> The North American bison and elk are also susceptible, but the virus may not be isolated from animals past 28 days postinoculation.<sup>19</sup>

## Environmental and Pathogen Factors

The virus is resistant to external influences, including common disinfectants and the usual storage practices of the meat trade. It may persist for over 1 year in infected premises, for 10 to 12 weeks on clothing and feed, and up to a month on hair. It is particularly susceptible to changes in pH away from neutral. Sunlight destroys the virus quickly, but it may persist on pasture for long periods at low temperatures. Boiling effectively destroys the virus if it is free of tissue, but autoclaving under pressure is the safest procedure when heat disinfection is used. The virus can survive for more than 60 days in bull semen frozen to  $-79^{\circ}\text{C}$  ( $-110^{\circ}\text{F}$ ). In general, the virus is relatively susceptible to heat and insensitive to cold. Most common disinfectants exert practically no effect, but sodium hydroxide or formalin (1% to 2%) or sodium carbonate (4%) will destroy the virus within a few minutes.

All uncooked meat tissues, including bone, are likely to remain infective for long periods, especially if quick-frozen, and to a lesser extent meat chilled or frozen by a slow process. The survival of the virus is closely associated with the pH of the medium. The development of acidity in rigor mortis inactivates the virus, but quick-freezing suspends acid formation, and the virus is likely to survive. However, on thawing, the suspended acid formation recommences, and the virus may be destroyed. Prolonged survival is more likely in viscera, bone marrow, and blood vessels and lymph nodes, where acid production is not so great. Meat pickled in brine or salted by dry methods may also remain infective. For example, dry-cured Serrano and Iberian hams from experimentally infected pigs were shown to contain viable virus for up to 6 months. Fomites, including bedding, mangers, clothing, motor tires, harness, feedstuffs, and hides, may also

remain a source of infection for long periods. There are claims that the virus can pass unchanged through the alimentary tracts of birds, which may thus act as carriers and transport infection for long distances and over natural topographic barriers such as mountain ranges and sea.

Some outbreaks in Europe have been associated with vaccine virus either accidentally escaping from the laboratory or that was incompletely inactivated. The 2007 outbreaks in southern England were caused by a derivative of a virus strain handled in two nearby FMD laboratories.<sup>20</sup>

### Immune Mechanism

In endemic areas, periodic outbreaks occur that sweep through the animal populations and then subside. A 6-year epidemic cycle was demonstrated in India in the 1990s. This was probably as a result of the disappearance of immunity that develops during an epidemic and the sudden flaring up from small foci of infection when the population becomes susceptible again. Immunity after natural infection lasts for 1 to 4 years in cattle and for a shorter time in pigs. When outbreaks follow each other in quick succession, the presence of more than one strain of virus should be suspected. In countries where general vaccination is practiced every year, outbreaks are usually associated with different strains imported in carrier animals or infected meat.

Studies of the interaction of FMDV with cells mediating the early, innate immune response of the host have shown that the virus has a distinct inhibitory effect on the response of the cells.<sup>21</sup> Following aerogenous administration of the virus, cattle were shown to develop a rapid and vigorous local antibody response throughout the respiratory tract in 4 to 5 days postinfection, and this led to IgM-mediated virus clearance.<sup>22</sup>

### Experimental Reproduction

The clinical signs and lesions of FMD can be reproduced by rubbing virus-containing material on the oral mucosa of susceptible cattle or by intradermal inoculation into the dorsum of the tongue. The disease can easily spread from infected to susceptible animals housed in close proximity (cohabitation). With mice and guinea pigs, inoculation of footpads of hindfeet is preferred (see “Clinical Pathology” section).

### Economic Importance

With the possible exception of bovine spongiform encephalopathy (mad cow disease), FMD is the most feared animal disease in the developed world, even though the mortality rate is low. This is because it is the most contagious disease of livestock, and it has a great potential for causing severe economic loss in high-producing animals. Losses occur in many ways, although loss of production, the expense of eradication, and the interference

with movement of livestock and meat between countries are the most important economic effects. There are also significant losses in agriculture and tourism as a result of restriction on human movement. The 2001 outbreak in the United Kingdom was eradicated within 7 months but resulted in the death of nearly 10 million livestock, with losses of up to 8 billion pounds sterling (about US\$12 billion). In the United States the median economic impact of an FMD outbreak in a dairy herd in California was estimated to result in national agriculture welfare losses of up to \$69 billion if the outbreak was not detected within 21 days.<sup>23</sup> However, in unimproved or low-grade *Bos indicus* cattle reared under an extensive or a nomadic system of management, or in pigs in some southeast Asian countries, FMD is often less severe and has fewer effects for the subsistent producer. Nevertheless, because of its severity in exotic or improved breeds and because of its effects on international trade, FMD control and eradication in such countries will still result in a strong benefit–cost ratio in places like Thailand.

### Zoonotic Implications

Humans are thought to be slightly susceptible to infection with the virus, and vesicles may develop in the mouth or hands. Very few cases have been reported, even among people working with infected carcasses and at laboratories. However, humans and particularly their clothing can be vehicles for transmission to animals.

### Biosecurity Concerns

Because FMD is highly contagious, there are biosecurity concerns regarding intentional or accidental introduction of the virus into nonendemic countries. Intentional introduction would be a form of agroterrorism, and this would be devastating in any country that is FMD-free because it would probably take some days before the disease would be recognized and much longer before it could be stamped out. Laboratories working with FMD virus or producing FMD vaccines and reagents must comply with OIE requirements for Containment Group 4 pathogens to ensure that there is no escape of the virus. There are also strict regulations for shipping diagnostic samples to national or international laboratories.

### PATHOGENESIS

The pathogenesis of FMD has been extensively studied and was recently reviewed.<sup>24–25</sup> The surface-exposed capsid proteins (VP1, VP2, and VP3) of the virus determine its antigenicity and the ability of the virus to interact with host receptors and cause disease.<sup>26</sup> Although strain and species differences have been reported, the basic pathogenesis involves the following three phases: (i) previremic phase characterized by infection and replication at the primary

replication sites or sites, (ii) viremic phase with generalization and vesiculation at secondary infection sites, and (iii) postviremia/convalescent phase including resolution of clinical disease that may result in long-term persistent infection.<sup>24</sup>

The previremic phase lasts for about 3 days depending on the infecting dose and the strain of virus and the host. Infection of cattle, sheep, and other ruminants generally occurs via the respiratory route by aerosolized virus attaching to cells lining the route. Infection can occur less efficiently through abrasions on the skin or mucous membranes. Pigs are much less susceptible to aerosol infection and usually become infected by eating FMDV-contaminated food or by direct contact with infected animals, or by being placed into recently infected premises. Following exposure, FMDV particles first attach to mucosal epithelial cells and penetrate into the cytoplasm of the cell. To survive in the host, the virus has evolved a mechanism to block host innate immunity by temporarily blocking interferon (IFN) response and influencing the ability of natural killer cells to recognize and eliminate FMDV-infected cells. This allows the virus to replicate rapidly for a few days, cause viremia, and become highly contagious.<sup>27–28</sup> There is no consensus in reports regarding the anatomic sites involved in early virus replication.<sup>29</sup> The primary replication site in cattle is probably the epithelial cells of the nasopharyngeal region and subsequent widespread replication in the lungs coinciding with onset of viremia.<sup>30</sup> In experimentally infected pigs, FMDV accumulated in mandibular lymphoid tissue up to 6 hours after infection and in the tissues draining the mandibular lymph node and tonsil, then disseminated throughout the body, where epithelial cells were the favored sites of (secondary) replication.<sup>31</sup>

Irrespective of the portal of entry, once infection gains access to the bloodstream (viremic phase), the virus is widely disseminated to many epidermal sites, probably in macrophages, but gross lesions develop only in areas subjected to mechanical trauma or unusual physiologic wear, such as the epithelium of the mouth and feet, the dorsum of the snout of pigs, and the teats. Characteristic lesions develop at these sites after an incubation period of 1 to 21 days (usually 3 to 8 days in most species). The initial phase of viremia is often unnoticed, and it is only when localization in the mouth and on the feet occurs that the animal is found to be clinically abnormal. Furthermore, the virus can be excreted in exhaled air, saliva, milk, semen, urine, and feces during this phase for about 2 weeks.

The postviremic phase is characterized by healing of lesions. The process can be rapid in the oral mucosa but often slow in the feet. Associated mastitis in dairy animals can also become chronic. Most adult animals will

recover from FMD, become immune to the serotype for years, and no longer be contagious. A few recovered ruminants can become carriers for several months, whereas the African buffalo are lifelong carriers. The virus is thought to persist in the oropharyngeal region, the germinal centers of lymph nodes,<sup>32</sup> and possibly in dendritic cells in lymphoid organs.

The experimental disease in sheep is characterized by an incubation period of 4 to 9 days after contact or 1 to 3 days after virus inoculation. Thereafter, viremia occurs at 17 to 74 hours and hyperthermia from 17 to 96 hours. Clinical signs are serous nasal discharge, salivation, and buccal lesions in 75% of cases and foot lesions in 25%. At the end of viremia, the animal recovers, but the virus may persist in the pharyngeal area of convalescent ruminants as previously discussed.

Bacterial complications generally aggravate the lesions, particularly those of the feet and the teats, leading to severe lameness and mastitis, respectively. In young animals, especially neonates, the virus frequently causes necrotizing myocarditis, and this lesion may also be seen in adults infected with some strains of the virus, particularly type O.

### CLINICAL FINDINGS

In typical field cases in cattle, there is an incubation period of 3 to 6 days, but it may vary between 1 and 7 days. The onset is heralded by a precipitate fall in milk yield and a high fever (40° to 41°C [104° to 106°F]), accompanied by severe dejection and anorexia, followed by the appearance of an acute painful stomatitis. At this stage, the temperature reaction is subsiding. There is abundant salivation, with the saliva hanging in long, rope-like strings; a characteristic smacking of the lips is present; and the animal chews carefully. Vesicles and bullae (1 to 2 cm in diameter) appear on the buccal mucosa, dental pad, and tongue. These rupture within 24 hours, leaving a raw, painful surface that heals in about 1 week. The vesicles are thin walled, rupture easily, and contain a thin, straw-colored fluid. Concurrently with oral lesions, vesicles appear on the feet, particularly in the clefts and on the coronet. Rupture of vesicles causes acute discomfort, and the animal is grossly lame and often recumbent, with a marked, painful swelling of the coronet.

Secondary bacterial invasion of foot lesions may interfere with healing and lead to severe involvement of the deep structures of the foot. Vesicles may occur on the teats; when the teat orifice is involved, severe mastitis often follows. Vesicles on the teats may be the primary clinical sign observed by the dairy farmer, as in the 2010/2011 epidemic in the Republic of Korea.<sup>33</sup> Pregnant animals may abort or have stillbirths. Very rapid loss of condition and fall in milk yield occur during the acute period, and these signs are

much more severe than would be anticipated from the extent of the lesions. Eating is resumed in 2 to 3 days as lesions heal, but the period of convalescence may be as long as 6 months. Young animals are more susceptible and may suffer heavy mortality from myocardial damage, even when typical vesicular lesions are absent in mouth and feet.

In most outbreaks, the rate of spread is high and clinical signs are as described earlier, but there is a great deal of variation in virulence, especially in beef cattle, and this may lead to difficulty in field diagnosis. For example, there is a malignant form of the disease in adults in which acute myocardial failure occurs. There is a typical course initially but a sudden relapse occurs on days 5 to 6 with dyspnea, a weak and irregular heart action, and death during convulsions. Occasional cases show localization in the alimentary tract with dysentery or diarrhea, indicating the presence of enteritis. Ascending posterior paralysis may also occur. On the other hand, there is a mild form that usually occurs when endemic strains infect only indigenous *Bos indicus* (Zebu) cattle. This is the form most commonly seen in endemic countries in Africa, Asia, and South America.

A sequela to FMD in cattle, probably as a result of endocrine damage, is a chronic syndrome of dyspnea, anemia, overgrowth of hair, and lack of heat tolerance. Affected cattle are described colloquially as “hairy panter.” The syndrome has been reported in European cattle breeds but has not been described in zebu cattle from India.<sup>34</sup>

In sheep and goats, the disease is often mild and may go unnoticed. FMD in small ruminants is important mainly because of the danger of transmission to cattle. Adult sheep may develop a syndrome identical to that of cattle, and thus it becomes a crippling disease with occasional loss of hooves from bacterial complications. Goats are sometimes spared during an outbreak. The more common syndrome in these species is the appearance of a few small lesions, but with more severe involvement of all four feet. As in cattle, young stock are more susceptible.

FMD in pigs can be very severe, and devastating epidemics involving pigs only or pigs and other species are reported from time to time in Asia. A porcophilic strain (0/Taiwan/97) has been identified and studied. Following intradermal inoculation, symptoms of depression and inappetence appeared at 1 day postinoculation (dpi), whereas vesicles were observed at the inoculation site at 1 dpi and on the mouth and snout the following day.<sup>35</sup> Teats can also be affected in nursing sows. Large vesicles and bullae may rupture to expose large, raw surfaces. Remnants of feet lesions may persist for more than 2 months, and such residual lesions may aid in clinical diagnosis. Experimentally infected feral swine were fully susceptible but exhibited a higher tolerance to

FMD than domestic swine; the latter showed clinical signs of the disease within 24 hours after contact with the feral swine, whereas feral swine did not do so until 48 hours after contact with domestic and feral swine.<sup>18</sup>

### CLINICAL PATHOLOGY

During FMD outbreaks, laboratory investigations are carried out to diagnose the disease rather than for clinical assessment as with most other diseases. Exhaustive laboratory studies are needed for diagnosis, determination of the type of the virus involved, and to differentiate the disease from vesicular stomatitis, vesicular exanthema, and swine vesicular disease. A handbook of the standard tests used worldwide is provided from time to time.<sup>36</sup> Fresh vesicular fluid and surrounding epithelial tissue should be collected in a transport medium composed of equal amounts of glycerol and 0.04 M phosphate buffer, pH 7.2 to 7.6, or glycerol and phosphate buffered saline for laboratory tests. This is the sample of choice. If the vesicles are already healing, blood should be collected, along with esophageal-pharyngeal (OP) fluid samples from ruminants or throat swabs from pigs. The OP samples should be collected from up to five animals with the use of a probang cup. In tropical countries with maximum temperature fluctuations, spoilage of FMD-suspect samples originating from remote areas can be minimized by using FTA Classic Cards for collection, shipment, storage, and identification of the FMDV genome by RT-PCR and real-time RT-PCR.<sup>37</sup> The major methods for diagnosis are as follows:

1. Identification of the agent in tissue or fluid
  - *Virus isolation* by inoculation into cell cultures or unweaned mice. The cell cultures should be examined for cytopathic effect for 48 hours. If no CPE is detected, the cells should be frozen and thawed, used to inoculate fresh cultures, and examined for CPE for another 48 hours. Alternatively, unweaned mice 2 to 7 days old can be used (see following discussion of experimental transmission). With diagnostic samples, neutralization of the virus by known antisera makes the technique highly efficient and specific.
  - Immunologic methods:
    - *Enzyme-linked immunosorbent assay (ELISA)*: This is the preferred test for the detection of FMD viral antigen and identification of viral serotype. It is an indirect sandwich test in which different rows in multiwell plates are coated with rabbit antisera to each of the seven serotypes of FMD virus. It can simultaneously test for swine vesicular disease (SVD) or

vesicular stomatitis (VS) where appropriate.

- **Complement fixation test (CFT):** This can be used if reagents for ELISA are not available. It is less sensitive and is affected by pro- and anticomplementary factors. Direct CFT on epithelial suspension used to be one of the fastest methods of making a positive diagnosis, within a few hours, but negative samples must be checked in tissue cultures because of the number of false negatives that occur with the CFT, especially in poorly collected and packaged samples.

- **Nucleic acid recognition methods:** These include reverse transcription polymerase chain reaction (RT-PCR) and in situ hybridization (ISH). The RT-PCR amplifies fragments of FMD genome in samples and can be used for typing. It is more sensitive than ELISA. The procedures used include agarose gel-based RT-PCR assay, real-time RT-PCR assay, and molecular epidemiology based on the comparison of genetic differences between viruses.<sup>36</sup> A reverse-transcription loop-mediated isothermal amplification (RT-LAMP) assay has been described that is simple and rapid and can be read within 1 hour, whereas conventional RT-PCR methods require 2 to 4 hours.<sup>38</sup> More recently, a lateral flow immunochromatographic (LFI) strip test has been reported that can diagnose FMD serotypes O, A, and Asia 1 using a generic rapid assay device.<sup>39</sup> The procedure takes only 10 minutes and can be done on-site; it also has high specificity and can be used for early detection of FMD in the field. In addition, a field-portable nucleic acid extraction and real-time PCR amplification platform has been developed for rapid detection of FMD.<sup>40</sup> The ISH detects FMD virus RNA in infected tissues, including those obtained during necropsy.

## 2. Serologic tests

- Serologic tests for FMD are of two types: those detecting antibodies to viral structural proteins (SPs) and those detecting antibodies to viral nonstructural proteins (NSPs).<sup>36</sup> The SP tests detect antibodies elicited by vaccination and infection and are serotype-specific and highly sensitive, provided that the virus or antigen used in the test is closely matched to the strain circulating in the field. They are the prescribed tests for international trade. Examples are as follows:
  - Virus neutralization (VN)

- Solid-phase competitive ELISA, another prescribed test
- Liquid-phase blocking ELISA

The NSP tests can be used to identify past or current infection with any of the seven serotypes of the virus, whether or not the animal has been vaccinated. The tests are more useful on a herd basis. For certifying animals for trade, the tests have the advantage over the SP methods in that the serotype of the virus does not have to be known. The assays measure antibodies to NSPs using antigens produced by recombinant techniques.

Antibodies to polypeptides 3AB or 3ABC are generally considered to be the most reliable indicators of infection. Examples include:

- Indirect ELISA
- Enzyme-linked immunoelectrotransfer blot assay.

Where vaccination has been carried out and a diagnosis has to be made by serologic methods, it is necessary to differentiate between infected and vaccinated animals (DIVA). An epitope-based ELISA has been described that can differentiate infected from vaccinated animals and appears to be promising test for FMD control and eradication.<sup>41</sup>

## 3. Experimental transmission

- The propagation of the virus in unweaned white mice can be used to detect the presence of virus in suspected material, the presence of antibodies in serum, and for investigations into the transmission of immunity and the pathogenesis of the disease. In guinea pigs, intradermal injection of fresh vesicular fluid into the plantar pads causes vesicles to appear on the pads in 1 to 7 days and secondary vesicles in the mouth 1 to 2 days later. Large-animal inoculation may be used for the differentiation of FMD, vesicular stomatitis, and vesicular exanthema based on the different species' susceptibilities to the three viruses (Table 21-3) and to test the potency of vaccines. To avoid disseminating the virus, animal inoculation should be done only in specially equipped facilities.

## NECROPSY FINDINGS

The lesions of FMD consist of vesicles and erosions in the mouth and on the feet and udder. The erosions often become ulcers, especially if secondary bacterial infection has occurred. In some cases, vesicles may extend to the pharynx, esophagus, forestomachs, intestines, trachea, and bronchi. The

teats and mammary gland are often swollen. In the malignant form and in neonatal animals, epicardial hemorrhages with or without pale areas are also present. Grossly, the ventricular walls appear streaked with patches of yellow tissue interspersed with apparently normal myocardium, giving the typical "tiger heart" appearance. If the animal survives, there is replacement fibrosis, and the heart is enlarged and flabby.

Histologically, vesicles start as foci of progressive swelling, necrosis, and lysis of infected keratinocytes in the deeper layers of the epidermis and accumulation of fluid in the space. This is followed by necrosis of overlying keratinocytes and rupture of vesicles to form erosions that may extend deep into the dermis to form ulcers, especially on the feet. There is only mild leukocytic infiltration around the erosions and ulcers. Similar changes in mammary gland epithelium lead to acinar necrosis and mild interstitial cellular infiltration. Heart (and occasionally skeletal muscle) lesions in the malignant form are characterized by severe hyaline degeneration, necrosis, and occasional calcification of myocardial fibers and marked interstitial infiltration by mononuclear cells. In addition, pancreatic islet and acinar degeneration has been reported in chronically infected cattle.

Tissues to be submitted for histopathology should include oral mucosa and skin containing vesicles or fresh erosions. The heart, mammary gland, and pancreas should also be included. Viral antigen can be detected in tissues by immunohistochemistry. Because most animals infected with FMD will not die and because it is important to make prompt diagnosis from clinical cases, histopathology of necropsy materials is often secondary.

## DIFFERENTIAL DIAGNOSIS

The need to identify foot-and-mouth (FMD) is of paramount importance in all countries. It is of particular importance in those countries in which the disease is not endemic because of the need to introduce strict control measures quickly. The field or zoo veterinarian must be able to recognize suspicious cases, take appropriate samples, and submit them to a laboratory facility able to confirm the diagnosis promptly. Clinical signs in sheep, goats, and zoo animals such as elephants, giraffes, and camels may be difficult to recognize. In countries where the disease is endemic, there are special difficulties in clinical recognition because of the frequent subdued severity of the oral and feet lesions, even in cattle. Where the other vesicular diseases do not occur, suspicions will be readily aroused, but in North America, the presence of vesicular stomatitis and vesicular exanthema may result in misdiagnosis. Vesicular stomatitis in horses, cattle, and swine, vesicular

\*White-skinned pigs fed on parsnips or celery and exposed to sunlight develop vesicles.

exanthema of swine, and swine vesicular disease resemble FMD closely (Table 21-3). Three other vesiculoviruses—Piry, Chandipura, and Isfahan—cross-react with vesicular stomatitis virus<sup>18</sup> but are much less virulent. The observations that white-skinned pigs fed parsnips or celery and exposed to sunlight will develop vesicles on the snout and feet and that cattle fed on grain treated with caustic soda can develop profuse salivation are further confounding factors in the differentiation of the vesicular diseases.

Bluetongue of sheep may also present a problem in differentiation. Details of these are provided separately, but a summary is given in Table 21-3. Rapid laboratory differentiation and diagnosis of these diseases may be achieved, as described under Clinical Pathology (see previous discussion).

Bovine viral diarrhea/mucosal disease, rinderpest, malignant catarrhal fever, and lumpy skin disease are easily differentiated by the lesions that develop in the mucosa and sometimes on the feet. The lesions are never vesicular, commencing as superficial erosions and proceeding to the development of ulcers. Pox infections of the mammary gland and foot rot in sheep should also be differentiated from FMD. Ingestion of any caustic material may cause oral vesiculation and salivation. Among zoo animals, giraffes, elephants, and camels are susceptible.

## TREATMENT

### TREATMENT AND CONTROL

**Treatment**  
Nonspecific

### Control

Vaccination with killed vaccine (R-1 in endemic areas)

Treatment with mild disinfectant and protective dressings to inflamed areas to prevent secondary infection is recommended in endemic countries where a slaughter policy is not in force. A good symptomatic response is reported to the administration of flunixin meglumine. In Kenya, ethnoveterinary remedies of natural soda ash solution (97% sodium bicarbonate), honey, and finger millet flour were used to manage FMD lesions during an outbreak in a medium-scale dairy farm.<sup>42</sup> The lesions were washed with soda ash solution to remove the necrotic tissue, after which raw honey and finger millet flour were applied daily for 3 days. Experimentally, it has been shown that administration of porcine type I interferon to pigs or bovine type III interferon to cattle can protect swine or significantly delay and reduce the severity of FMD in cattle challenged with FMDV for up to 7 days.<sup>43-44</sup> These interferons can thus inhibit FMDV replication before an inactivated vaccine can induce protection in the face of an outbreak in endemic areas.

### CONTROL

Many factors govern the control procedure in a given area. The procedures commonly used are (a) control by eradication and (b) control by vaccination, or a combination of the two. In countries where the disease is endemic, or where there are wildlife reservoirs, eradication is seldom practicable. In

areas with only occasional epidemics, slaughter of all infected and in-contact animals is usually carried out. It must be remembered that vaccination is costly and sometimes ineffective and that eradication would be the ideal objective in all countries. For countries in large continents, international cooperation is required for eradication. The European Union phased out mass vaccination in 1991 to increase its international competitiveness in trade in livestock and livestock products. Soon after, outbreaks of FMD in Italy were controlled by surveillance and slaughter of thousands of cattle, sheep/goats, and pigs in all-infected and contact herds. A similar procedure was adopted in 2001 in England, Ireland, and France and with some modification in the Netherlands, and the outbreaks were successfully controlled within months. Similar results were obtained in Taiwan during periodic outbreaks between 1997 and 2011. On the other hand, a 2010 epidemic in Japan was eradicated within 3 months in an area with high density of cattle and pigs by strict movement control and emergency vaccination.<sup>4</sup>

As in the control of all epidemic infectious diseases, the problems posed for administrators are complex and continually changing. For example, the prospect of making a wrong decision about when to switch from an eradication-by-slaughter program to a containment-by-vaccination program, when an outbreak is raging and public sentiments are running high, is a daunting one. A wrong decision may cost a livestock industry many millions of dollars. To avoid making such errors, it is customary to develop a mathematical or computer

model that simulates the progress of an outbreak in terms of numbers of animals infected, affected, and dead, and how these numbers will change under pressure from control procedures, management practices, and prevailing weather. An essential aspect of such an analysis is the economic effect of various control programs and their outcomes. The cost-benefit aspects of computer simulation models and the meteorologic predictions of the likely spread of the disease are used to determine an appropriate strategy for control. Even then, conclusions from such models may still be controversial, as was the case in the 2001 outbreak in England, where a culling policy driven by unvalidated predictive models rather than experience contributed to the death of approximately 10 million animals.<sup>44-45</sup>

### Control by Eradication

The success of an eradication program depends on the thoroughness with which it is applied. As soon as the diagnosis is established, all cloven-footed animals in the exposed groups should be immediately slaughtered and burned or buried on site. No reclamation of meat should be permitted, and milk must be regarded as infected. Inert materials that may be contaminated must not leave infected premises without proper disinfection. This applies particularly to human clothing, motor vehicles, and farm machinery. Bedding, feed, feeding utensils, animal products, and other articles that cannot be adequately disinfected must be burned. Barns and small yards must be cleaned and disinfected with 1% to 2% sodium hydroxide or formalin or 4% sodium carbonate solution. Acids and alkalis are the best inactivators of the virus, and their activity is greatly enhanced by the presence of a detergent. The effective pH at a disinfection surface may be grossly altered by the presence of organic matter and needs to be adequately maintained. When all possible sources of infection are destroyed, the farm should be left unstocked for 6 months and restocking permitted only when "sentinel" test animals are introduced and remain uninfected. There are strict international requirements for demonstrating freedom from infection.

Recommendations for outdoor sites are difficult to make. Observations in Argentina suggest that contaminated pastures and unsheltered yards are clear of infection if left unstocked for 8 to 10 days. No animal movement can be permitted, and human and motor traffic must be reduced to a minimum. Persons working on the farm should wear waterproof clothing, which can be easily disinfected by spraying and subsequently removed as the person leaves the farm. Clothing not suitable for chemical disinfection must be boiled. Because of the rapidity with which the disease may spread, immediate quarantine must be imposed on all farms

within a radius of 16 to 24 km (10 to 15 miles) of the outbreak.

Although the eradication method of control is favored when the incidence is low, it imposes severe losses on the animal industry in affected areas and is economically impracticable in many countries. However, it must be regarded as the final stage in any control program. The standard strategy is the containment of the disease by ringing the outbreak with a zone of vaccinated animals and setting about reducing the infection rate within the ringed area and eventually eradicating remaining hotspots by slaughter. Containment of an outbreak is a difficult task with high rewards, as shown by various cost-benefit analyses.

The controversy about whether to eradicate or vaccinate is ongoing. For example, the 1967-1968 epidemic in the United Kingdom involving the slaughter of nearly half a million animals at a cost of US\$250 million was so damaging financially that it was arranged for vaccination to be available should there be a recurrence of such an epidemic. Nevertheless, the slaughter policy was still adopted in 2001, and many more animals were killed. Part of the increased concern about a test and slaughter policy derives from the following factors:

- Increasing size of herds
- Risks involved if infection is introduced
- Environmental concerns regarding carcass disposal if thousands or millions of animals are to be slaughtered within a short time. During the 1997 epidemic in Taiwan, it was reported that a disposal capacity of 200,000 pigs per day was reached despite ring vaccination. In England, disposal capacity was overwhelmed in 2001, even with military intervention, and carcasses were sometimes left for days before burial or burning. A recent study in the United States concluded that depopulation of a large feedlot during an FMD outbreak would be difficult to complete in a humane and timely fashion.<sup>46</sup>

### Vaccination

Regular vaccination against FMD is a way of life for most of the world, and vaccine production is a major industry. In the endemic countries, eradication does not seem possible within the foreseeable future, and countries free of the disease may require regional vaccination during outbreaks. Consequently, it has been estimated that 1.5 billion monovalent doses of the FMD vaccine are administered annually, with South America alone accounting for some 1300 million doses.

Killed trivalent (containing O, A, and C strains) vaccines are in general use, but because of the increasing occurrence of antigenically dissimilar substrains, the production of vaccines from locally isolated virus is becoming a more common practice. The

virus is obtained from infected tongue tissue, a cell culture of bovine tongue epithelium, or other cell culture. Baby hamster kidney (BHK) is a favored viral cultural medium, and BHK vaccine is now in general use. Its principal virtue is its adaptability to deep suspension culture, in contrast with its growth on monolayer culture, enabling large-scale production of the virus to be carried out within practicable space limits. Inactivation of the virus to produce a killed vaccine used to be done with formalin, but there are disadvantages with its use, and more sophisticated agents, especially binary ethylene imine (BEI) are now used. Serviceable immunity after a single vaccination can be relied on for only 6 to 8 months. Vaccines produced from "natural" virus give longer immunity than those produced from "culture" virus. Vaccines produced in oil-adjuvant form offer promise of providing longer immunity and require only annual revaccination in adult cattle and biannual revaccination for young stock or every 4 to 6 months in pigs.

A general vaccination program for an area must be planned for that area. Thus in continental Europe, the program until 1991 included an annual vaccination of all adults, with an additional campaign every 6 months to vaccinate calves as they reached about 4 months of age. In South America, the specific recommendations are that calves from unvaccinated dams should be vaccinated at 4 months and revaccinated at 8 months of age, but calves from vaccinated cows should be vaccinated twice, the first at 6 months and the second at 10 months of age. The important considerations in calves are to avoid vaccination while the calf is still carrying maternal antibodies derived from colostrum and to avoid infection before they can develop active immunity. Calves as young as 1 week old respond as actively to vaccination as adult animals, provided they are free of maternally derived antibody. Immunity is present 7 to 20 days after vaccination, depending on the antigenicity of the vaccine. It is not usual to include sheep, goats, and pigs in a general vaccination program unless they are also affected during outbreaks. After the outbreak in Taiwan, it was recommended that piglets be vaccinated at 8 to 12 weeks followed by a boost 4 weeks later, and that sows be vaccinated 3 to 4 weeks before farrowing or every 4 to 6 months.

Because of the short duration of the immunity produced by killed vaccines, attention has been focused on the production of an attenuated living-virus vaccine. The major difficulty encountered so far has been the narrow margin between loss of virulence and loss of immunogenicity. Attenuated vaccines have been produced by passage through white mice, embryonated hen eggs, rabbits, and tissue culture. Their use has contributed to the eradication of the disease in cattle in South Africa. Vaccines

have also been instrumental in eliminating FMD from most countries in South America under the Pan American Centre for Foot and Mouth Disease (PANAFTOSA).

Provided constant surveillance can be maintained over vaccinated animals, their value in such circumstances cannot be denied. However, their early promise has not been fulfilled, and improved killed vaccines are most generally favored. In spite of the uncertain stability of the lapinized virus, control of the disease in Russia was reported after the use of a rabbit-passaged vaccine. In those countries where vaccination of very large numbers of animals is carried out annually, one of the emerging problems is the quality control of vaccines with respect to innocuity and to immunizing capacity or potency. The techniques to monitor these characteristics are available, but they do add to the costs of the vaccine, and if commercial competition is keen, this aspect of production may be spared. Some outbreaks have been linked to attenuated vaccines.

A great deal has been written about genetically engineered FMD vaccines produced by biotechnological manipulation and their distinct safety advantages over whole-virus vaccines. Initial reports of a polypeptide vaccine (protein VP1) in cattle are encouraging, and the peptide can be chemically synthesized and incorporated into the core of hepatitis B virus to produce a vaccine. Research is ongoing, and at least one novel molecular vaccine has been licensed for emergency use in the United States.<sup>47</sup> However, much work still needs to be done, and these newly developed vaccines cannot yet replace the classical inactivated vaccines.

General vaccination as a means of control is recommended for countries where the disease is enzootic or where the threat of introduction is very great (e.g., Israel). If an outbreak occurs, a booster vaccination with the relevant serotype will greatly increase the resistance of the population. However, the strategy of general vaccination has many difficulties. The following disadvantages are suggested:

- To be effective, the program should consist of vaccination against a number of strains three times yearly. More frequent vaccination may be necessary in the face of outbreaks during optimum conditions for spread. Young animals with maternally derived antibodies do not respond to vaccination.
- Vaccination of sheep and pigs is also used in control programs. In pigs, a bi- or trivalent, inactivated, adjuvant vaccine gives strong immunity for 6 months and some resistance for 12 months. Severe local reactions (abscesses and granulomas) at vaccination sites can be reduced by the inclusion of an oil-adjuvant. However, vaccination of pregnant sows leads to a

high rate of abortions and stillbirths. In sheep, monovalent or trivalent vaccines give immunity for 5 to 6 months, but the sheep may act as inapparent carriers. One study suggested that a single emergency vaccination would be effective in the control of an epidemic involving cattle and sheep, but would be less effective in pigs.<sup>47</sup>

- Inapparent infections may occur in animals whose susceptibility has been reduced by vaccination, permitting the existence of "carrier" foci. It has become generally recognized that the number of carrier animals produced by vaccination is very much greater than was previously thought. Apart from the fact that these animals are a potent method of spreading the disease, they also provide an excellent medium for the mutation of existing virus strains because the hosts are immune. The carrier state in vaccinated and unvaccinated cattle may persist for as long as 6 months and be capable of causing new outbreaks in all species. But the problem must be kept in perspective. The number of carriers produced in this way is directly related to the rate of occurrence of the disease in the population, and if this is kept to a minimum by an assiduous vaccination program and a strict limitation on the movement of infected animals into the population, the rate of occurrence of carriers can be very small. Nevertheless, in FMD-free countries, vaccinated animals are subsequently slaughtered to comply with OIE regulations so as to resume meat export as soon as possible. However, this policy is now being challenged from the point of view of animal welfare.
- Importation of vaccinated animals is often prohibited even though trade in these animals and their products poses minimal risk of transmitting FMD.<sup>11</sup> An additional disadvantage is the production of sensitivity resulting in anaphylaxis in 0.005% of cattle vaccinated repeatedly, especially when the vaccines contain antibiotics or the vaccine contains foreign protein not associated with the antigen, or the virus has been killed with formalin that has also denatured the protein in the vaccine. Edema, urticaria, dermatitis, abortion, and fatal anaphylaxis all occur. Cows in early and late pregnancy or otherwise stressed from other diseases are most susceptible to adverse effects of vaccination. Satisfactory purification and standardization of the vaccine can eliminate many of the problems because the hypersensitivity is to the culture medium and to the agent used to kill the virus, rather than the virus itself.

- Countries that vaccinate during an outbreak have to reestablish their FMD-free status to the satisfaction of their trading partners. This is difficult because currently available vaccines stimulate production of antibodies indistinguishable from those following infection, and because vaccinated animals can be infected and become carriers. The detection of antibodies to nonstructural proteins is helpful in making the distinction at herd level, and further research is ongoing to standardize the techniques.

Alternatives to general vaccination are modified programs, including "ring" vaccination to contain outbreaks, "frontier" vaccination to produce a buffer area between infected and free countries, and vaccination of selected herds on a voluntary basis when an outbreak is threatened. Such emergency vaccinations can reduce the risk of spreading infection by reducing the rate of virus excretion. It is generally conceded that vaccination of an entire population may be necessary when eradication is incapable of preventing the spread of the disease. For this reason, many countries have strategic reserves of concentrated vaccines, but no such vaccine banks exist in Africa.

Prevention of entry of the disease into free areas is an ever-increasing problem because of modern developments in communications. The following prohibitions are necessary if the disease is to be excluded:

- There must be a complete embargo on the importation of animals and animal products from countries where FMD is endemic. The embargo should include hay, straw, and vegetables. Where the disease occurs only as occasional outbreaks, importation of animals can be permitted provided they are subjected to a satisfactory period of quarantine.
- Particular attention should be given to preventing entry of uncooked meats from ships, airplanes, and other forms of transport and in parcels originating in infected areas. In danger areas, all swill fed to pigs must be cooked and all food waste satisfactorily disposed of.
- Personal clothing and other items belonging to people arriving from infected areas should be suitably disinfected. Persons arriving from endemic countries or countries experiencing outbreaks should keep away from livestock for several days.
- The risk of introducing the disease through importation of semen or fertilized ova is now thought to be minimal. The virus can survive in frozen bull semen and possibly in some fertilized ova (e.g., zona pellucida-free bovine embryos) but not in others (e.g., zona pellucida-intact bovine embryos). However, because even viremic animals

do not transmit the disease through their embryos, bovine embryos with intact zona pellucida can be safely imported from enzootic areas regardless of the serologic status of the donor. Consequently, if exotic or special animals have to be imported from enzootic countries, embryo transfer may be a means of controlling the transmission of FMD. Even for llama embryos that lack a zona pellucida, the risk of FMD transmission was calculated to be close to zero if favorable epidemiologic or ecological conditions exist in the region of origin of the embryos.

In summary, the control and eventual eradication of FMD in a country, region or worldwide can only be achieved if the international community recognizes that the control of FMD is a global public good that will benefit all populations and future generations.<sup>2</sup> In South America, under the auspices of the PANAFTOSA's new Plan of Action 2011–2020, it is hoped that several challenges will be overcome to ensure eradication of FMD from the Americas by 2020.<sup>48</sup>

## RIFT VALLEY FEVER

### SYNOPSIS

**Etiology** Rift Valley fever virus, genus *Phlebovirus*, a member of the family *Bunyaviridae*.

**Epidemiology** Enzootic in sub-Saharan Africa and Egypt. First occurrence outside African continent in 2000 affecting Arabian Peninsula. Virus maintained in floodwater mosquitoes and transmitted by hematophagous insects. Ruminants are amplifying hosts. Epizootics in high rainfall periods. A major zoonosis with mortality rate of 1% in humans.

**Clinical findings** Acute febrile disease in lambs and calves characterized by hepatitis

and high mortality; abortion in adult sheep and in cattle. In humans, influenza-like disease and, in rare instances, hemorrhagic fever.

**Necropsy findings** Hepatic necrosis.

### Diagnostic confirmation

Immunohistochemical localization of viral antigens in tissues.

**Treatment** No specific treatment available; supportive.

**Control** Vaccination, vector control, control of livestock movement.

## ETIOLOGY

Rift Valley fever virus is a single-stranded RNA virus of the family *Bunyaviridae*, genus *Phlebovirus*. There is only one serotype recognized, with only minor genetic variation between strains.<sup>1</sup>

The virus remains viable in aerosols at 25°C (77°F) for 1 hour or longer but can survive in serum at 4°C (40°F) for several months. Infected sheep plasma can retain its infectivity over years with storage and shipment under a variety of refrigeration conditions. Infectious material thus presents a potential source of infection for laboratory personnel or veterinarians for a prolonged period of time.<sup>2</sup>

## EPIDEMIOLOGY

### Occurrence

Rift Valley fever (RVF) was first recognized in 1930 in the Rift Valley in Kenya but now exists and occurs as epizootics throughout sub-Saharan Africa, with recent extensions into Egypt, Mauritania, and Madagascar. The first RVF outbreaks outside Africa were recorded in 2000 in Yemen and Saudi Arabia. The most recent outbreaks recorded by the World Health Organization (WHO) occurred in Somalia (2006/2007), Kenya (2007/2008), Tanzania (2007), Sudan (2007/2008), Madagascar (2008/2009), South Africa (2008, 2009, and 2010), Mauritania (2010 and 2012), Botswana (2010), and Namibia (2010).<sup>3</sup> The disease has great potential for spread to other countries either through legal or illegal movement of infected livestock or the encroachment of mosquitoes into new areas.<sup>4</sup> The pattern of occurrence is cyclical epidemics that are inherently linked to regional climate variability, particularly to rainfall patterns.<sup>4</sup> Outbreaks occur with periods of quiescence of 5 to 15 years in duration.<sup>2</sup>

Climate changes and livestock movement facilitate the spread of the disease and present an increasing risk of introduction of the disease into the Mediterranean basin and Europe.<sup>2</sup>

## Risk Factors

### Animal Risk Factors

Rift Valley fever is an infectious disease primarily affecting ruminants but to which

other species, including humans, are also susceptible. There is a clear age predisposition to clinical disease rendering lambs, goat kids, puppies, and kittens extremely susceptible, with mortality rates between 70% and 100%. Adult sheep and calves have been categorized as highly susceptible, with mortality rates between 20% to 70%. Adult cattle, goats, African and domestic buffalo, and humans are moderately susceptible, with mortality rates of less than 10%.<sup>1</sup> Camelids, equids, pigs, and adult dogs and cats are considered resistant to clinical disease, with infection being inapparent in these species. A large number of different African wildlife species were found to have seroconverted in endemic areas.

### Environmental Risk Factors

Outbreaks of RVF have been associated with above-normal rainfall and climatic conditions favorable to competent vectors. More precisely, epidemics have been reported in four epidemiologic systems<sup>2</sup>:

- **“Dambo” areas in East Africa.** These areas are valleys near a river in which outbreaks occur following heavy rainfall events.
- **Semiarid areas of western Africa** (including Senegal and Mauritania). In these regions, which are characterized by temporary areas of water, outbreaks could not be directly related to flood-like rainfalls; rather, they occurred during the rainy season with abundant regular rainfall.
- **Irrigated areas** (including the Nile Delta or Senegal River basin). In artificially irrigated areas the permanent availability of water favors the persistence of a vector population throughout the year.
- **Temperate and mountainous areas** (including regions in Madagascar). Transmission of RVFV in these regions results from vector-borne transmission associated with livestock movement.

RVF outbreaks were found to occur with a cyclic pattern in association with the warm phase of the El Niño/Southern Oscillation (ENSO) phenomenon. The ENSO is associated with varying climate effects on a 3- to 7-year interval.<sup>4</sup>

### Source of Infection

The live cycle of RVFV consists of an epizootic cycle that is associated with outbreaks of RVF and an enzootic or interepizootic cycle, during which the virus persists in a host but is not associated with clinical disease. During the interepizootic cycle the RVFV is maintained through vertical transmission in *Aedes* mosquito eggs. These eggs are drought-resistant and survive several years without hatching, thereby maintaining the virus during interepizootic periods. These interepizootic vectors belong to the *Aedes* subgenus *Neomelanimon* in East Africa

and the subgenus *Aedimorphus* in West Africa. Epizootics occur in enzootic areas when wet and flood conditions enable the infected eggs to mature and hatch. *Aedes* mosquitoes hatched from infected eggs transmit the virus to susceptible animals, particularly domestic ruminants on which they feed preferentially.

Once a susceptible animal, which is considered an amplifying host, is infected, a transient viremic phase occurs, permitting virus transmission between susceptible individuals through any hematophagous insect species. These insects, which include *Culex* and *Anopheles* spp., function as secondary arthropod vectors but do not transmit the virus transovarially and therefore do not act as RVFV reservoirs during interepizootic periods.<sup>1</sup>

For **humans**, direct contact with infected animal tissues, blood, or other body fluids and also inhalation of aerosolized infected material are considered the predominant routes of infection.<sup>5</sup> Accordingly, certain occupational groups, such as farmhouse, slaughterhouse, or laboratory personnel and veterinarians, are at increased risk of infection. Biting insects appear to have a limited role in the transmission of RVFV to humans. Nevertheless, during the 2000/2001 outbreak of RVF in Saudi Arabia, with over 400 confirmed clinical cases in humans and 85 deaths, 23% of all infections were estimated to have occurred through mosquito exposure.<sup>5</sup> In contrast, during a South African outbreak, 89% of clinical cases in humans were associated with direct contact with infectious material. Ingestion of unpasteurized milk was incriminated as a possible route of infection based on epidemiologic evidence, but this has not been demonstrated conclusively.<sup>5</sup>

### Method of Transmission

In ruminants RVFV is transmitted between animals through primary and secondary arthropod vectors. Direct transmission between animals through contact with viremic fluid, such as blood or lochia fluid, is strongly suspected but has thus far not been confirmed. The presence of virus in the nasal or lachrymal secretions, urine, or feces of infected animals has not been demonstrated.<sup>2</sup>

In humans there is no evidence for person-to-person transmission of infection. Vertical transmission from an infected mother to her baby has been reported in two instances during the outbreaks in Saudi Arabia in 2000 and in Sudan in 2007.<sup>6</sup>

### Experimental Reproduction

The disease can be transmitted by most routes, including inoculation and the inhalation of aerosols. Following inoculation of sheep and cattle the incubation period is 1 to 2 days, and high virus titers are found in blood. The virus persists in the body for

approximately 3 weeks, but long-term carriage has not been observed. Pregnant animals abort, but infection may be clinically mild in nonpregnant animals. IgM antibody can be detected as early as 4 days after infection and persists for 2 to 6 months.

### Zoonotic Implications

Although humans are susceptible to infection and disease, infection with RVFV in the large majority of cases is asymptomatic, as is suggested by retrospective serologic studies following epidemics. If clinically apparent, the disease is usually a transient flulike illness, but complications of hemorrhagic fever, retinal and renal disease, and encephalitis occur.<sup>1</sup> Traditionally, the occupational groups at greatest risk are laboratory workers handling the virus and those working among infected animals or their products, including veterinarians. However, cases were not limited to these groups in the large outbreaks in Egypt in 1977 and 1978 and the more recent outbreaks in the Arabian Peninsula. The occurrence rate of clinical disease in humans was very high in Egypt (more than 20,000 cases and 600 deaths). The mortality rate in humans is estimated to be 1% to 2%.<sup>7</sup> The pathogen is identified as a potential agent for bioterrorism.

### Economic Importance

The disease causes significant morbidity and mortality in calves and lambs and has been associated with abortion storms in adult ruminants, with pronounced health and economic impacts. The economic losses solely attributable to trade disruptions occurred during the RVF outbreaks of 2007 in Sudan have been estimated to exceed \$60 million.<sup>8</sup>

### PATHOGENESIS

Hepatocytes are the primary site of viral replication in lambs and calves, and age is a determining factor in the progression and outcome of infection. In very young animals, hepatic lesions progress from degeneration and necrosis of individual hepatocytes to extensive necrosis throughout the liver, resulting in hepatic insufficiency and failure. In young animals, encephalomyelitis may also occur.

### CLINICAL FINDINGS

The clinical presentation of RVF varies by species and age. The disease is most severe in young ruminants, particularly lambs. After an incubation period of between 12 and 36 hours, anorexia, weakness associated with fever, and lymphadenopathy become apparent. Hemorrhagic diarrhea with abdominal pain may be seen. In calves, icterus is a common clinical finding. Mortality rates are high and can reach 90% to 100% in lambs and 70% in calves.

In adult sheep and cattle, abortion is the outstanding and in many cases only clinical

sign. Abortion storms affecting up to 100% of ewes and 85% of cows can occur. In clinical cases in cattle and adult sheep there is febrile disease, with anorexia, weakness, and a drop in milk production that can be associated with hemorrhagic diarrhea. In severe cases the mortality rate in adult sheep may be as high as 25% and 10% in cattle. Goats show a febrile reaction but few other clinical signs.

Clinical signs can be unspecific when considering an individual animal, but RVF should be suspected whenever high abortion rates in adult ruminants and high mortality rates in neonatal ruminants occur in combination with flulike disease in humans who had contact with sick ruminants.

### CLINICAL PATHOLOGY

Severe leukopenia is a common finding.

**Virus isolation** is usually performed from inoculated hamsters, mice, or cell cultures. Virus identification can also be done by immunofluorescence carried out on impression smears of liver, spleen, or brain or immunostaining of histology slides.<sup>1</sup> The agar gel immunodiffusion (AGID) test is an alternative for laboratories without tissue culture facility. Polymerase chain reaction (PCR) is used for rapid detection of viral RNA.

Serology can be conducted by virus neutralization (VN), which is the prescribed test for international trade, by means of an enzyme-linked immunosorbent assay (ELISA) or by hemagglutination inhibition. The virus neutralization test requires the use of live RVFV, making this test unsuitable to be used outside endemic areas.<sup>1</sup> Several RVFV antibody ELISAs are available as commercial test kits and can be performed with inactivated antigen and thus are suitable for the use outside RVFV-endemic areas. The IgM-capture ELISA allows diagnosis of a recent infection.<sup>1</sup> Antibodies appear in the serum about 1 week after infection, and persistence depends on antibody type.

### NECROPSY FINDINGS

**Extensive hepatic necrosis** is the characteristic lesion in RVF. In neonates, the liver is enlarged and has a yellow–orange discoloration, whereas in older animals, pale foci of necrosis impart a mottled appearance to the organ. Other nonspecific lesions include congestion and petechiation in the heart, lymph nodes, gallbladder, and alimentary tract. Abomasal and intestinal content may be dark brown to red as a result of hemorrhage.

Microscopically there is multifocal or diffuse necrosis of the liver, and there may be acidophilic intranuclear inclusion bodies in hepatic cells. The lesions are much more extensive in newborn lambs and calves than in older animals. Immunohistochemical localization of viral antigens in tissues provides a specific diagnosis.

### Samples for Confirmation of Diagnosis

- **Virology**—liver, spleen, brain (virus isolation, fluorescence antibody test, PCR)
- **Histology**—liver, spleen, brain (light microscopy, immunohistochemistry)

**Note the zoonotic potential of this disease when handling these specimens.**

#### DIFFERENTIAL DIAGNOSIS

In regions where this disease has not occurred it should be suspect when there is an area outbreak of abortion and neonatal mortality in sheep and cattle coupled with an area outbreak of flu-like disease in humans.

- Wesselsbron disease
- Bluetongue
- Ephemeral fever
- Bacterial septicemias
- Anthrax
- Vibriosis
- Trichomoniasis
- Toxic plants

### TREATMENT

Little attention has been given to the aspect of treatment of the disease, and no known treatment is of any value.

### CONTROL

Measures to control Rift Valley fever include the following:

- Control of livestock movement
- Vector control
- Vaccination

The role of **livestock movement** over long and short distances in the spread of the disease throughout the African continent is well documented, and phylogenetic studies suggest that ruminant trade is the main reason for the spread of the disease from the African continent to the Arabian Peninsula.

**Vector control** is most effective when larvicides are used in mosquito breeding sites. Limitations of this approach are that breeding sites must be clearly identified and must have a limited surface to be manageable. Particularly with heavy rainfalls and flooding, mosquito-breeding sites are too numerous and wide to be controlled. Ecological, health, and financial issues around applying large amounts of insecticides to the environment further complicate this type of control.

### Vaccines

**Live attenuated vaccines (Smithburn strain)** and mutagenized live virus vaccines provide good protection that lasts for at least 28 months but are not recommended for pregnant animals because they are abortigenic, causing fetal death and some teratogenic anomalies. The recorded problems include hydrops amnii, arthrogryposis, hydranencephaly, and microencephaly. There is also a concern for reversion to virulence.

Live attenuated vaccines, furthermore, are pathogenic for humans, and exposure to live attenuated vaccines may present a health risk.<sup>5</sup>

**Killed-virus vaccines** require repeat administration for good immunity, and annual vaccination of all dairy cattle is recommended as a cost-effective control program in endemic countries. They are also recommended for pregnant and young animals.

A **mutagen attenuated vaccine** protects against challenge in both sheep and cattle. Viremia following vaccination is minimal and thought not to be a risk for infection of susceptible mosquitoes. Mutagenic vaccines were initially thought to have no deleterious effect on the fetus, but abortion and teratogenicity have been observed in the lambs of sheep vaccinated early in pregnancy.

Prevention of the introduction of Rift Valley fever into countries free of the disease requires the prohibition of the importation of all susceptible species from Africa. All necessary steps to prevent the introduction of infective insects and infected biological materials should be taken. The possibility of humans carrying the infection from country to country is very real.

### BLUETONGUE

#### SYNOPSIS

**Etiology** Bluetongue virus (BTV), an orbivirus with several serotypes and considerable genetic heterogeneity.

**Epidemiology** An infectious, noncontagious disease primarily of sheep, but also occurring in cattle, wild ruminants, New World camelids, and goats. Transmitted by *Culicoides* spp. Cattle are the reservoir and amplification hosts. Severe disease is most common in European fine wool and mutton breeds of sheep. Certain serotypes can cause severe disease in cattle.

*Continued*

Infection, but not disease, is endemic in tropical and subtropical regions. Disease occurs in epidemic and incursive areas when climatic conditions allow the expansion of vector occurrence or when naïve animals are introduced into an endemic area.

**Clinical findings** Fever, apathy, serous to bloody nasal discharge, respiratory distress, oral erosions and ulcerations with hypersalivation. Lameness as a result of coronitis, myositis, and muscle necrosis.

**Clinical pathology** Virus isolation or detection of viral RNA (reverse-transcription polymerase chain reaction [RT-PCR]) in blood or tissue specimens. Serologic tests to identify BTV-specific antibodies or a rise in antibody titer (competitive enzyme-linked immunoabsorbent assay [C-ELISA], virus neutralization test, agar gel immunodiffusion [AGID]).

**Necropsy findings** Mucosal lesions, hemorrhage and necrosis of skeletal and cardiac muscles, hemorrhagic lesion at base of pulmonary artery. Congestion of heart, lung, liver and kidney.

**Diagnostic confirmation** Detection of viral nucleic acid, virus isolation, rising titer with serology.

**Treatment** None specific, supportive.

**Control** Reduction of exposure to vector is attempted, but major method of control in epidemic areas is by vaccination.

## ETIOLOGY

Bluetongue virus (BTV) is an arthropod-borne *Orbivirus* in the family Reoviridae with a genome composed of 10 dsRNA segments. The bluetongue viruses are stable and resistant to decomposition and to some standard virucidal agents, including sodium carbonate. They are sensitive to acid, inactivated below pH 6.0, and susceptible to 3% sodium hydroxide solution and organic iodides.

Worldwide there are currently 26 recognized serotypes of BTV.<sup>1-4</sup> The virus is characterized by its high genetic variability resulting from the genetic drift of individual gene segments and from reassortment of gene segments when ruminants or the vectors are infected with more than one strain. The occurrence of different BTV serotypes varies by geographic region.

## EPIDEMIOLOGY

### Occurrence

Bluetongue virus has been identified on all continents except Antarctica and is considered endemic in the domestic livestock populations of all tropical and subtropical countries. Until the end of last century, BTV was considered an exotic disease in the Palearctic, but a series of outbreaks caused by different serotypes apparently originating from adjacent enzootic regions has occurred in the Mediterranean basin since 1998.<sup>5</sup>

Whereas historically the enzootic area was considered to be limited to the area between latitude 35° S and 50° N, this zone appears to have extended to areas north of 53° NN over the last decade. BTV outbreaks observed in these new regions in the past years are thought to be the result of climate change from global warming.

The distribution and intensity of infection in regions of the continents is determined by the climate, geography, and altitude, which affect the occurrence and activity of the *Culicoides* vectors, and by the presence of susceptible mammalian hosts. There is a gradation from continuous BTV activity in tropical areas to absence of virus transmission in colder areas. In large countries that span different latitudes, such as the United States and Australia, there are endemic areas and regions that are free of BTV infection.

In **endemic areas**, the infection is always present, but clinical disease of the indigenous species is unusual. It can occur with new BTV strains and when nonindigenous susceptible species are introduced to the area.

**Epidemic zones** also exist, where infection and clinical disease occur every few years. Infection in these areas is highly focal, and outbreaks occur when climatic conditions allow the vector to spread beyond its usual boundaries and to infect susceptible ruminants.

**Incursive disease** can occur in regions that do not normally experience infection and may be caused by windborne movement of infected *Culicoides* with subsequent insect breeding in the summer before “die-out” in the autumn and winter. This method of spread is thought to have been the genesis of several serious outbreaks of bluetongue in countries normally free of the disease and of the outbreaks in Portugal in 1956, in Cyprus in 1977, in Turkey and Greece in 1979 to 1980, and in Israel in 1960 to 1980. The recent epidemic of BTV-8 in northern and central Europe between 2006 and 2008, which caused the most severe outbreak of the disease on record, made clear that alternative, thus far unidentified, ways of virus introduction into previously unaffected regions must be considered. This serotype 8, which was previously only identified in the sub-Saharan region, was first isolated in the Netherlands in 2006, having entirely bypassed the southern part of the continent. To this day no plausible explanation for the introduction of serotype 8 into the northern European region has been proposed.

In the **United States** the prevalence of seropositive cattle varies from high in the southern and western states to low in the northern states, especially the northeastern states. In the northwestern region, there are epidemics of infection in the summer and fall every few years, associated with movement of infected vectors from the south. **Canada** is free of infection except for

periodic incursions into the Okanagan Valley in British Columbia from windborne-infected *Culicoides* from south of the border. In **Australia**, there has been a sequential introduction of bluetongue serotypes from Indonesia by windborne *Culicoides* spp., but endemic infection is limited to northern cattle areas with extension down the East Coast. In **central and northern Europe and the United Kingdom**, no new cases of BTV have been recorded since 2009, and thus wide parts of the continent have been declared free of BTV. In **southern Europe** BTV is currently present in the southern part of Italy, Spain, Portugal, and Corsica.<sup>6</sup>

## Host Occurrence

Under natural conditions infection occurs in sheep and cattle, but it is also recorded in New World camelids, elk, white-tailed deer, pronghorn antelope, camels, and other wild ruminants. Natural infection rarely occurs in goats, but the infection can be transmitted experimentally. Although clinical disease primarily occurs in sheep, certain strains are highly virulent in cattle and wild ruminants. **Cattle** are the major **reservoir host**. In carnivores, infection after vaccination with BTV-contaminated vaccines has been documented.

## Method of Transmission

The disease is not contagious and is almost exclusively **transmitted biologically** by specific species of *Culicoides*. There are approximately 1500 species of *Culicoides* worldwide, of which only limited types have been associated with BTV. Only about 50 *Culicoides* species are susceptible to BTV infection. Of these species, only those having ruminants as sole or predominant hosts are epidemiologically relevant for the transmission of BTV.

*Culicoides* breed in damp, wet areas, including streams, irrigation channels, muddy areas, and fecal runoff areas around farms, and habitats for them exist on the majority of farm environments. Only female *Culicoides* are hematophagous and feed on their main or preferred host species, requiring at least one blood meal for the completion of the ovarian cycle. They feed nocturnally on animals in open pens and fields, and the optimal temperatures for activity are between 13°C and 35°C (55° and 95° F).

Virus present in ingested blood cells infects cells of the midgut of the vector, replicates, and subsequently is released to the salivary gland. The virus is then transmitted through saliva to the host the infected midge is feeding on. Vertical transmission of infectious virus from adult midge to its larvae does not appear to occur. In temperate areas the disease is **seasonal** because *Culicoides* do not tolerate low ambient temperatures, resulting in a vector-free season during late fall and winter.

### Culicoides Species

Different *Culicoides* species have different geographic occurrence, and their distribution in a country is determined by climatic factors and the presence of a preferred host. In the **United States**, *C. sonorensis* is the predominant vector throughout much of the country, except in the southeast, where it is *C. insignis*. *C. insignis* is also the predominant vector for most BTV strains in the **Caribbean** and Central and **South America**. Other epidemiologically relevant *Culicoides* species in this region are *C. pucillus*, *C. insignis*, *C. pusillus*, and *C. filarifer*. In **Africa**, *C. imicola* is a predominant vector, and in the **Middle East and Asia**, *C. fulvis*, *C. imicola*, *C. obsoletus*, *C. nudipalpis*, and *C. orientalis*. In **Australia**, *C. wadai*, *C. actoni*, *C. brevipalpis*, *C. peregrinus*, *C. oxystoma*, *C. brevipalpis*, and *C. fulvus* are vectors or potential vectors. They have different distribution in the country, which oscillates depending on climate. *C. imicola* has been involved in the recent expansion of bluetongue in **southern Europe**, but *C. obsoletus*, *C. pulicaris*, and *C. dewulfi* have been implicated as new vectors associated with recent BTV outbreaks in **central and northern Europe**, where *C. imicola* does not occur.

### Other Vectors

Other vectors may transmit the disease mechanically but are unlikely to be of major significance in disease epizootics. The argasid tick *Ornithodoros coriaceus* has been shown experimentally to be capable of transmitting the virus and be a potential vector. The sheep ked (*Melophagus ovinus*) ingests the virus when sucking the blood of infected sheep and can transmit the infection in a mechanical manner. Mosquitoes may play a role in transmission, and *Aedes lineatopennis* and *Anopheles vagus* have been suspect.

### Overwintering

Survival of the virus during the vector-free season is termed *overwintering*. As is documented by an annual recrudescence of bluetongue in several temperate areas, BTV can survive several months of cold season presumably in the absence of adult biological vectors. The mechanisms involved are not yet fully understood. Proposed hypotheses to explain the overwintering ability of BTV include persistence of the virus within surviving adult vectors, transovarian transmission within the vector, and prolonged or even persistent infection of viremic or aviremic vertebrate hosts.<sup>5</sup> The average life span of an adult *Culicoides* is between 10 and 20 days but can occasionally extend up to 3 months.<sup>7</sup> In addition, entomologic surveillance in northern Europe has demonstrated the presence of a small number of active *Culicoides* during the winter season inside barns.<sup>8</sup> Overwintering within the adult vector population has therefore been proposed as a plausible explanation for a

sustained BTV transmission cycle. In contrast, no evidence supporting vertical (transovarian) transmission of BTV within the vector is currently available.

Overwintering of BTV could also occur in hosts with prolonged viremic phases, such as cattle, where viremia commonly lasts between 20 and 50 days.<sup>9</sup> It is assumed that, in general, **viremia in cattle ceases by 60 days** after infection, although viremic phases of up to 100 days have been reported.<sup>10</sup>

### Transplacental Infection

Transplacental infection has been documented experimentally and under field conditions after **infection with modified live laboratory strains** commonly used for vaccine production (modified live vaccines), suggesting that modification of BTV field strains can markedly increase the ability of the virus to cross the placenta and cause fetal infection. Of the 26 currently known wild-type serotypes, only **serotype 8** was repeatedly documented to cause fetal infection through transplacental transmission in cattle and sheep under field conditions.<sup>11,12</sup> Before the appearance of BTV-8 the observed incidence of transplacental transmission was estimated to be near zero, and the few documented cases were associated to the use of modified live vaccines.<sup>13</sup> In contrast, transplacental virus transmission after infection with wild-type BTV-8 was shown to occur with considerable frequency.<sup>14</sup> A study conducted during the BTV-8 epidemic in northern Europe between 2006 and 2008 revealed that virus RNA could be retrieved from 41% of aborted fetuses where BTV was suspected as causative pathogen and from over 18% of fetuses where BTV was not suspected as cause of abortion.<sup>11</sup>

Although the epidemiologic relevance of the vertical transmission of certain BTV serotypes is to be determined, intrauterine infection of the fetus, possibly resulting in a virus-shedding neonate, also presents a possible mechanism for virus survival during the vector-free season.

The outcome of transplacental infection primarily depends on the stage of pregnancy at the time of infection of the dam and can range from abortion to different sorts of congenital defects to healthy-looking lambs or calves. Infection or vaccination of the dam with virus strains capable of crossing the placenta at early stages of pregnancy most commonly results in abortion. Congenital defects of the nervous system can occur when pregnant ewes or cows are exposed to BTV-8 or vaccinated with attenuated vaccine virus before midgestation. At birth, affected neonates characteristically also have circulating BTV-specific antibodies before ingestion of colostrum but no infectious BTV. Dams infected at a later stage of pregnancy give birth to calves without congenital malformation that may be viremic with or without BTV-specific

antibody titer. The viremic phase of newborn calves infected in utero is of similar duration as in animals infected after birth. BTV infection in cattle is therefore considered to be transient and neither persistent nor immunotolerant.<sup>15</sup>

Observed congenital defects include excessive gingival tissue, agnathia (tilted mandible), arthrogryposis, hydranencephaly, and porencephaly. The severity of the brain lesions decreases with increasing fetal age. Infection at 243 days results in a mild encephalitis and the premature birth of calves that are still viremic but poorly viable.

### Persistent Infection

Persistent infection in immunotolerant animals following in utero infection has been implied in a single study and was consequently thought to be of paramount epidemiologic importance. However, a large number of experimental and field studies failed to produce any evidence supporting the occurrence of persistent infection or the existence of a BTV carrier status. Persistent infection is therefore currently considered a highly unlikely scenario.

### Venereal Transmission

Bluetongue virus can be found in the **semen** of infected bulls during the viremic period, and infection has been transmitted through bull semen to susceptible cows, but it is unlikely that this is a significant mechanism of transmission. Transplanted **embryos** from infected donors are free of the virus because it does not appear to penetrate the zona pellucida. Embryo transfer is regarded as a minimal risk procedure for the transmission of BTV in cattle and sheep as long as the guidelines of the International Embryo Transfer Society (IETS) are followed. Recommended procedures include visual inspection, rigorous washing of the embryo, and, in some instances, treating with trypsin to inactivate infectious virus particles. Virus transmission when doing embryo transfers could occur as a result of contamination of media or equipment used to manipulate the embryos.<sup>16</sup>

### Oral Transmission

Studies reporting or suggesting oral transmission BTV have been published recently. These studies include one report of infection of adult cattle after ingestion of BTV-8-infected placenta and several reports where infection of newborn calves after consumption of infected colostrum was described.<sup>17-19</sup> The epidemiologic relevance if this route of transmission remains to be determined.

### Pathogen and Vector Risk Factors

The geographic occurrence of bluetongue serotypes varies and is changing with time. There are differences in virulence between serotypes. The virulence of the virus is also

related to the infectious dose, which, among other factors, depends on the vector species, its competence, and its occurrence. Different *Culicoides* species vary in susceptibility to infection (i.e., vector competence), and some known vectors are resistant to infection with some serotypes, which in part explains regional differences in serotype occurrence.

### Climate

Climate is a major risk factor because *Culicoides* require warmth and moisture for breeding and calm, warm, humid weather for feeding. A cold winter or a dry summer can markedly reduce vector numbers and risk for disease. Moisture may be in the form of rivers and streams or irrigation, but rainfall is the predominant influence; rainfall in the preceding months is a major determinant of infection.

Precipitation affects the size and persistence of breeding sites and the availability of humid microhabitats to allow shelter from desiccation during hot summer and autumn periods. Optimal temperature is also essential for survival and activity of the vector and for virus replication within the vector. Ambient temperatures for survival of adult midges and larvae must be above a mean of 13°C (55°F) and range between 18° and 30°C (64° and 86°F) for optimal adult activity. The rate of virus replication within an infected midge also largely depends on the ambient temperature. Whereas at 30°C midges may start shedding virus within days of infection, this takes several weeks at ambient temperatures of 15°C (59°F).<sup>1</sup> Virus replication within the vector apparently ceases completely at temperature below approximately 12°C (54°F), although the virus may persist in infected midges and replication may resume with increasing temperatures.<sup>1</sup> Geographic information systems (GIS) can be used to predict area risk.

### Serotype Occurrence

Genetic studies indicate that BTV tends to exist in discrete, stable ecosystems and that BTV serotypes that circulate in one region of the world are largely different from those in other regions. In the **United States**, four serotypes (10, 11, 13, and 17) associated with *C. sonorensis* are considered endemic south of the so-called “Sonorensis Line” going from Washington in the West to Maryland in the East. Serotype 2 is another strain occurring in the United States, but it is restricted to the southeast of the country, the habitat of *C. insignis*.

In the **Caribbean** region and **South and Central America**, serotypes 1, 3, 5, 6, 8, 12, 14, 17, 19, 22, and 24 were reported. In **Australia**, BTV is endemic in the northern and northeastern areas of the country, and most of the western, southern, and central parts of the country are considered free of bluetongue.<sup>20</sup> Serotypes 1 and 21 are the predominant strains in northwestern Australia, the

Northern Territory, Queensland, and the northeastern areas of New South Wales.<sup>21</sup> In total 10 serotypes (1, 2, 3, 7, 9, 15, 16, 20, 21, and 23) have been isolated in the country. Six of these (3, 9, 15, 16, 20, and 23) have only been found in the north of the Northern Territory. Since 2008, BTV-2 has been detected in northern and eastern Australia, in regions in which only serotypes 1 and 21 had been recorded previously.<sup>21</sup> The virus has been isolated from infected *Culicoides* and sentinel animals, and although there is serologic evidence of infection in Queensland and New South Wales, there has been no clinical disease. In **Africa**, 22 of the known 26 serotypes have been identified. Serotypes 1, 16, 18, 19, and 24 are the predominant serotypes isolated, and serotypes 20, 21, 25 and 26 are considered exotic.<sup>22</sup> In **Asia**, serotypes 1, 4, 7, 9, 10, 12, 16, 17, 20, 21, and 23 have been identified. The new serotype 26 was recently identified in Kuwait.<sup>4</sup> Serotypes 1, 2, 4, 6, 8, 9, 11, and 16 are associated with disease in the expansion of BTV infection in **Europe** since 1998. BTV serotype 8 is the strain associated with repeated BTV outbreaks observed between 2006 and 2008 affecting most of central and northern Europe, including the United Kingdom and parts of Scandinavia.<sup>23</sup> Serotypes 6 and 11 isolated in northern Europe in that same period have been related to vaccine strains used in modified live vaccines produced in South Africa and are thought to have been introduced through the illegal use of modified live vaccines in the region.<sup>1</sup> Currently, large parts of Europe are declared free of BTV. Exceptions are Spain (serotypes 1 and 4), Portugal (serotype 1), the southern part of Italy (serotypes 1, 2, 4, 8, 9, 16), Corsica (serotypes 1, 2, 4, 8, 16), the Channel Islands (serotypes 1, 8), Cyprus (serotypes 4 and 6), and the Greek islands of Lesbos, Dodekanisa, and Samos (serotypes 1, 4, 8, 16).<sup>6</sup>

### Host Risk Factors

Although all ruminant species are susceptible to infection with BTV, most virulent strains cause clinical disease primarily in sheep, whereas infection often remains asymptomatic in the majority of infected cattle, goats, and wild ruminants.

### Cattle

Although some BTV strains, such as serotype 8, can cause severe clinical disease in cattle, infection with most other virulent BTV strains remains subclinical or causes only mild clinical signs in this species. Cattle are therefore considered the **reservoir and amplifying host** and have a high titer viremia. Cattle appear to be much more attractive to *Culicoides* spp., and this may enhance the importance of cattle as carriers. A **critical density** of cattle in a region may be required to sustain bluetongue in regions where the *Culicoides* vector is strongly cattle associated. Seroprevalence increases with

age, probably a reflection of increased duration of exposure.

### Sheep

All breeds of sheep are susceptible to infection, although to varying degrees. **European fine-wool and mouton breeds** are most susceptible to severe clinical disease. There are also differences in age susceptibility to clinical disease, which, inexplicably, vary with different outbreaks. Exposure to **solar radiation** can increase the severity of the disease, as can excessive droving, shearing, poor nutrition, and other forms of stress.

### Goats and Wild Ruminants

Goats, like other ruminant species, are susceptible to infection but rarely show clinical signs. Among wild ruminants, **white-tailed deer** and pronghorn antelopes were found to be highly susceptible to infection resulting in clinical disease. Surveys conducted throughout Europe during the epidemic caused by BTV serotype 8 documented the broad susceptibility to infection of the wild ruminant population.<sup>24,25</sup>

### New World Camelids

Evidence for natural infection of South American camelids with different BTV serotypes is available from Peru, the United States, and Europe, where seroconversion in unvaccinated animals has been reported.<sup>26-28</sup> Following the recent BTV-8 outbreak in northern and central Europe, a mean animal seroprevalence of 14.3% of the tested New World camelid population was reported in Germany, a value that is considerably below prevalence rates determined in other ruminant species in the same region.<sup>28</sup> Historically, South American camelids were considered to be resistant to clinical bluetongue, but incidental case fatalities that have been associated with BTV infection have been reported in the recent literature.<sup>29-31</sup>

### Morbidity and Case Fatality

When the disease occurs in a flock for the first time, the incidence of clinical disease may reach 50% to 75% and the mortality 20% to 50%. Outbreaks in Cyprus and Spain were accompanied by mortality rates of 70% in affected flocks, but most outbreaks result in much lower mortality. Mortality rates of 2% to 30% are reported under field conditions in South Africa and from 0% to 14% in field outbreaks in the United States. High mortality can occur when a new strain of BTV emerges in an area.

Before the occurrence of BTV-8 in northern and central Europe, bluetongue in cattle was considered a predominantly subclinical disease, and clinical cases were observed sporadically only. During the European BTV-8 outbreak between 2006 and 2008, morbidity rates ranging from 0% to 32% were reported. Mortality ranged between 0% and 17% in sheep and 0% and 4% in cattle.<sup>32</sup>

Immunity to BTV tends to be strain specific, and in epizootics, more than one strain may be introduced into an area. Infections caused by different serotypes may follow one another in quick succession in a sheep population. The serotypes vary widely in their virulence, with a corresponding variation in the severity of the disease produced. However, sequential infection with more than one type of BTV results in the development of heterotypic antibody and may result in protection against heterologous serotypes not previously encountered.

### Experimental Reproduction

Infection is readily produced by experimental infection of sheep, cattle, and New World camelids, but it is common for the clinical presentation of the experimental disease to be **very mild** despite the fact that the isolate might have been associated with severe disease in the field. In many cases experimental infection produces viremia, fever, leukopenia, and an antibody response, but the localizing, identifying lesions are often minimal, with erythema of the coronary bands as the only visible abnormality in some cases.

### Economic Importance

Economic losses from bluetongue are attributable to direct effects of the infection, such as animal losses and abortion, to which costs associated with treatment and disease control have to be added. Production losses are also of great importance in sheep and cattle alike. Adult sheep either lose their fleece from a break in the growth of the staple or develop a weakness (tender wool) that causes breaks in processing and markedly reduces the value of the fleece. Pregnant ewes commonly abort. There is a severe loss of condition, and convalescence is prolonged, particularly in lambs. The loss from clinical disease and from reduced wool quality and suboptimal production following infection in sheep are significant. Production losses associated with the BTV-8 outbreak in Europe affecting the dairy industry were estimated to be considerably higher compared with sheep in part because of the higher value of the individual animal, but also because of the marked and sustained effect on milk production lasting for several weeks (up to 2 kg per cow and day) and the increased incidence of reproductive failures.<sup>33</sup>

Major financial losses result from **restrictions in international trade**. The severe disease that occurred in the outbreaks in Cyprus and the Iberian Peninsula in the 1940s and 1950s resulted in bluetongue being placed on List A of veterinary diseases by the OIE. At the time, persistent infection of ruminants resulting in carrier animals was thought to be a major factor explaining the worldwide spread of the disease; as a result, restrictions on the international movement of cattle and sheep and their products from

countries that have this infection to those that do not have been instituted. For countries where BTV virus is endemic and clinical disease is rare, such as the United States, costs resulting from these trade restrictions by far outweigh direct costs related to the disease. It is estimated that the United States has an annual loss of \$144 million because of the inability to trade with BTV-free countries.

### PATHOGENESIS

#### Sheep

The pathology of bluetongue can be attributed to vascular endothelial damage resulting in changes to capillary permeability and fragility, with subsequent disseminated intravascular coagulation and necrosis of tissues supplied by damaged capillaries. These changes result in edema, congestion, hemorrhage, inflammation, and necrosis.

Following inoculation of the virus through the skin by a bite of an infected vector, the virus reaches the regional lymph node, where a first replication occurs. The virus that targets all blood cells and thrombocytes is then disseminated by these cells throughout the entire organism. Secondary virus replication takes place in lymphoid tissues such as the lymph nodes and spleen and particularly in the lungs. Viremia is detectable by day 3, and peak viremia, associated with fever and leukopenia, usually occurs 6 to 7 days after infection. Circulating virus concentrations subsequently fall with the appearance of circulating interferon and specific neutralizing antibodies. With the viremia, there is localization of the virus in vascular endothelium, which causes endothelial cell degeneration and necrosis with thrombosis and hemorrhage. There is also the development of a hemorrhagic diathesis and coagulation changes consistent with disseminated intravascular coagulation. The distribution of the lesions is thought to be influenced by mechanical stress and the lower temperatures of these areas in relation to the rest of the body.

#### Cattle and Wild Ruminants

With infection in cattle and wild ruminants by most virus strains, endothelial cell damage is minimal. The viremia in cattle is highly cell associated, particularly with erythrocytes and platelets. Although the virus does not replicate in the erythrocytes, it is protected from circulating neutralizing antibody, and infected erythrocytes are likely to circulate for their life span. With the life span of bovine erythrocytes being longer than that of ovine erythrocytes, this results in the prolonged viremia in cattle with concomitant presence of neutralizing antibodies. Although virus RNA may be detectable for up to 140 days after infection, the viremic phase (i.e., period of presence of infectious virus in blood) rarely exceeds 60 days. Viremic phases of up to 100 days have been reported

incidentally.<sup>10</sup> Before the BTV-8 outbreak in Europe, sporadic clinical cases observed in cattle were thought to be the result of type I hypersensitivity reaction triggered by repeated exposure to virus-specific IgE.

In white-tailed deer, which are highly susceptible to bluetongue, disseminated intravascular coagulopathy (DIC) develops as a result of BTV-induced vascular damage. Affected animals develop potentially life-threatening hemorrhagic diathesis.<sup>15</sup>

### CLINICAL FINDINGS

#### Sheep

Naturally occurring florid bluetongue in sheep has the following clinical characteristics. After an incubation period of less than a week, a severe febrile reaction with a maximum temperature of 40.5° to 41° C (105–106° F) is usual, although afebrile cases may occur. The **fever** continues for 5 or 6 days. About 48 hours after the temperature rise, nasal discharge and salivation, with reddening of the buccal and nasal mucosae, are apparent. The **nasal discharge** is mucopurulent and often blood stained, and the saliva is frothy. Swelling and edema of the lips, gums, dental pad, and tongue occur, and there may be involuntary movement of the lips. **Excoriation** of the buccal mucosa follows, the saliva becomes blood stained, and the mouth has an offensive odor.

Lenticular necrotic ulcers develop, particularly on the lateral aspects of the tongue, which may be swollen and purple in color, but more commonly is not. **Hyperemia** and ulceration are also common at the commissures of the lips, on the buccal papillae, and around the anus and vulva. Swallowing is often difficult for the animal. Respiration is obstructed and stertorous and is increased in rate up to 100/min. Diarrhea and dysentery may occur.

Foot lesions, including **laminitis** and **coronitis** and manifested by lameness and recumbency, appear only in some animals, usually when the mouth lesions begin to heal. The appearance of a dark-red to purple band in the skin just above the coronet, as a result of coronitis, is an important diagnostic sign. **Wryneck**, with twisting of the head and neck to one side, occurs in a few cases, appearing suddenly around day 12. This is apparently attributable to the direct action of the virus on muscle tissue, as is the pronounced muscle stiffness and weakness, which is severe enough to prevent eating. There is a marked and rapid loss of condition. There is **facial swelling** with extensive swelling and drooping of the ears, and hyperemia of the nonwooled skin may be present. Some affected sheep show severe conjunctivitis, accompanied by profuse lacrimation. A break occurs in the staple of the fleece. Vomiting and secondary aspiration pneumonia may also occur. Death in most fatal cases occurs about 6 days after the appearance of signs.

In animals that recover, there is a **long convalescence**, and a return to normal may take several months. Partial or complete loss of the **fleece** is common and causes great financial loss for the farmer. Other signs during convalescence include separation or cracking of the hooves and wrinkling and cracking of the skin around the lips and muzzle. Although the subsequent birth of lambs with porencephaly and cerebral necrosis is usually recorded after vaccination with attenuated virus, it also occurs rarely after natural infections.

In sheep in **enzootic areas**, the disease is much less severe and often inapparent. Two syndromes occur: (i) an abortive form in which the febrile reaction is not followed by local lesions and (ii) a subacute type in which the local lesions are minimal, but emaciation, weakness, and extended convalescence are severe. A similar syndrome occurs in lambs, which become infected when colostrum immunity is on the wane.

### Cattle

**Most infections are inapparent**, although some BTV strains, such as serotype 8, are highly virulent in cattle. Affected animals may develop a clinical syndrome not unlike that seen in severely affected sheep. The incubation period was estimated to be between 6 and 8 days. Although fever in the range of 40° to 41° C (104–106° F) is often but not consistently observed, affected animals are lethargic and show anorexia and a drop in milk production. Skin and mucosal lesions on the muzzle, oral cavity, and tongue develop in early stages of the disease. Lesions are characterized by ulceration, necrosis, and eventually by superficial crusting. Mucopurulent and sometimes blood-tinged nasal discharge and fetid breath is a common finding. Hypersalivation and regurgitation are often observed. Skin lesions with erythema, ulcers, and necrosis can be found on the udder skin, on and around the coronary band, and sometimes around the eyes. Localized distal limb edema contributes to the observed reluctance to move of affected animals. Photodermatitis may develop at later stages of the disease (2–3 weeks after infection) on unpigmented skin. Contraction of the infection during early pregnancy may cause abortion, stillbirth, or **congenital deformities**, including hydranencephaly, microcephaly, arthrogryposis, blindness, and deformity of the jaw.

During the viremic phase, infected bulls are likely to shed virus in semen. The presence of BTV in the **semen** of bulls is accompanied by structural abnormalities of the spermatozoa and by the presence of virus particles in them.

### Goats

Infected goats show very little response clinically. There is a mild to moderate fever and hyperemia of the mucosae and conjunctivae.

BTV infections in deer produce an acute disease that is clinically and pathologically identical to epizootic hemorrhagic disease of deer and characterized by multiple hemorrhages throughout the body.

### New World Camelids

Although New World camelids were considered to be resistant to clinical disease associated with BTV, several reports of clinical disease with fatal outcome have been published in the recent literature.<sup>29–31</sup> Common to all reports is that only individual animals of a flock were affected while the rest of the flock remained clinically healthy. Common clinical findings were a rapid onset with anorexia, lethargy, and rapidly progressing respiratory distress. In most cases animals became recumbent and died within 24 hours of first clinical signs. Postmortem findings were severe alveolar edema of the lungs, hydrothorax, and hydropericardium, and severe congestion of the liver, spleen, and kidneys. In one case abortion was reported, and virus RNA was retrieved in fetal tissue.<sup>30</sup>

Experimental infection studies and epidemiologic field survey suggest that New World camelids are susceptible to infection, showing seroconversion, but only very rarely show clinical signs of disease.<sup>26,34</sup>

### Wild Ruminants

Among wild ruminants, **white-tailed deer** were found to be most susceptible to bluetongue. Clinical presentation resembles the epizootic hemorrhagic disease of deer. Acute cases are characterized by **hemorrhagic diathesis** resulting from disseminated intravascular coagulopathy (DIC). Affected animals have widespread hemorrhages throughout the body, bloody diarrhea, swelling of head and neck, and blood-stained nasal discharge.

### CLINICAL PATHOLOGY

There is a fall in packed cell volume and initial leukopenia followed by leukocytosis. In severe disease there is marked leukopenia, largely as a result of lymphopenia. Infected cattle show a similar manifestation of leukopenia. The skeletal myopathy that occurs in this disease is reflected by a rise in creatine phosphokinase.

Specific diagnosis is either by isolation of the virus, detection of viral antigen or nucleic acid, or detection of specific antibodies in serum. Serologic assays can detect prior exposure to BTV but cannot establish if the animal is viremic, which is currently still important for movement decisions concerning cattle.

Material that can be used for virus isolation include heparin or EDTA blood; biopsies or postmortem tissue samples of the spleen, lung, lymph nodes, liver, and bone marrow; and, when indicated, heart or skeletal muscle tissue and brain tissue of aborted or stillborn fetuses.

### Virus Isolation

Virus isolation commonly is carried out by tissue culture or culture in embryonated chicken eggs (ECEs). Material obtained from inoculated chick embryos can either directly be examined (e.g., by using molecular methods such as PCR or in vitro hybridization) or be further propagated in cell cultures. Cell lines used for this purpose can be of insect origin, such as the KC cell lines derived from *Culicoides sonorensis* or mammalian cell lines such as the baby hamster kidney cells (BHK), calf pulmonary artery endothelium cells (CPAE), or African green monkey kidney cells (Vero). The cytopathic effect produced by BTV is only observed in cell lines of mammalian origin. Virus identification from cell cultures can then be conducted by methods such as immunofluorescence and immunoperoxidase assays using BTV-specific monoclonal antibodies. Virus isolation is the most reliable confirmation of BTV infection because there are difficulties with the interpretation of serologic test results. However, traditional isolation methods require 2 to 4 weeks.

Less commonly, diagnosis is by inoculation of blood into susceptible sheep, a method that is considered as one of the most sensitive and reliable methods of BTV isolation. A positive test depends on the appearance of clinical signs and/or the mounting of a BTV-specific antibody response. This method is used occasionally with samples containing very low virus titers but has widely been replaced by ECE inoculation.

### Detection of Antigen or Nucleic Acid

Immunohistochemical tests, including immunofluorescence, immunoperoxidase, and immunoelectron microscopic techniques using monoclonal antibody, can be used for rapid sensitive and specific detection of antigen. In situ nucleic acid hybridization and reverse-transcription polymerase chain reaction (**RT-PCR**) can be used for detection of the virus even after the viremic phase. This method has the advantage of speed over tissue culture virus isolation and can also differentiate between wild-type isolates and vaccine strains. Tests that detect viral RNA prove exposure to the virus but do not necessarily indicate that infectious virus is still present.

### Serologic Tests

Serologic tests for detection of either group-reactive antibodies or serotype-specific antibodies are available. The commonly available tests include the complement fixation test (CFT), the agar gel immunodiffusion test (AGID), a number of different ELISA tests, and serum neutralization (SN). The **AGID test** is easy to perform and inexpensive but is also relatively **insensitive** and detects cross-reacting antibodies to other orbiviruses. Over the last decades the CFT and AGID have been replaced in many

laboratories by the more rapid, sensitive, and specific competitive ELISA.

Numerous ELISA tests have been developed using group-specific monoclonal antibodies and present valuable alternatives to the AGID for routine diagnosis and international trade. The **competitive ELISA (c-ELISA)**, which is the most sensitive and highly specific group-specific test, is the preferred test for serodiagnosis of bluetongue. The c-ELISA cannot differentiate between infection and vaccination with modified live vaccines but is ideally suited to identify seroconversion in an unvaccinated population or to monitor the efficiency of a vaccination campaign in noninfected animals.

The **serum neutralization test (SNT)** is serotype specific and thus allows differentiation between antibodies against specific BTV serotypes. The biological detection system (either ECE or cell cultures) is reacted with a reference serum for specific BTV serotypes, and the amount of virus neutralization is determined. Although the SNT is highly sensitive and specific, it is also expensive and time consuming and is therefore not used as routine diagnostic procedure.

## NECROPSY FINDINGS

### Sheep

Sheep dying from bluetongue show edematous face and ears and a dry, crusty exudate on the nostrils and the conjunctiva. The coronary bands of the hooves are often hyperemic, and hemorrhages may extend down to the horn. The oral mucosa is usually cyanotic or hemorrhagic, with erosions and ulcers commonly affecting the tongue and dental part and sometimes extending to the rumen and abomasum. Acute cases will show subcutaneous and intermuscular edema, which may be serous or suffused with blood; the lesion is most marked in the head, neck, and abdominal regions. There may be serous effusions in the pleura, pericardium, and peritoneum. A characteristic and almost pathognomonic lesion for bluetongue is hemorrhage at the base of the pulmonary artery. Foci of muscle necrosis may be present in the heart, esophagus, pharynx, and other muscles. There may be aspiration pneumonia secondary to damaged esophageal/pharyngeal musculature, or the lungs may be diffusely edematous, especially when there are cardiac lesions.

The outcome of fetal infection in both sheep and cattle is age-dependent, with distinctive cavitating lesions of the brain (hydranencephaly or porencephaly) in fetuses that survive infection during early gestation, whereas fetuses infected in late gestation may be born viremic but without brain malformations.<sup>35</sup>

### Cattle

Mortality is less common in cattle. Lesions can include severe and extensive ulceration of the muzzle, oral mucosa, and teats;

rhinitis and mucohemorrhagic nasal discharge; epiphora and periorcular inflammation; and limb edema and interdigital necrosis and ulceration.<sup>35</sup> In some cases, the skin is ulcerated or eroded with a dry, crusty exudate, or it may have thick folds, particularly in the neck region. The coronary band is often hyperemic, and there may be pulmonary edema and serous effusion into body cavities. As in sheep, infected fetuses may develop central nervous lesions depending on the strain of the virus and the stage of gestation when infected. Several cases of congenital hydranencephaly and other anomalies were reported in calves during the initial outbreaks of BTV serotype 8 in Europe.<sup>35,36</sup>

Microscopically, bluetongue virus infection in sheep and cattle is characterized by thrombosis and widespread microvascular damage leading to hemorrhage, edema, myodegeneration, and necrosis. Inflammation is mild.

## Samples for Confirmation of Diagnosis

- **Histology**—fixed oral and mucocutaneous lesions, abomasum, pulmonary artery, skeletal muscle from a variety of sites, left ventricular papillary muscle; brain from aborted fetus (light microscopy, immunohistochemistry)
- **Virology**—chilled lung, spleen; CNS tissues, thoracic fluid from aborted fetus (ISO, PCR, in situ hybridization, ELISA, etc.)

## DIFFERENTIAL DIAGNOSIS

Foot-and-mouth disease
Epizootic hemorrhagic disease (wild ruminants)
Contagious ecthyma (sheep)
Sheep pox (sheep)
Bovine viral diarrhea/mucosal disease (cattle)
Malignant catarrhal fever (cattle)
Acute photodermatitis (cattle)
Bovine herpes mammillitis (cattle)

## TREATMENT

There is currently no specific treatment for bluetongue available. Symptomatic and supportive treatment should be considered to provide relief. Local irrigations with mild disinfectant solutions may afford some relief. Affected sheep should be housed and protected from weather, particularly hot sun, and fluid and electrolyte therapy and treatment to control secondary infection may be desirable.

## CONTROL

### Reduction of Infection Through Vector Abatement

Attempts to control bluetongue through a reduction of infection consist of reducing the

risk of exposure to infected *Culicoides* and reduction in *Culicoides* numbers. Neither is particularly effective.

Reducing the risk of exposure is attempted by spraying cattle and sheep with repellents and insecticides and housing sheep at night. Biweekly application of permethrin was found not to be effective in preventing infection.

During transmission periods, avoidance of low, marshy areas or moving sheep to higher altitudes may reduce risk. Because of the preference of some *Culicoides* for cattle as a host, cattle have been run in close proximity to sheep to act as vector decoys. Widespread spraying for *Culicoides* control is not usually practical and has only a short-term effect.

There is a high mortality in *Culicoides* that fed on cattle that have been treated with a standard anthelmintic dose of ivermectin and also a larvicidal effect in manure passed for the next 28 days for *Culicoides* that breed in dung.

Movement of ruminants from areas where specific BTV strains are circulating to regions where this serotype does not occur should only be considered after confirmation of absence of viremia.

## Vaccination

Vaccination is the only satisfactory control procedure once the disease has been introduced into an area. Vaccination will not prevent or eliminate infection, but it is successful in keeping losses to a very low level, provided immunity to all local strains of the virus is attained. Current vaccines are usually **polyvalent attenuated** virus vaccines and are in use in South Africa and Israel and available in other countries. These vaccines have been used in South Africa for more than 50 years, and they are known to induce effective and long-lasting immunity.

Reactions to vaccination are slight, but ewes should not be vaccinated within 3 weeks of mating because anestrus often results. **Annual revaccination** 1 month before the expected occurrence of the disease is recommended. Immunity is present 10 days after vaccination, and thus early vaccination during an outbreak may substantially reduce losses. Lambs from immune mothers may be able to neutralize the attenuated virus and fail to be immunized, whereas field strains may overcome their passive immunity. In enzootic areas, it may therefore be necessary to postpone lambing until major danger from the disease is passed, and lambs should not be vaccinated until 2 weeks after weaning. Rams should be vaccinated before mating time.

Live attenuated vaccines should not be used in **pregnant ewes** because of the risk of congenital defects in the lambs or embryonic death. The danger period is between the 4th and 8th weeks of pregnancy, with the greatest

incidence of deformities occurring when vaccination is carried out in ewes pregnant for 5 to 6 weeks. The incidence of congenital defects may be as high as 13%, with an average of 5%. Abortions do not occur, although some lambs are stillborn.

The preparation and use of **attenuated vaccines** against BTV is **problematic**. The neutralizing epitopes are highly conserved on some serotypes, but they are highly plastic on others. It is therefore necessary to continually monitor the identity and prevalence of the serotypes that need to be in the vaccine.

There are also concerns for the use of attenuated live vaccines to control insect-borne diseases because of the risk of the vaccine strain being transmitted, of being exalted in virulence by passage, and of recombinants resulting in the development of new virus strains with unwanted characteristics. There is evidence for the emergence of a **reassortment strain** from a vaccine virus in the United States and Europe and suspicion of occurrence elsewhere. However, attenuated live vaccines are used for practical reasons, including the fact that inactivated vaccines do not provide protection against infection. The difficulty in obtaining safe vaccines may be overcome by the use of recombinant DNA technologies. There is also good reason to suggest that cattle should be a major target of vaccination for bluetongue control.

### International Movement of Livestock

Countries that are free of BTV infection have traditionally erected barriers to avoid its introduction by prohibiting the importation of any ruminant animals from countries where the disease occurs. Others have less severe restrictions, and several procedures aimed at permitting limited movement are in force; their stringency varies with the importing country. Some countries only require a negative serologic test or series of tests before movement. Others require a negative test in conjunction with a period of quarantine. The introduction of bovine **semen** from low-risk areas after suitable tests of donors and a prolonged storage period is accepted by most countries. Most countries allow the importation of **embryos**.

A more enlightened understanding of the epidemiology of bluetongue will probably result in a reevaluation of these requirements in the future, including regionalization within a country to allow exports from areas where there is no prevalence or transmission.

## MALIGNANT CATARRHAL FEVER (BOVINE MALIGNANT CATARRH, MALIGNANT HEAD CATARRH)

### SYNOPSIS

**Etiology** Alcelaphine herpesvirus-1, the wildebeest-associated malignant catarrhal fever (MCF) virus; ovine herpesvirus-2, the sheep-associated MCF virus

**Epidemiology** Highly fatal disease of cattle, farmed deer, and bison in the United States; Bali cattle (Banteng) in Indonesia; and occasionally pigs but rarely goats. Disease associated with contact with sheep, often weaned lambs, and in Africa also with wildebeest calves. Disease may occur sporadically or in outbreaks.

**Clinical findings** Fever, ocular and nasal discharge, erosive stomatitis and gastroenteritis, erosions in the upper respiratory tract, keratoconjunctivitis, encephalitis, cutaneous exanthema, and lymph node enlargement. The head and eye form is most common, and there is a distinctive lesion in the cornea.

**Clinical pathology** Competitive inhibition enzyme-linked immunosorbent assay (ELISA) for serology. Polymerase chain reaction (PCR) detection of viral DNA.

**Necropsy findings** Lymphoproliferative disorder involving dysregulation of T-lymphocytes. Erosions in gastrointestinal tract and lymphadenopathy. Necrotizing vasculitis.

**Diagnostic confirmation.** Detection of viral DNA by PCR.

**Treatment** Supportive.

**Control** Avoid cattle having contact with sheep and wildebeest.

### ETIOLOGY

Malignant catarrhal fever (MCF) is really two diseases, clinically and pathologically indistinguishable, but associated with two different infectious agents with different ecologies:

- Alcelaphine herpesvirus-1 (AIHV1) is now allocated to a new genus *Macavirus* (previously known as *Rhadinovirus*) of the subfamily Gammaherpesvirinae in the family Herpesviridae. This is the **wildebeest-associated MCF virus**, transmitted to cattle from blue wildebeest (*Connochaetes taurinus*).
- Ovine herpesvirus-2 (OvHV2) is also a *Macavirus* of the subfamily Gammaherpesvirinae. This is the **sheep-associated MCF virus** transmitted to cattle from sheep.

Neither agent appears to transmit from cattle to cattle, and neither of the viruses causes any disease in the principal hosts, the wildebeest and the sheep. AIHV1 can be grown in eggs and tissue culture, but OvHV2

has never been propagated *in vitro*. The molecular genomic structure of these viruses is described. A gammaherpesvirus closely related to OvHV2 has been isolated from goats and called caprine herpesvirus-2 (CpHV2), and another, also closely related, has been isolated from deer and called deer herpesvirus (DVH). The pathogenicity of these newly recognized viruses is not known. Complete genome sequences of AIHV1 (130,608 base pairs) and OvHV2 (135,621 base pairs) have been published.<sup>1</sup>

## EPIDEMIOLOGY

### Occurrence and Prevalence

The broad range of natural hosts for MCF can be divided into two categories: reservoir hosts (sheep, goats, wildebeest) and clinically susceptible hosts (cattle, bison, deer).<sup>2</sup>

### Alcelaphine MCF

Wildebeest-associated MCF occurs in most African countries in cattle that commingle with clinically normal wildebeest and hartebeest. It is epizootic and seasonal. It can also occur in zoologic gardens in other countries.

### Sheep-Associated MCF

Sheep-associated MCF occurs worldwide. Cases mostly occur when cattle have had contact with lambing ewes and usually start 1 to 2 months later. Goats can also act as a source of OvHV2 infection for cattle, and rare reports of clinical disease in goats exist.<sup>3</sup> Cases without apparent or recent exposure to sheep do occur but are uncommon.

The morbidity rate varies. Usually the disease is sporadic and presents as a single or small number of cases over a short period, but on occasion up to 50% of a herd may be affected in rare but devastating outbreaks that may be short-lived or last for several months. The disease with both agents is **almost always fatal, with rare reports of recovery in cattle**.

Besides cattle, MCF is also an important disease of farmed deer. It is an occasional disease of pigs and is recorded in pigs that had contact with sheep on a farm and in a petting zoo.

### Methods of Transmission

Both AIHV1 and OvHV2 appear to be transmitted by contact or aerosol, primarily from respiratory secretions of wildebeest calves (AIHV1) and weaned lambs (OvHV2) under 1 year of age. Nose-to-nose contact appears to provide the most efficient method of spread, but transmission can also occur via fomites.<sup>4</sup> The MCF-susceptible species are thought to be dead-end hosts that do not shed virus and are therefore not infectious. Acute MCF in cattle is caused by either AIHV1 or OvHV2, with almost all cases in North American cattle being caused by OvHV2.

### Alcelaphine MCF

Infection with AIHV1 in wildebeest occurs in the perinatal period by horizontal and occasional intrauterine transmission, and infected young wildebeest up to the age of about 4 months have viremia and shed virus in ocular and nasal secretions. The disease is transmitted from wildebeest to cattle by contact or over short distances, probably by inhalation of aerosol or ingestion of pasture contaminated by virus excreted by young wildebeest in nasal and ocular discharges. In contrast, infected cattle do not excrete virus in nasal or ocular secretions. The disease can transmit between wildebeest and cattle over a distance of at least 100 m, and it is suggested that cattle need to be kept at least 1 km from wildebeest to avoid disease.

In Kenya the peak incidence of alcelaphine MCF occurs when 3- to 4-month-old wildebeest are in maximum numbers. In South Africa the peak incidence is at a time when young wildebeest are 8 to 10 months old and not infectious, requiring that there be another, high-volume source of the infection. The proportion of sheep in a wildebeest area that are serologically positive and presumably infected with the wildebeest-associated virus is very high.

### Sheep-Associated MCF

Virtually all domestic sheep raised under natural flock conditions are infected with OvHV2, which causes an inapparent infection in sheep. **High rates of seropositivity** have been found in domestic sheep and goats over 1 year of age in several surveys. In a study of 14 species of North American wildlife, a high rate of seropositivity was also found in muskox (*Ovibos moschatus*) and bighorn sheep (*Ovis canadensis*), suggesting that they might be sources of infection. There were low seropositivity rates in clinically susceptible species such as deer and bison.

In contrast to AIHV1 infection in wildebeest, the transmission of OvHV2 between sheep appears minimal in the perinatal period. There is no evidence for transplacental infection, and although antigen, detected by PCR, is present in colostrum and milk from infected ewes, the majority of lambs are not infected until after 2 to 3 months of age. The rate of infection in lambs and the age at infection is not influenced by passively acquired maternal immunity and appears to be dose dependent. Infected sheep excrete OvHV2 in nasal secretions, but **very high levels of excretion occur between 6 and 9 months of age**, suggesting that the 6- to 9-month period is the time when most virus is shed into the environment. Viral antigen has been detected in the ejaculate of rams, but there is little epidemiologic evidence for significant venereal transmission.

The means by which OvHV2 spreads from infected sheep to cattle is not known

but is presumably by inhalation or ingestion of respiratory secretions. The common epidemiologic association of diseased cattle having had contact with lambing ewes suggests that perinatal lambs play a role in transmission similar to that played by wildebeest calves; however, the age at infection of lambs and the excretion patterns of the virus do not fit this assumption. Shedding from ewes does not increase in the lambing period. Contact with ewes is not a prerequisite, one outbreak having occurred when cattle commingled with rams. Infection can also occur when sheep and cattle are housed in the same building but with no common contact through feeding or watering points.

An interesting insight into transmission is provided by a Canadian outbreak where 45/163 bison died following exposure for less than 1 day to sheep at a sale barn.<sup>5</sup> Bison deaths started 50 days later and peaked at 60 to 70 days after exposure to sheep, with the last death occurring 7 months after initial exposure. Despite the high mortality rate, there was no evidence of bison-to-bison transmission.

Occasional cases occur in cattle that have had no apparent contact with sheep, and the persistence of the infection in a particular feedlot, or on a particular farm, from year to year when no contact with sheep exists, is unexplained. Persistence of the virus on inanimate fomites has been suggested, but the virus is a most fragile one, and this seems unlikely. The observation that some recovered cattle show a **persistent viremia** for many months suggests that carrier cattle may be the source of these carryover infections. In addition, the virus, detected by PCR, has been demonstrated in cattle and farmed deer with no evidence of MCF disease. It is possible that stress could activate a latent infection in animals with no sheep contact.

### Experimental Reproduction

Sheep-associated MCF virus does not replicate in tissue culture. It has a close association with lymphoblastoid cells, particularly large granular lymphocytes, which can be grown in tissue culture and induce MCF when injected. MCF can also be transmitted to cattle by transfusion of large volumes of blood if given within 24 hours of collection. Wildebeest-associated MCF virus can be readily transmitted by several routes. It has been adapted to grow on egg yolk sac and tissue culture, and transmission to rabbits to yolk sac to cattle has been achieved.

### Environment Risk Factors

The disease shows the greatest incidence in late winter, spring, and summer months. There have been suggestions that copper deficiency or exposure to bracken fern might be environmental stressors that predispose the expression of the disease in cattle.

### Animal Risk Factors

Clinical disease had been described in over 30 species of ruminants. In Africa, assorted **wild ruminants** contract the disease and suffer a severe illness and a high mortality rate. Similar species in zoos are also commonly affected, for example, Père David's deer (*Elaphurus davidianus*) and Greater kudus (*Strepsiceros kudu*).

Among **domestic animals**, all ages, races, and breeds of cattle are equally susceptible, but banteng (*Banteng sondaicus*), buffalo (*Bubalus bubalis*), bison (*Bison bison*), and deer are more susceptible and suffer a more severe form of the disease than do commercial cattle. Bison are estimated to be approximately 1000 times more susceptible to clinical MCF than cattle.<sup>2</sup> Disease is recorded in captive deer or farmed deer including sika deer (*Cervus nippon*), roe deer (*Capreolus capreolus*), white-tailed deer (*Odocoileus virginianus*), rusa deer (*C. timorensis*), and red deer (*C. elaphus*).

MCF is considered one of the most important diseases of **farmed deer**. The clinical signs and necropsy findings closely resemble those of MCF in cattle, but the morbidity and mortality can be disastrously high, resulting in heavy losses for the deer farmer.

### Economic Importance

Losses attributable to the disease can be catastrophic on rare individual farms. For the most part it is a nuisance because of its resemblance to mucosal disease and bluetongue and its historic resemblance to rinderpest, which has been eradicated.

### PATHOGENESIS

MCF is a fatal, multisystemic disease characterized by lymphoid proliferation and infiltration and widespread **vascular** epithelial and mesothelial lesions, which are morphologically associated with lymphoid cells. CD8+ T-lymphocytes are the predominant cells associated with the vascular lesions. Involvement of the vascular adventitia accounts for the development of gross lesions, including the epithelial erosions and keratoconjunctivitis. The lymph node enlargement is a result of atypical proliferation of sinusoidal cells. The cerebromeningeal changes, usually referred to as encephalitis, are in fact a form of vasculitis. There is commonly synovitis, especially involving tibiotarsal joints, and this also is associated with a lymphoid vasculitis. It is thought that the pathogenesis of this disease is the result of direct virus–cell interactions or perhaps immune-mediated responses directed against infected cells.

### CLINICAL FINDINGS

The **incubation period** in natural infection varies from 3 to 8 weeks, and after artificial infection averages 22 days (14 to 37 days). MCF is described as occurring in a number

of forms, although fever, corneal edema, and oculonasal and oral lesions are almost always present in cattle with acute MCF. The forms identified are:

- Peracute
- Alimentary tract form
- Common “head-and-eye” form
- Mild form

However, these forms are all gradations, with cases being classified on the predominant clinical signs. In serial transmissions with one strain of the virus, all of these forms may be produced. The most common manifestation is the head-and-eye form.

In cattle, the presence of nasal discharge, corneal edema, fever, and lymphadenopathy is very helpful in differentiating MCF from mucosal disease or bluetongue.<sup>6</sup> The mean duration of clinical signs before death in one outbreak was 6 days, with a range of 1 to 26 days.<sup>7</sup>

### Head-and-Eye Form

There is a sudden onset of the following symptoms:

- Extreme dejection
- Anorexia
- Agalactia
- High fever (41° to 41.5° C [106–107° F])
- Rapid pulse rate (100 to 120/bpm)
- Profuse mucopurulent nasal discharge
- Severe dyspnea with stertor as a result of obstruction of the nasal cavities with exudate
- Ocular discharge with variable degrees of corneal edema
- Blepharospasm and uveitis
- Congestion of scleral vessels

Superficial necrosis is evident in the anterior nasal mucosa and on the buccal mucosa. This begins as a diffuse reddening of the mucosa and is a consistent finding at about day 19 or 20 after infection. Discrete local **areas of necrosis** appear on the hard palate, gums, and gingivae. The mouth is painful at this time, and the animal moves its jaws carefully, painfully, and with a smacking sound. The mucosa as a whole is fragile and splits easily. The mouth and tongue are slippery, and the mouth is hard to open. The erosive mucosal lesions may be localized or diffuse. Lesions may occur on the following areas:

- Hard palate
- Dorsum of the tongue
- Gums below the incisors
- Commissures of the mouth
- Inside the lips

The cheek papillae inside the mouth are hemorrhagic, especially at the tips, which are later eroded. At this stage there is excessive salivation, with saliva that is ropelike and bubbly hanging from the lips. The skin of the muzzle is extensively involved, commencing with discrete patches of necrosis at the nostrils that soon coalesce, causing the entire muzzle to be covered by tenacious scabs. Similar lesions may occur at the skin–horn junction of the feet, especially at the back of

the pastern. The skin of the teats, vulva, and scrotum in acute cases may slough off entirely upon touch or become covered with dry, tenacious scabs.

**Nervous signs**, particularly weakness in one leg, incoordination, a demented appearance, and muscle tremor, may develop very early, and nystagmus, head-pushing, paralysis, and convulsions may occur in the final stages. Trismus has been described, but it is probably a result of pain in the mouth rather than a neuromuscular spasm. There is one report in young calves where nervous signs were the predominant feature.<sup>8</sup>

In natural cases the superficial lymph nodes are often visibly and usually palpably enlarged. **Lymphadenopathy** is also one of the earliest, most consistent, and persistent signs of the experimental disease. The consistency of the feces varies from constipation to profuse diarrhea with dysentery. In some cases there is gross hematuria, with the red coloration most marked at the end of urination.

**Edema (opacity) of the cornea** is always present to some degree, commencing as a narrow, gray ring at the corneoscleral junction (perilimbal) and spreading centripetally with conjunctival and episcleral hyperemia (Fig. 21-1). Anterior uveitis (keratic precipitates, aqueous flare, fibrin deposition in the anterior chamber, hypopyon, iris hyperemia and edema, miosis) is observed in some

**Fig. 21-1** A, The right eye of an adult cow with early clinical signs of malignant catarrhal fever. Moderate corneal edema is present. Intraocular structures can be seen but not in detail. B, The left eye of an adult cow with advanced malignant catarrhal fever. Severe corneal edema is present, and intraocular structures cannot be observed. (Reproduced with permission from Zemljič T, Pot SA, Haessig M, Spiess BM. Clinical ocular findings in cows with malignant catarrhal fever: ocular disease progression and outcome in 25 cases [2007-2010]. *Veterinary Ophthalmology* 2012; 15:46-52.)

cases. The progression of corneal edema and nonimprovement of anterior uveitis indicate that survival is unlikely.<sup>9</sup>

In cases of longer duration, **skin changes**, including local papule formation with clumping of the hair into tufts over the loins and withers, may occur. In addition, eczematous weeping may result in crust formation, particularly on the perineum, around the prepuce, in the axillae, and on the inside of the thighs. Infection of the cranial sinuses may occur, with pain on percussion over the area. The horns and rarely the hooves may be shed. Persistence of the fever is a characteristic of MCF, even in cases that persist for several weeks, with a fluctuating temperature that usually exceeds 39.5°C (103°F).

During some outbreaks an occasional animal makes an apparent recovery but usually dies 7 to 10 days later of acute encephalitis. In the more typical cases the illness lasts for 3 to 7 days and rarely up to 14 days.

### Peracute and Alimentary Tract Forms

In the peracute form the disease runs a short course of 1 to 3 days, and characteristic signs and lesions of the head-and-eye form do not appear. There is usually a high fever, dyspnea, and acute gastroenteritis. The alimentary tract form resembles the head-and-eye form, except that there is marked diarrhea and only minor eye changes consisting of conjunctivitis rather than ophthalmia. This form of the disease has been encountered in outbreak form in cattle in large dairy herds in drylots, with only indirect contact with sheep, and in cattle to which transmission was attempted and farmed deer. A feature of this form of the disease is reported to be a brief period of slight illness followed by the final fulminating disease, which is common in deer.

### Mild Form

The mild form occurs most commonly in experimental animals but is observed in natural outbreaks. There is a transient fever, and mild erosions appear on the oral and nasal mucosae. Mild disease may be followed by complete recovery, recovery with recrudescence, or chronic MCF. A distinctive clinical feature in chronic MCF is persistent bilateral ocular leukomata.

### Pigs

The disease in pigs is similar to the head-and-eye form in cattle and manifests with fever and tremor, ataxia, hyperesthesia, and convulsions and death.

### CLINICAL PATHOLOGY

Leukopenia, commencing at first illness and progressing to a level of 3000 to 6000/ $\mu$ L, has been recorded but is not a general observation. The leukopenia recorded was mainly the result of agranulocytosis. In our experience moderate leukocytosis is more common.

**Virus isolation** is not practical with either virus because of the instability of cell-associated ALHV1 and the fact that OvHV2 does not replicate in cell culture. **Transmission** can be used for diagnosis using whole blood, nasal swabs or washings, and preferably lymph node collected by biopsy, with histologic lesions in the recipient rabbits or calves as the criterion. **Detection of viral nucleic acid** by PCR has largely replaced transmission experiments.

There are a number of **serologic tests** that can be used, but they have limited value for diagnosis of clinical cases because only a small percentage of animals seroconvert and do so late in the course of the disease. The antibody titer is low, and there is cross-reaction with other herpes viruses. A **competitive-inhibition ELISA** using a monoclonal antibody to a broadly conserved epitope of the MCF virus can be used for detection of antibody and has largely replaced other serologic tests. It is of particular value for epidemiologic studies. The development of antibody following infection is delayed in a significant proportion of young animals, and serology is unreliable for determining infection status until after 1 year of age.

Uninfected lambs or kids under 4 months of age may test positive because of the presence of maternal antibody.

**Detection of viral nucleic acid** by PCR techniques is the current accepted diagnostic technique. The buffy coat is probe-positive 2 days after experimental infection with alcelaphine herpesvirus-1. Virus can be present in cattle without clinical MCF, and if these have a disease that is not MCF, but test probe positive, a **false diagnosis** is possible.

### NECROPSY FINDINGS

Lesions in the mouth, nasal cavities, and pharynx vary from minor degrees of hemorrhage and erythema through extensive, severe inflammation to discrete ulcers. These lesions may be shallow and almost imperceptible or deeper and covered by cheesy diphtheritic deposits. **Erosion** of the tips of the cheek papillae, especially at the commissures, is common. Longitudinal, shallow erosions are present in the esophagus. The mucosa of the forestomachs may exhibit erythema or sparse hemorrhages or erosions. Similar but more extensive lesions occur in the abomasum. Catarrhal enteritis of moderate degree and swelling and ulceration of the Peyer's patches are constant. The feces may be loose and blood stained.

Similar lesions to those in the mouth and nasal cavities are present in the trachea and sometimes in the bronchi, but the lungs are not usually involved except for occasional emphysema or secondary pneumonia. The liver is swollen, and severe hemorrhage may be visible in the urinary bladder. All lymph nodes are swollen, edematous, and often hemorrhagic. The gross ocular lesions are as described clinically. Petechial hemorrhages

and congestion may be visible in brain and meninges.

**Histologically**, MCF is characterized by perivascular mononuclear cell cuffing in most organs and by degeneration and erosion of affected epithelium. The pathognomonic lesion is a **necrotizing vasculitis** that features infiltration of the tunica media and adventitia by lymphoblast-like cells and macrophages. Acidophilic, intracytoplasmic inclusion bodies in neurons have been described, but their identity as viral inclusions has not been established. Large numbers of inclusion bodies have been observed in the tissue of artificially infected rabbits. The histologic features of the panophthalmitis have been described.

Cattle with chronic MCF have chronic bilateral central stromal keratitis with or without corneal pigmentation. An **obliterative arteriopathy** is characteristic, and this vascular lesion is present in all major organs. Results of a competitive inhibition ELISA serologic test suggesting a role for the virus in the development of obliterative arterial lesions in cattle have been supported by *in situ* PCR and immunohistochemical studies of the disease in bison that demonstrated OvHV2 within the infiltrating lymphocytes. These lymphoblast-like cells were also shown to be CD8+ T cells.

A PCR technique or immunohistochemical stains can be used to confirm the presence of viral antigen in whole blood or in tissues harvested at necropsy. When transmitted to rabbits, both the wildebeest- and sheep-associated viruses elicit a rapidly fatal lymphoproliferative disorder. The newer molecular biology-based techniques have made this bioassay method obsolete.

### Samples for Confirmation of Diagnosis

- **Histology**—fixed brain, lymph node, alimentary tract mucosa including pharynx, esophagus, rumen and Peyer's patch, liver, adrenal gland, kidney, urinary bladder, salivary gland (immunohistochemistry, light microscopy); Bouin's-fixed eye (light microscopy)
- **Virology**—lymph node, spleen, lung (PCR)

### DIFFERENTIAL DIAGNOSIS

- Mucosal disease
- Infectious bovine rhinotracheitis (IBR)
- Bluetongue
- Sporadic bovine encephalomyelitis
- Rinderpest (included for historic reasons)
- Jembrana disease

### TREATMENT

Treatment of affected animals is unlikely to influence the course of the disease.

Nonsteroidal antiinflammatories may ease the discomfort.

### CONTROL

Isolation of affected cattle is usually recommended, but its value is questioned because of the slow rate of spread and the uncertainty regarding the mode of transmission. Because of the field observation that sheep are important in the spread of the disease, **separation** of cattle and sheep herds is recommended. The introduction of sheep from areas where the disease has occurred to farms with cattle should be avoided. A program to produce sheep free of OvHV2 infection by separation and isolation of lambs before they become infected is recommended for sheep used in petting zoos.

An effective vaccine is not available and is likely to remain unavailable in the foreseeable future.<sup>10</sup> Attempts to immunize cattle with live or inactivated culture vaccines with Freund's incomplete adjuvant do not provide protection against experimental challenge or natural challenge by exposure to wildebeest herds. High and persistent levels of virus-neutralizing antibody are demonstrable following vaccination, but humoral mechanisms are probably not important in determining resistance to infection with the virulent virus. An inactivated wildebeest-associated MCF virus vaccine has provided protection against challenge with virulent viruses. Establishing a respiratory mucosal barrier of antibody is currently thought to provide the best chance of protective immunity,<sup>11</sup> but this will be challenging to attain with IM or SC vaccines.

## MALIGNANT CATARRH IN PIGS

Malignant catarrh virus outbreaks are not common in pigs, but they do occur sporadically, usually when pigs are kept together with sheep, which are the main reservoir of infection. Information on the disease is not extensive.

### ETIOLOGY

The cause is ovine herpes virus 2 (OvHV2), and there is a sheep-associated form and a wildebeest-associated form.<sup>1</sup>

### EPIDEMIOLOGY

The condition has been reported in pigs in Europe in Germany, Norway, Italy, Finland,<sup>2,3</sup> and Switzerland. In a recent outbreak in the United Kingdom it was described in two ailing Kune Kune<sup>4</sup> that lived in a "traveling circus" with sheep and goats and other species that were often transported together in a mobile trailer.

In most cases described, pigs have had contact or been housed together with sheep.<sup>5</sup> Nasal discharges may be the source of infection, particularly from lambs.

The pig is a dead-end host, and thus spread is limited.<sup>6</sup> In the cases in Brazil,<sup>7</sup> there was transfer of the infection from asymptomatic boars to sows via the semen of infected boars.

### PATHOGENESIS

Pathogenesis is unknown as yet in the pig.

### CLINICAL SIGNS

Pigs are depressed and recumbent, have abnormal respiration, and produce hard, mucus-covered scant feces. The condition develops to ataxia and severe balance loss, which is sometimes violent. There is corneal edema with severe uveitis. In the Kune Kune cases, they were blind, with bilateral corneal opacity, excessive lacrimation, and eyelid thickening. Eventually there was a fine tremor with circling.

A recent report described the infection in asymptomatic swine without any history of contact with sheep in Norway.<sup>8</sup> The disease is difficult to diagnose in pigs because of the nonspecific nature of the clinical signs and the sporadic nature of the disease. Usually only one or two animals are affected, although an outbreak in 41 pigs has been described.<sup>3</sup>

In the Brazilian cases, gilts and sows had depression, abortion, and anorexia. Subsequently, a whole range of neurologic signs developed, such as ataxia, tremors, convulsions, and aggressive behavior. Animals that survived had locomotory abnormalities with forelimb paralysis and were dog-sitting. Infected boars shed virus but remained clinically healthy. In the Finnish study the dead sows had anorexia and high fever.<sup>1</sup>

### PATHOLOGY

There are quite often very few gross signs. There may be a crusty skin and areas of cyanosis. The respiratory tract may be covered in a mucopurulent exudate. Lungs may be congested and edematous. In the Finnish study, the sows had swollen lymph nodes, a pale-brown liver, and congested kidneys. There may be pale kidneys with petechiae, small erosions on the lining of the stomach,

and congested meninges. In many cases, there were only small lesions in the lung and pancreas.

In the Kune Kune<sup>4</sup> there were ulcerations of the skin, and mucocutaneous ulcerations were found in the mouth. There was also ulceration of the soft palate and tonsils and lymphadenopathy with enlarged spleen and adrenals and meningeal edema and meningitis.

The disease is essentially a lymphoproliferative vasculitis. Histopathologically, there was a severe nonpurulent meningoencephalitis with lymphocytic cuffing around vasculitis. Edema, fibrinoid necrosis, and lymphocytic infiltration were also observed. The lesions are more severe in the kidneys (severe, multifocal, interstitial, nonsuppurative nephritis) associated with fibrinoid necrosis of the vessels.

### DIAGNOSIS

The differential diagnosis includes Aujeszky's disease (ADV), classical swine fever (CSF), porcine enterovirus (PEV), and rabies. OHV2 DNA can be detected in the clinically affected pigs. A combination of clinical signs, histopathology, and the detection of virus-specific antibodies is usually suggestive. A competitive inhibition ELISA test has been developed and also a direct ELISA. PCR and quantitative reverse-transcription PCR (qRT-PCR) have also been developed for the detection of the virus in tissues.

## JEMBRANA DISEASE

Jembrana disease is the name of a fatal infectious disease that occurs in Bali cattle (*Bos javanicus*) and buffaloes (*Bubalus bubalis*) on the island of Bali in Indonesia. The disease is endemic in areas of Indonesia only, but the severe disease of the initial outbreak has modified with time.

### ETIOLOGY

The disease is caused by a lentivirus, the Jembrana disease virus (JDV), genetically related to but distinct from bovine immunodeficiency virus (BIV), a more benign infection found in Indonesia and many other countries. Both viruses resemble human immunodeficiency virus (HIV) in their structural, genomic, antigenic, and biological properties. JDV has a capsid protein (p26) that is used as an antigen source for serologic diagnosis, but it cross-reacts with sera from

BIV-infected cattle.<sup>1</sup> Furthermore, although JDV is genetically very stable, it has strain variation, and under experimental conditions, atypical responses to infection characterized by reduced viral loads, lower or absent febrile responses, and absence of specific antibody responses were observed in 15% of infected cattle.<sup>2-3</sup>

## EPIDEMIOLOGY

### Occurrence

The disease originally occurred in Jembrana district on the Island of Bali, Indonesia, in 1964 and rapidly spread to the rest of the island, resulting in the deaths of approximately 17% of Bali cattle. Since 1964, the disease has been endemic on Bali island but with lower morbidity and mortality rates. It has subsequently spread to the Indonesian islands of Sumatra, Java, and Kalimantan, producing initial epidemic disease with high mortality followed by endemic disease with lower morbidity and mortality. The current mortality rate is approximately 15% to 20%.<sup>4-5</sup>

### Transmission

Transmission probably occurs by direct contact with infective secretions in the acute phase of the disease when viral titers are greater than 10(6) genomes/mL<sup>6</sup> and by mechanical transmission by hematophagous insects or mechanically by needles during mass vaccination of animals for the control of diseases such as hemorrhagic septicemia.

### Experimental Reproduction

The disease can be experimentally transmitted by intravenous (IV) or intraperitoneal inoculation of blood or spleen into *B. javanicus*. The virus is present in high titer in the blood during the febrile phase and in the saliva and milk. In *B. javanicus* an incubation period of 4 to 12 days is followed by fever lasting from 5 to 12 days and clinical signs typical of the enzootic form of the disease. Persistent infection occurs for periods of at least 2 years following recovery.

Experimental challenge of *B. indicus*, *B. taurus*, and crossbred (*B. javanicus* and *B. indicus*) cattle results in only a transient febrile response, mild clinical disease, and viremia that persist for 3 months, although antibody persists for at least 4 years following infection. Infection, as determined by antibody response, but not clinical disease, can be transmitted experimentally to pigs, sheep, goats, and buffaloes.

## PATHOGENESIS

Jembrana disease is not typical of other lentivirus infections, which are usually characterized by chronic progressive disease with long incubation periods. Instead, JDV causes an acute and sometimes fatal disease after a short incubation period. There is a high viremia during the febrile stage, with virus titers being as high as 10(12) virus/mL of

plasma. Initial virus proliferation in the spleen is followed by widespread dissemination during a second proliferative phase and infection in lymph nodes, lungs, bone marrow, liver, and kidney. Affected animals do not develop detectable antibodies to the virus until at least 6 weeks after recovery from the acute phase, and surviving animals are resistant to reinfection but remain infectious for at least 2 years.

The specific cell types infected by Jembrana disease virus have not yet been identified, but during the febrile phase, there is marked depletion of CD4+ T cells and increase in CD8+ T cells and CD21+ B cells.<sup>7</sup> The persistent depletion of CD4+ T-cell numbers, through lack of T-cell helper to B cells, may explain the lack of production of JDV-specific antibodies for several weeks after recovery despite an increase in CD21+ B-cell numbers.<sup>7</sup> Furthermore, viral antigen is present in IgG-containing cells, including plasma cells in lymphoid tissues, and in macrophage-like cells in the lungs.<sup>8</sup>

## CLINICAL FINDINGS

Natural clinical disease is reported only in *B. javanicus*; other cattle types and buffalo are subclinically infected in natural outbreaks. After an incubation period of 4 to 12 days, clinical signs include fever (40–42°C [104–107°F]) that lasts up to 12 days, anorexia, generalized lymphadenopathy, nasal discharge, increased salivation, and anemia. In severely affected cattle there is diarrhea followed by dysentery. Mucosal erosions can occur but are rare. Hemorrhages are present in the vagina, mouth, and occasionally the anterior chamber of the eye in severe disease. Where the disease is enzootic and less severe in presentation, clinical signs include inappetence, fever, lethargy, reluctance to move, enlargement of the superficial lymph nodes, mild erosions of the oral mucosa, and diarrhea.

## CLINICAL PATHOLOGY

During the febrile period there is a moderate normocytic normochromic anemia and leukopenia with lymphopenia, eosinopenia, and thrombocytopenia. The lymphopenia is attributable to a significant decrease in both the proportion and absolute numbers of CD4+ T cells.<sup>7</sup> Bone marrow shows no microscopic changes. Elevated blood urea concentrations and diminished total plasma protein are seen in *B. javanicus* but not *B. taurus*. An ELISA test and an agar gel immunodiffusion test can be used for serologic surveys. Both are specific, but the ELISA test has greater but limited sensitivity. A combination of real-time PCR and JDV p26-his ELISA has been recommended for the detection of infection with JDV in Indonesia.<sup>1</sup>

## NECROPSY FINDINGS

Necropsy lesions in *B. javanicus* include generalized lymphadenopathy, with enlarge-

ments up to 20-fold, and generalized hemorrhages. The spleen is enlarged to 3 to 4 times its normal size. Histologically, there is marked proliferation of lymphoblasts in parafollicular (T-cell) areas of lymph nodes and spleen, and atrophy of the follicles (B-cell areas). In addition, there is lymphoproliferation around blood vessels in the liver, kidney, and other organs.<sup>5</sup>

Specimens for histopathology should include lymph nodes, spleen, liver, and kidney.

## TREATMENT AND CONTROL

### TREATMENT AND CONTROL

#### Treatment

None except supportive

#### Prophylaxis

Vaccination (R-2)

Treatment is supportive. There is currently no specific control. Vaccination has been attempted using virus-containing plasma and spleen tissue from acutely affected cattle with the virus inactivated with triton X-100 and the vaccine adjuvanted with either mineral oil or Freund's incomplete adjuvant. Protection is only partial and not of real value in control, except perhaps in reducing the risk of virus transmission, because vaccinated animals have a greatly reduced viral load.<sup>6</sup>

## BOVINE EPHEMERAL FEVER

### SYNOPSIS

**Etiology** Arthropod-borne rhabdovirus of the genus *Ephemerovirus*.

**Epidemiology** Enzootic in tropical areas. Transmitted by insect vectors. Episodic epizootics in summer in incursive areas probably initiated by wind-borne transmission of insect vector. High morbidity but low case fatality.

*Continued*

**Clinical findings** Disease of cattle with fever, respiratory distress, muscular shivering, stiffness, lameness, and enlargement of the peripheral lymph nodes.

Generally spontaneous recovery in 3 days and low case-fatality rate.

**Clinical pathology** Leukocytosis, hyperfibrinogenemia, hypocalcemia, elevated creatine kinase. Blocking enzyme-linked immunoabsorbent assay (ELISA) for serology.

**Necropsy findings** Serofibrinous polyserositis.

**Diagnostic confirmation** Demonstration of specific bovine ephemeral fever (BEF) viral antigen by immunofluorescence or by isolation in mice.

**Treatment** Nonsteroidal antiinflammatory drugs cause remission of clinical signs.

**Control** Vaccination and supportive treatment.

## ETIOLOGY

Bovine ephemeral fever (BEF) is associated with an arthropod-borne rhabdovirus that is the type species of the genus *Ephemerovirus*. There are a number of strains that vary antigenically. Other antigenically related but nonpathogenic species of *Ephemerovirus* occur in the same environment in Australia. The BEF virus is closely associated with the leukocyte-platelet fraction of the blood, and it can be maintained deep frozen or on tissue culture and chick embryos.

## EPIDEMIOLOGY

### Occurrence

A disease of cattle, ephemeral fever is enzootic in the tropical areas of Africa, in most of Asia, the Middle East, the East Indies, and in much of Australia, with extensions into the subtropics and some temperate regions. In these areas the disease presents as episodic epidemics. Area outbreaks can last several months, with the spread of infection following prevailing winds, and during this period most herds within a region will be infected. The proportions of herds affected in outbreaks in the Jordan Valley in Israel in 1990 and 1999 were 79% and 98% respectively.

The morbidity rate in outbreaks is usually between 25% and 45%, but if the population is highly susceptible or the infecting strain virulent, the morbidity rate may reach 100%. In enzootic areas, only 5% to 10% will be affected. A rate of 1% for case fatality and loss from involuntary culling is usual with low-virulence strains but can approach 10%.

### Source of Infection

The source of infection is the animal affected with the clinical disease and biological vectors (hematophagous biting insects).

### Method of Transmission

A great deal of work in recent years has not clearly defined the **vector** list, which

probably includes the mosquitoes *Aedes* spp., *Culex annulirostris*, *Anopheles bancroftii* and *A. annulipes*, and the biting midge *Culicoides brevitarsis*. *Culex annulirostris* has been identified as a biological vector in Australia. This mosquito can transmit infection within a week of feeding on an infected animal, and the epidemiology of the disease in Australia supports transmission by mosquitoes rather than *Culicoides* spp.

The **reservoir** host, other than cattle, has not been identified. This is of particular importance when the epidemiologic pattern of occurrence of the disease changes, as it has done in Australia after being introduced in approximately 1936.<sup>1</sup> The disease now occurs annually in areas where it used to occur only once each decade, probably because of establishment of the virus in indigenous vectors.

Spread by **wind-borne carriage** of vectors has been documented.<sup>2,3</sup> Epidemiologic studies suggest that outbreaks in Japan originate from Korea, and those in Israel originate from Turkey.<sup>2</sup> Transboundary movement can also occur by animal transport,<sup>2</sup> although transmission does not occur through contact with infected animals or their saliva or ocular discharge. The disease is not spread through semen, nor is intrauterine administration of the virus a suitable route of transmission.

### Experimental Reproduction

The disease can be transmitted by the injection of whole blood or the leukocyte fraction of it. Experimental reproduction in cattle requires IV administration, and viremia lasts 3 days with a maximum of 2 weeks. There is no carrier state.

### Environment Risk Factors

The disease occurs in the **summer** months, outbreaks are **clustered** and relatively **short-lived**, and spread depends largely on the insect vector population and the force and direction of prevailing winds. The disease tends to disappear for long periods to return in epizootic form when the resistance of the population is diminished.

Recurrence depends primarily on suitable environmental conditions for increase and dissemination of the insect vector and the degree of population immunity, as indicated by neutralizing antibody titers and immunity coverage.<sup>4</sup> During periods of quiescence the disease is still present, but the morbidity is reputed to be very low. However, in many enzootic areas the degree of surveillance is less than intense, and clinical cases may occur without being observed. Temporary protection against infection is provided by subclinical infections by other unrelated arboviruses (e.g., Akabane, Aino, and others).

### Animal Risk Factors

Among domestic animals, only **cattle** are known to be naturally affected, but antibod-

ies can be found in African ruminant wildlife. All **age groups** of cattle are susceptible, but calves less than 3 to 6 months old are not affected by the natural disease. With experimental infections calves as young as 3 months old are as susceptible as adults to experimental infection but do not show clinical disease.

In dairy cattle, higher-producing cows are at greater risk, and clinical disease may be minimal in cows under 2 years of age. A recent Israeli study in 10 beef herds found average morbidity and mortality rates of 46.2% and 4.8%, respectively, with higher rates in bulls than cows and a higher morbidity in cows 2 to 5 years of age than in heifers less than 2 years of age. In natural outbreaks there is no breed susceptibility.

In Africa, based on serologic results, the virus is thought to be cycling in populations of wild ruminants between epidemics in domestic cattle. Buffalo (*Bubalus bubalis*) are susceptible to experimental infection, but it is unlikely that they play any part as a reservoir host. After experimental infection of cattle there is solid immunity against homologous strains for up to 2 years. Immunity against heterologous strains is much less durable, which probably accounts for the apparent variations in immunity following field exposure.

### Economic Importance

Although the case-fatality rate is very low, considerable loss occurs in **dairy herds** as a result of the depression of milk flow—up to 80% in cows in late lactation. In an Israeli study of eight infected dairy herds, the decline in milk yield from preinfection levels varied between cows and ranged from 30% to 70%, with the highest-yielding cows having the greatest drop. Following recovery from disease, milk production was still less than that of preinfection levels.

There is also a lowered resistance to mastitis. Reproductive inefficiency is associated with a significant delay in the occurrence of estrus, abortion in cows, and temporary sterility in bulls. Occasional animals die of intercurrent infection, usually pneumonia, or prolonged recumbency. Bovine ephemeral fever can have a serious effect on the agricultural economy in countries where cattle are used as **draught animals**. For cattle-exporting countries such as Australia, BEF causes interference with movement of cattle when receiving countries insist on evidence of freedom from the disease.

## PATHOGENESIS

Experimental production of the disease requires the IV route of transmission. Virus multiplication probably occurs primarily within the **vascular system**. The BEF virus alters cellular biology in cattle to enhance virus entry and replication. This includes activation of intracellular signaling pathways to up-regulate clathrin and

dynamin 2 expression and activation of COX-2-mediated E-prostanoid receptors 2 and 4 to enhance clathrin-mediated endocytosis of the virus.<sup>5-7</sup> After an incubation period of 2 to 10 days, there is a biphasic fever with peaks 12 to 24 hours apart. The fever lasts 2 days, and increased respiratory rate, dyspnea, muscle trembling, limb stiffness, and pain are characteristic at this time.

There is **generalized inflammation** with vasculitis and thrombosis, serofibrinous inflammation in serous and synovial cavities, and increased endothelial permeability at the same sites. The virus can be detected in circulating neutrophils and plasma, the serosal and synovial fluids, the mesothelial cells of synovial membrane and epicardium, and in neutrophils in the fluids. Clinical signs are thought caused by the expression of mediators of inflammation coupled with a secondary hypocalcemia.

### CLINICAL FINDINGS

Calves are least affected, with those less than 3 to 6 months of age showing no clinical signs. Overweight cows, high-producing cows, and bulls are affected the most. Deaths are relatively uncommon and are usually less than 1% of the herd.<sup>3</sup>

In most cases the disease is acute. After an incubation period of 2 to 4 days, sometimes as long as 10 days, there is a sudden onset of **fever** (40.5°–41°C [105°–106°F]), which may be biphasic or have morning remissions. **Anorexia** and a sharp **fall in milk yield** occur. There is severe constipation in some animals and diarrhea in others. Respiratory and cardiac rates are increased, and stringy nasal and watery ocular discharges are evident. The animals shake their heads constantly, and muscle shivering and weakness are observed. There may be swellings about the shoulders, neck, and back.

Muscular signs become more evident on the second day, with severe **stiffness**, clonic muscle movements, and weakness in one or more limbs. A **posture** similar to that of acute laminitis, with all four feet bunched under the body, is often adopted. On about the third day, the animal begins eating and ruminating, and the febrile reaction disappears, but lameness and weakness may persist for 2 to 3 more days. A common name of “**3-day sickness**” is applied because animals typically progress through onset of disease to severe illness and recovery within 3 days.<sup>3</sup>

Some animals remain standing during the acute stages, but the majority go down and assume a position reminiscent of parturient paresis, associated with **hypocalcemia**, with the hindlegs sticking out and the head turned into the flank. Occasionally, animals adopt a posture of lateral recumbency. Some develop clinically detectable pulmonary and subcutaneous (SC) emphysema, possibly related to a nutritional deficiency of

selenium. In most cases recovery is rapid and complete unless there is exposure to severe weather or unless aspiration of a misdirected drench or ruminal contents occurs. Some cases have a second episode of clinical disease 2 to 3 weeks after recovery.

Occasional cases show persistent recumbency and have to be destroyed, and abortion occurs in a small proportion of cases. Affected bulls are temporarily sterile. Milder cases, with clinical signs restricted to pyrexia and lack of appetite, may occur at the end of an epizootic.

### CLINICAL PATHOLOGY

Blood taken from cattle in the febrile stage clots poorly. Marked **leukocytosis** with a relative increase in neutrophils occurs during the acute stage of the disease. There is a shift to the left and lymphopenia. Plasma fibrinogen levels are elevated for about 7 days, and there is a marked increase in **creatinine kinase activity**. In natural cases, but not experimentally produced ones, significant **hypocalcemia** occurs.<sup>8</sup> Available serologic tests include a complement fixation test, serum neutralization, fluorescent antibody test, agar gel immunodiffusion (AGID) test, and a **blocking ELISA**, which is reported to be simple and the preferred test.

### NECROPSY FINDINGS

Postmortem lesions are not dramatic. The most consistent lesions are a **serofibrinous polyserositis**, involving the synovial, pericardial, pleural, and peritoneal cavities, with a characteristic accumulation of neutrophils in these fluids and surrounding tissues. Hemorrhage may also be observed in the periarticular tissues, and there may be foci of necrosis in the musculature of the limbs and back. All lymph nodes are usually enlarged and edematous. **Pulmonary emphysema** and fibrinous bronchiolitis are standard findings, and subcutaneous emphysema along the dorsum may be observed. Characteristic microscopic findings consist of a mild vasculitis of small vessels, with perivascular neutrophils and edema fluid plus intravascular fibrin thrombi.

Necropsy examinations of animals that develop persistent recumbency have shown severe degenerative changes in the spinal cord similar to those produced by physical compression, but the pathogenesis of these lesions remains uncertain. Although nucleic acid sequences of the agent are known, PCR tests are not yet widely utilized.

Antigen in reticuloendothelial cells can be detected by immunoperoxidase and immunofluorescent techniques.

### Samples for Confirmation of Diagnosis

- **Virology**—chilled lung, spleen, synovial membrane, pericardium (virus isolation)
- **Serology**—pericardial fluid (ELISA)
- **Histology**—formalin-fixed samples of previously mentioned tissues

### DIFFERENTIAL DIAGNOSIS

The diagnosis of ephemeral fever in a cattle population is not difficult on the basis of its epidemiology and clinical presentation. It can produce difficulties in individual animals where differentials include the following:

- Botulism
- Parturient paresis
- Pneumonia
- Traumatic reticulitis

### TREATMENT

Palliative treatment with **nonsteroidal anti-inflammatory** drugs such as IV or IM flunixin meglumine (2.2 mg/kg/d), or IM ketoprofen (3 mg/kg/d) results in **remission** of signs without in any way influencing the development of the disease. There is little effect on the respiratory manifestations of the disease but a major effect on stiffness, lameness, and anorexia. All treatments are continued for 3 days. Phenylbutazone may be most effective, but the injection frequency is not practical and creates slaughter residue concerns. Moreover, phenylbutazone use in cattle is not permitted in some countries. Parenteral treatment with **calcium borogluconate** should be given to cows that show signs of hypocalcemia, and field observations are that parenteral treatment with calcium solutions often helps to get a recumbent cow to her feet. Proper nursing of the recumbent animal is required.

### CONTROL

Restriction of movement from infected areas is practiced, but **vaccination** is the only effective method of control. Vaccines prepared from **attenuated** tissue culture virus or in mouse brain and adjuvanted in Freund's incomplete or Quil A adjuvants are commercially available in Australia, Japan, Taiwan, and South Africa. Two vaccinations are required and are effective in preventing disease in natural outbreaks for periods up to 12 months. The use of vaccination in Japan is credited with preventing further major outbreaks. Attenuated vaccines are expensive to produce and have a short shelf-life, and breakdowns are recorded after their use. There is also concern about back-mutation of the attenuated strain to a virulent form, particularly given the high mutation rate of RNA viruses, and contamination with other viruses during preparation of the vaccine.<sup>9,10</sup> The use of inactivated vaccines therefore offers an attractive alternative, such as formalin **killed** vaccines with and without adjuvants. Unfortunately, inactivated vaccines appear to need at least three vaccinations to provide longer-term immunity,<sup>9,10</sup> requiring frequent boosting for effect. Immunity is positively correlated with the level of specific antibody measured with a blocking ELISA or as virus-neutralizing antibody.

## NAIROBI SHEEP DISEASE

Nairobi sheep disease (NSD) is a tick-transmitted disease of small ruminants, particularly sheep, caused by the Nairobi sheep disease virus (NSDV) and characterized by fever, hemorrhagic gastroenteritis, abortion, and high mortality. NSDV was first recognized at the beginning of the twentieth century as a disease of sheep and goats in Kenya. The virus is the prototype of the genus *Nairovirus*, family *Bunyaviridae*, and it is endemic in East and Central African countries of Kenya, Uganda, Tanzania, Ruanda, Somalia, and Ethiopia. A similar virus known as Ganjam virus (GV) has been recognized in India and Sri Lanka, where it is associated with febrile illness in humans and disease in sheep and goats. Recent genomic analysis has shown that NSDV is highly diverse and that the Ganjam virus is a variant of the NSDV.<sup>1</sup> Furthermore, it has been suggested that GV probably spread from India to Africa in the nineteenth century and that both virus variants could be referred to as NSDV/GV.<sup>2</sup> Other antigenically related viruses are the Crimean Congo hemorrhagic fever virus in humans and the Dugbe fever virus in cattle in the drier parts of West and East Africa. The *Bunyaviridae* family also include two significant pathogens of animals, Cache Valley virus and Akabane virus, both of which have a tropism for fetal tissues and are responsible for embryonic losses and multiple congenital deformities in domestic ruminants.<sup>3</sup> Nairobi sheep disease virus does not affect cattle, horses, or pigs, but can cause a mild febrile disease in humans, hence a zoonosis.

The most common vector for NSDV in Africa is the brown ear tick *Rhipicephalus appendiculatus*, but other species may be involved, including the bont tick, *Amblyomma variegatum*. In India, GV is found in a number of ticks, primarily *Haemophysalis intermedia*.<sup>1</sup> Transmission by *R. appendiculatus* is both transstadial and transovarial. Animals bred in endemic areas are usually immune, and hence the virus is of little consequence in stable populations of sheep and goats. The virus can persist in ticks for long periods, more than 2 years in unfed adults, thereby enhancing endemic stability in resident animals.

The pathogenesis of NSDV/GV infection has been investigated recently.<sup>4</sup> The virus is regarded as one of the most pathogenic

agents for sheep and goats, with mortality ranging from 40% in Merino sheep to 90% in Masai sheep. Like other viral hemorrhagic diseases, including Crimean Congo hemorrhagic fever in humans, MSDV/GV has developed an efficient mechanism to circumvent or inhibit innate immunity of the host by inhibiting interferon induction and action.<sup>4</sup> This makes it easier for the virus to invade cells and replicate in them. In experimentally infected sheep, the virus has also been shown to cause profound leukopenia, most likely as a result of large-scale apoptosis, and to cause increased levels of some proinflammatory cytokines, including tumor necrosis factor (TNF $\alpha$ ), which has the effect of increasing endothelial permeability, leading to hemorrhages.<sup>2</sup> As the sheep began to recover from the infection, the level of interferon gamma was found to increase.

Clinical disease occurs when susceptible animals are moved into endemic areas (e.g., for marketing purposes or for livestock improvement) or when there is a breakdown in tick control measures. Outbreaks occur outside endemic areas when there has been unusual increase in tick population brought about by excessive or prolonged rains. There are differences in susceptibility among different breeds of sheep and goats, and unlike in most other diseases, some indigenous breeds are more susceptible than exotic breeds, like the Merino. A sudden onset of fever is followed by anorexia, nasal discharge, dyspnea, and severe diarrhea, sometimes with dysentery, abortion, and death in 3 to 9 days. There may be hyperemia of the coronary band and hemorrhages in the oral mucosa.<sup>2</sup> The case-mortality rate is 30% to 90% but is lower in goats.

The necropsy picture is typical of a hemorrhagic diathesis and consists of hemorrhages on serous surfaces of visceral organs and on mucosal surfaces, particularly the abomasum, colon, and female genital tract. Lymph nodes and spleen are enlarged. Later, a hemorrhagic gastroenteritis becomes more obvious, and there may be zebra striping in the mucosa of the colon and rectum. The uterus and fetal skin are hemorrhagic. Ticks are likely to be found on the body, especially on the ears and head. Common histopathologic lesions outside the gastrointestinal tract include myocardial degeneration, nephritis, and necrosis of the gall bladder.

Differential diagnoses include peste des petits ruminants (PPR), Rift Valley fever, heartwater, parasitic gastroenteritis, and salmonellosis, all to be confirmed by laboratory tests.

Specimens for laboratory diagnosis should include uncoagulated blood, mesenteric lymph node, and spleen, collected safely to avoid aerosol infections. The virus is first isolated in tissue culture or in infant mice, and the disease can be reproduced in susceptible sheep. The polymerase chain reaction (PCR) technique has been used on whole

blood or the buffy coat.<sup>2</sup> The blood should be collected in EDTA. A quantitative PCR assay can also be used on ticks and for carrying out surveys.<sup>5</sup>

The recommended serologic test is the indirect fluorescent antibody test, but others are the complement fixation test (CFT) and the indirect hemagglutination test. For viral identification, the recommended tests used to be immunofluorescence, agar gel immunodiffusion, CFT, and ELISA.

There is no treatment for NSD and no vaccine for commercial use, even though a killed tissue culture vaccine or an attenuated vaccine has been suggested. Vector control is crucial when animals have to be moved to endemic areas.

## WESSELSBRON DISEASE

## SYNOPSIS

**Etiology** Wesselsbron virus, genus *Flavivirus*, a member of the family *Flaviviridae*.

**Epidemiology** Enzootic in sub-Saharan Africa. Maintenance host not yet identified but presumably domesticated herbivores. Transmitted by mosquitoes of the genus *Aedes*. Infection can occur in small and large ruminants, pigs, donkeys, horses, and ostriches. Infections occur year round in warmer and moister coastal areas; dryer regions have lower prevalence and outbreaks in high rainfall periods often occurring in conjunction with Rift Valley fever.

**Clinical findings** Acute febrile disease in lambs characterized by hepatitis, abortion in pregnant ewes with congenital central nervous system malformation and arthrogryphosis in aborted fetuses; subclinical infection predominates in calves, adult nonpregnant sheep, goats, and cattle; occasional abortions.

**Necropsy findings** Jaundice, diffuse hepatic necrosis.

**Diagnostic confirmation** Virus isolation, serum neutralization, or immunohistochemical localization of viral antigens in tissues; serology.

**Treatment** No specific treatment available, supportive.

**Control** Vaccination is no longer available; vector control not cost effective.

## ETIOLOGY

Wesselsbron virus is an arthropod-borne enveloped single stranded RNA virus of the family *Flaviviridae*, genus *Flavivirus*, that has not been well characterized thus far.

## EPIDEMIOLOGY

### Occurrence

Wesselsbron disease (WBD) was first described in 1955 in an 8-day-old lamb in the Wesselsbron district of the Orange Free State in South Africa. Serologic evidence indicates high infection prevalence in the moister and warmer regions of South Africa, Mozambique, and Zimbabwe. Animals with antibody titer are, in contrast, less common in the dryer South African inland.<sup>1</sup> Wesselsbron virus has been isolated from vertebrates and arthropod vectors in many African countries, including Cameroon, the Central African Republic, Nigeria, Senegal, South Africa, Uganda, and Zimbabwe and in Madagascar. Although serologic studies suggest an enzootic presence of virus over wide parts of the subcontinent, the incidence of clinical disease is very low.<sup>2</sup>

The pattern of occurrence is year round in the warmer and moister coastal regions of southern and eastern Africa. Cyclical outbreaks that are typically linked to periods of heavy rainfall, in contrast, occur in the dryer areas of the continent. Outbreaks frequently occur in conjunction with Rift Valley fever epizootics.

### Risk Factors

#### Animal Risk Factors

Wesselsbron disease is an infectious disease primarily affecting sheep, with a clear age predisposition. Newborn lambs in the first days of life are most susceptible to clinical disease, with mortality rates in the range of 30%. In adult pregnant ewes a common presentation of the disease is abortion that may be associated with a febrile episode.

Other species, including cattle, goats, camels, donkeys, horses, and ostriches, are susceptible to infection but do not typically develop disease; abortions that have been associated with Wesselsbron virus infection have, however, been reported in cattle and goats.<sup>3,4</sup>

#### Environmental Risk Factors

A warm and moist environment that is favorable to competent vectors is an important risk factor for the spread of the virus. Abnormally heavy rainfalls and the ensuing increase in the mosquito population can result in epizootics in dryer regions of the African continent.<sup>1</sup>

### Source of Infection and Method of Transmission

Floodwater breeding mosquitoes of the genus *Aedes*, including the species *A. caballus* and *A. circumluteolus*, are considered the principal vectors of the Wesselsbron virus. The high seroprevalence of infection in

domesticated herbivores in affected areas suggests that these species may function as maintenance hosts for the virus. Direct transmission of the virus between animals has not been documented. In humans, however, infection after handling infectious material has been reported.<sup>4</sup>

### Zoonotic Implications

Although humans are susceptible to infection and disease, infection with the Wesselsbron virus in the large majority of cases is asymptomatic. If clinically apparent, the disease is usually a transient flulike illness associated with a transient fever, headache, and muscle and joint pain; cutaneous hypersensitivity and skin rashes may occur.<sup>4,5</sup> Person-to-person transmission of infection has not been reported.

### Economic Importance

The disease primarily causes disease in lambs and pregnant ewes; evidence that the disease causes significant economic damage is, however, lacking.<sup>1</sup>

### PATHOGENESIS

Wesselsbron virus has been classified as pantropic virus with marked hepatotropic properties in newborn lambs and latent neurotropic properties in embryonic and fetal tissue in pregnant ewes.<sup>6</sup> Hepatocytes are the primary site of viral replication in lambs, and age seems to be a determining factor in the progression of infection. Liver necrosis is the most consistent finding in infected young lambs, resulting in hepatic insufficiency and cholestasis. In general, the extent and severity of liver necrosis is considerably less severe than in lambs infected with the Rift Valley fever virus.<sup>6</sup>

### CLINICAL FINDINGS

The clinical presentation of WBD varies by species and age. The disease is most severe in young lambs. After an incubation period of between 1 and 4 days, nonspecific clinical signs, such as anorexia, listlessness, and fever, become apparent. Similar symptoms are rarely observed in neonates of other species. Jaundice associated with liver cell necrosis may become apparent in more severe cases. Mortality rates are in the range of 25% in lambs.

In adult sheep and cattle, the only apparent sign may be a fever episode. In pregnant ewes, infection may result in abortion, mummification, stillbirth, or birth of weak lambs. Stillborn or aborted lambs may show congenital neurologic defects or arthrogryposis. The occurrence of hydrops amnii has also been associated with Wesselsbron virus infection in pregnant ewes.<sup>2,6</sup> Death of the ewe may occur, presumably as a complication of the abortion.

### CLINICAL PATHOLOGY

Wesselsbron disease is diagnosed by identification of the causative virus or by serology.

Virus identification can be done by direct virus isolation, by means of the complement fixation test (CFT) or the serum neutralization test (SNT).<sup>2</sup> The virus can be isolated from most organs of clinically affected lambs, but blood serum or liver tissue from aborted fetuses and liver or spleen of dead lambs are most commonly used. Immunohistochemistry has also been used for virus identification in liver tissue of deceased lambs.<sup>5</sup>

Serology can be conducted by virus neutralization (VN), complement fixation, and hemagglutination inhibition. The hemagglutination inhibition test shows a high degree of cross-reactivity with other flaviviruses. More recently, an antibody ELISA has been developed that is more sensitive and less cross-reactive than the hemagglutination inhibition test.<sup>5</sup>

### NECROPSY FINDINGS

In aborted fetuses, congenital malformations of the central nervous system, such as porencephaly and cerebellar hypoplasia, have been reported. These were associated in some instances with arthrogryposis.<sup>6</sup> In neonates, moderate to severe icterus is a prominent finding. The liver is friable with a yellow to orange-brown color and may be congested and enlarged in some instances. Other nonspecific lesions include petechiation on the serosal surface of the entire digestive tract and on the abomasal mucosa.<sup>2</sup> Subcutaneous edema has also been reported.

On histopathology, mild to severe necrosis of the liver characterized by diffuse necrosis of individual or few grouped hepatocytes that are scattered randomly throughout the liver is the predominant finding. Proliferation of Kupffer cells and bile ducts is another consistent finding.<sup>2</sup> Hepatic lesions associated with Wesselsbron disease can be differentiated from those observed with Rift Valley fever by the absence of well-defined primary foci of coagulative necrosis of hepatocytes and the lacking parenchymal hemorrhage that characterize infection with Rift Valley fever.<sup>1</sup>

### Samples for Confirmation of Diagnosis

- **Virology**—liver, spleen, brain (virus isolation, serum neutralization, complement fixation)
- **Histology**—liver, spleen, brain (light microscopy, immunohistochemistry)

### DIFFERENTIAL DIAGNOSIS

- Rift Valley fever
- Bluetongue
- Ephemeral fever
- Bacterial septicemias
- Anthrax
- Vibriosis
- Trichomoniasis
- Toxic plants

## TREATMENT

Little attention has been given to the aspect of treatment of the disease, and no known treatment is of any value.

## CONTROL

Measures to control Wesselsbron disease that have been proposed in the past include vector control and vaccination. Although vector control is in theory possible, it requires that *Aedes* spp. breeding sites have been identified and have a limited surface to be manageable. Particularly with heavy rainfalls and flooding mosquito-breeding sites are too numerous and wide to be controlled. Ecological, health, and financial issues around applying large amounts of insecticides to the environment further complicate this type of control.

A modified live vaccine was available in the past. Injudicious vaccination of pregnant ewes, however, resulted in considerable economic loss as a result of abortion and a high incidence of fetal malformations. Because of the limited economic damage caused by WBD and the complications experienced with vaccination, the production of the vaccine has been discontinued.

## CAPRINE HERPESVIRUS-1 INFECTION

### SYNOPSIS

**Etiology** Caprine herpesvirus-1

**Epidemiology** Most infections subclinical. High seroprevalence in Mediterranean countries. Latent infection common and outbreaks of abortion and neonatal mortality with no known precipitating cause.

**Clinical findings** Abortion, neonatal disease, vulvovaginitis, balanoposthitis.

**Clinical pathology** Leukopenia in systemic disease in kids.

**Lesions** Ulceration and necrosis of vulva and prepuce. Multifocal necrosis in intestine and organs of aborted fetus and young (1–2 week olds) kids with systemic disease.

**Diagnostic confirmation** Virus isolation, polymerase chain reaction (PCR).

**Treatment and control** No effective treatment. Herd biosecurity. Experimental vaccine shows protection.

## ETIOLOGY

Caprine herpesvirus-1 (CpHV1) is an alpha-herpesvirus within the family Herpesviridae. Restriction endonuclease analysis indicates that there are different strains, but these are not geographically clustered.

## EPIDEMIOLOGY

### Occurrence

The disease is recorded in the United States, Canada, Australia, New Zealand, South America, and many countries in Europe, and it probably has worldwide distribution. Within the countries where it occurs, there is serologic evidence that the infection is widespread. Seroprevalence is particularly high in Mediterranean countries with high goat populations, such as Greece, Italy, France,<sup>1</sup> and Spain.

In adults, the systemic disease is clinically inapparent, but a genital form of the disease can be transmitted sexually. The virus mostly causes latent or subclinical infections, such as vulvovaginitis and balanoposthitis, which may sometimes present with very serious lesions.<sup>2</sup> It is also associated with occasional but severe outbreaks of abortion, where the abortion rate may exceed 50%.<sup>3</sup> CpHV1 is also associated with severe systemic disease in 1- to 2-week-old kids. This may occur in herds where does are also aborting or occasionally in herds without accompanying abortion.

### Transmission and Experimental Reproduction

Transmission is thought to be by inhalation, ingestion or genitally. The virus is found in nasal, pharyngeal, and vaginal discharges; the prepuce; and feces. It is shed by affected females for 10 to 12 days after infection and for up to 24 days by males.<sup>4</sup> The extended shedding period in bucks is probably important in the high transmission rates of infection that occur with the genital form of this disease.

Only goats are affected naturally; lambs and calves are not infected by intranasal inoculation, but lambs can be infected by IV injection. After primary infection, CpHV1 establishes a latent infection in the third and fourth sacral ganglia, but it is difficult to reactivate these infections by experimental or natural means. Reactivation occurs at the time of estrus, and outbreaks of vulvovaginitis often occur during or after the mating period.<sup>1</sup>

Abortion occurs 1 to 7 weeks after experimental challenge. However, the factors that precipitate occasional outbreaks of abortion and disease in young kids are not known. Challenge of females in early pregnancy is followed by fetal stunting and death, whereas challenge in midpregnancy causes no impairment of fetal growth, with the fetus carried to term but born dead.

### Economic Importance

Losses include deaths of young goats, in which the morbidity and case-fatality rates

are high, and abortion and stillbirths in does. Although the disease is not common, abortion rates can be high in those herds that experience disease.

## PATHOGENESIS

Viremia can occur in 1- to 2-week-old unweaned kids, with infection of various organs, especially the alimentary and respiratory tract. The virus can infect the placenta, causing placentitis and invading the fetus.

## CLINICAL SIGNS

### Adults

In both the experimentally produced and the natural disease there is no prodromal clinical disease preceding abortion, and aborted kids are usually full term. Where there are twins, one may be born dead and the other alive. With the genital disease, there is erythema and edema of the vulva and shallow erosions, ulcers, and occasionally a diphtheritic membrane on the mucosae of the vulva and vagina.<sup>1</sup> The vaginal discharge is clear to mucopurulent, and lesions heal in approximately 1 week. Outbreaks occur during or after mating and are not necessarily followed by abortion. In males, there is an ulcerative balanoposthitis, with hyperemia, edema, and ulceration of the penis and prepuce, often with a purulent exudate, with lesions healing within 15 days of infection.<sup>4</sup>

### Newborn Kids

Consistent signs include weakness, anorexia, cyanosis and dyspnea, increased heart and respiratory rates, abdominal pain, and fluid gut contents accompanied by diarrhea, and, in some cases, dysentery. Vesicles and ulcers may also be present on the coronets. Conjunctivitis, seropurulent nasal discharge, erosions of the oral mucosa, and petechial hemorrhages in the skin are also seen.

## CLINICAL PATHOLOGY

Leukopenia is a consistent finding in sick newborn kids. The virus can be isolated from all secretions or identified by PCR and restriction endonuclease analysis. In serum, antibodies can be demonstrated by serum neutralization or ELISA tests.<sup>5</sup>

## NECROPSY FINDINGS

### Adults

In does, ulceration and necrosis of the vaginal and vulval mucosae and placentitis are standard findings. Males have inflammation and ulceration of the penis and prepuce. A few adults develop an acute pneumonia with thick fibrinous exudate in the pleural cavity. Miliary foci of hepatic necrosis may or may not be grossly visible in aborted fetuses, but microscopic multifocal necrosis is commonly seen in the liver, adrenal glands, lung, and kidney. Herpesvirus intranuclear inclusions can be found in some of these tissues.

### Newborn Kids

Prominent lesions include ulceration and necrosis of the mucosae of the rumen, abomasum, intestine, cecum, and colon. Lesions are particularly severe in the large intestine. Vesicles and ulcers on the coronet of the feet may also be seen. Microscopically, foci of necrosis are often seen in the adrenal glands, urinary bladder, spleen, liver, lungs, and other tissues. Characteristic intranuclear inclusion bodies may be seen in mononuclear cells associated with these lesions.

### Samples for Confirmation of Diagnosis

- **Virology**—*Kids, fetuses*—liver, lung, adrenal gland. *Adults*—genital ulcers, vesicles. Chilled swabs in viral transport media (virus isolation, PCR). It may be difficult to isolate virus from aborted fetuses, but it can be demonstrated by real-time PCR.<sup>6</sup>
- **Histology**—formalin-fixed samples of affected tissues

### DIFFERENTIAL DIAGNOSIS

The systemic disease needs to be differentiated from the severe mycoplasmal infections and bacterial septicemias. Ulcerative dermatosis may be a confusing diagnosis in the genital form.

The differential diagnosis of causes of abortion in the ewe and doe are summarized in Table 18-1.

### TREATMENT AND CONTROL

The immunosuppressive drug mizoribine enhances the antiviral activity of acyclovir, but this combination is a model for treatment of human herpesvirus infections rather than a practical treatment for goats.<sup>7</sup> NSAIDs may ease the discomfort from the genital lesions caused by CpHV1, but effective quarantine and serologic testing of all introduced goats is the only effective control measure that can be suggested at the present time.

The disease is probably not of sufficient economic importance to justify developing a commercial vaccine. However, experimental vaccines based upon glycoprotein D from a nonpathogenic bovine herpes virus-4 have provided good protection against challenge with pathogenic CpHV1.<sup>8</sup>

## EQUINE VIRAL ARTERITIS

### SYNOPSIS

**Etiology** Equine arteritis virus

**Epidemiology** Infection and disease in equids. Outbreaks of disease as a result of lateral transmission by infected body fluids. Venereal transmission by persistently infected but clinically normal stallions, with subsequent lateral spread among mares.

**Clinical signs** Abortion. Upper respiratory disease with systemic signs including edema and respiratory distress.

**Clinical pathology** Serology. No characteristic changes in hemogram or serum biochemistry.

**Diagnostic confirmation** Virus isolation or reverse-transcription polymerase chain reaction (RT-PCR) detection of viral genome in blood, sperm-rich fraction of semen, nasopharyngeal swabs or tissue. Seroconversion or increase in complement fixation titer or enzyme-linked immunosorbent assay (ELISA).

#### Differential diagnosis:

- The systemic disease—viral respiratory disease
- Abortion—equine herpesvirus-1 (EHV1), mare reproductive loss syndrome
- Similar disease in neonates—EHV1 or other septicemia

**Treatment** There is no specific treatment

**Control** Vaccination, especially of stallions and seronegative mares to be inseminated by seropositive stallions and to control outbreaks at racetracks. Quarantine. Hygiene.

### ETIOLOGY

Viral arteritis of horses, donkeys, zebras, and mules (EVA) is associated with an **arterivirus**—equine arteritis virus (EAV). There is an as yet unsubstantiated suspicion that New World camelids can be infected.<sup>1</sup> EAV is a small enveloped, positive-sense, single-stranded RNA virus that is the prototype virus in the family Arteriviridae (genus: *Arterivirus*), order Nidovirales. This taxonomic grouping includes porcine reproductive and respiratory syndrome virus (PRRSV; see Chapter 18), simian hemorrhagic fever virus (SHFV), lactate dehydrogenase-elevating virus (LDV) of mice, and newly identified wobbly possum disease virus (WPDV), the cause of neurologic disease among free-ranging Australian brushtail possums (*Trichosurus vulpecula*) in New Zealand.<sup>2,3</sup> Although there is only one known EAV serotype, field strains of the virus differ in their virulence and neutralization phenotype,<sup>4</sup> with some strains causing no detectable disease and others being associated with severe clinical signs in adult horses and death in foals.<sup>5-7</sup>

The structural proteins of the EAV virion include seven envelope proteins (E, GP2, GP3, GP4, ORF5a protein, GP5, and M) and the nucleocapsid (N) protein.<sup>4,8</sup> Equine EAV-specific polyclonal antisera and EAV neutralizing monoclonal antibodies bind to the N-terminal hydrophilic ectodomain of GP5.<sup>4</sup> Interactions among the GP2, GP3, GP4, GP5, and M envelope proteins play a major role in determining the CD14+ monocyte tropism, whereas tropism for CD3+ T-lymphocytes is determined by the GP2, GP4, GP5, and M envelope proteins but not the GP3 protein.<sup>9</sup>

There is considerable genomic variation among isolates, with EAV of North American and European origin clustering in geographically approximate, but distinct, viral clades. Phylogenetic analysis based on sequences of the hypervariable region of ORF5 is valuable for tracing the origin of EAV strains.<sup>8,10-19</sup> Isolates of EAV cluster into two distinct groups: North American and European, with there being two clusters within the European clades (EU-1 and EU-2). Viral clades within a country tend to be consistent—for example, most isolates from horses in South Africa, Poland, and Argentina are from one of the European clades,<sup>11,12,15,20</sup> whereas those in Turkey cluster within the North American clade.<sup>16</sup> An outbreak in Quarter horses (which characteristically have a very low prevalence of serum antibody titers to EAV) and Arabians in North America in 2006 to 2007 was associated with a novel strain of virus from the EU-1 clade.<sup>6</sup> However, increasing international movement of horses has resulted in the geographic spread of virus clades, with there being molecular genetic evidence of recent introduction of new viral clades into France and Argentina (and likely elsewhere).<sup>10,18</sup> For instance, of 22 French EAV isolates, 11 isolates obtained before January 28, 2003 clustered within either the EU-1 (9 isolates) or EU-2 (2 isolates) subgroup, whereas 11 isolates obtained after January 30, 2003 belonged to the North American group, strongly suggesting that these strains were recently introduced into France.<sup>10,21</sup> Infected stallions, or infected straws of semen, are the most frequent mode of introduction of new strains to an area.<sup>10,12,18,19</sup>

Nine South African strains isolated from a single donkey are phylogenetically distinct and different from EAV strains isolated from horses in North America and Europe, donkeys in Europe, and the group of South African Lipizzaner stallions.<sup>10</sup>

Novel phenotypic variants of EAV can emerge during persistent infections in stallions, and this is an important feature in the development of disease in exposed mares and foals.<sup>4-6</sup> Persistently infected carrier stallions harbor EAV between breeding seasons, enabling emergence of genetic diversity of the virus.<sup>4</sup> The degree of nucleotide sequence identity among EAV strains isolated from a

single persistently infected stallion on 11 occasions over 7 years ranged from 98.92% to 100%, and amino acid homology ranged from 98.06% to 100%.<sup>17</sup> An outbreak of EVA in France in 2007 was linked to a single persistently infected stallion in which the EAV evolved from relatively innocuous strains into a pathogenic strain. The stallion was monitored, and EAV strains available for examination, from 2000 to 2007, enabled determination that the source of the outbreak was a viral strain that developed in this horse.<sup>21</sup> This means of development of new quasispecies is likely more important for the emergence of genetic diversity among EAV strains than is the minimal virus diversity that is generated during small or restricted outbreaks of EVA when the virus is transmitted by respiratory or venereal, or both, routes.<sup>6</sup>

## EPIDEMIOLOGY

### Occurrence

**Serologic evidence** of infection by EAV with or without evidence of disease is found in horse populations in North and South America, Europe, Africa, Asia, Australia, Britain, Spain, Italy, France, Poland, the Netherlands, South Africa, and Germany. It is probable that the disease is now present in most countries with substantial populations of horses. New Zealand has evidence that it is free of infection, and there are no reports of the disease from Japan.<sup>22</sup> International shipment of horses and frozen semen contributes to the spread of the EAV.

The proportion of seropositive horses varies considerably among populations, with there being marked differences among breeds. Overall, 2% of horses in the United States are seropositive to EAV (serum neutralization titer >1:4), with 8.4% of horse operations having seropositive horses. Twenty-five percent of operations whose principal activity was breeding had at least one unvaccinated seropositive horse, whereas 4% of racing operations had a least one unvaccinated seropositive horse. The prevalence of titers to EAV is higher in mares and in horses used for breeding. The frequency with which horses in the United States have serum titers greater than 1:4 varies with breed, with 24% of Standardbreds, 4.5% of Thoroughbreds, 3.6% of Warmbloods, and 0.6% of Quarter horses being seropositive. Approximately 19% of Warmblood horses imported into the United States have antibodies to EAV, with horses from Germany and the Netherlands having the highest prevalence (21% and 25% respectively). Between 55% and 93% of Warmblood and Lipizzan breeds in Austria have serologic evidence of exposure to EAV. Of horses in Anatolia, Turkey, ~24% are seropositive.<sup>23</sup> Of approximately 8000 sera tested in Greece, 3.3% were positive for antibodies to EAV.<sup>24</sup>

Disease in Great Britain and North America has been associated with

importation of infected stallions or semen. The disease spreads rapidly in a group of susceptible horses, and although the course of clinical disease is short, an outbreak in a group of horses may persist for a number of weeks. Naturally acquired infections in newborn foals can occur as an outbreak and cause severe disease.

### Origin of Infection and Transmission

EAV is spread in two ways:

1. **Horizontal transmission** of virus by predominantly nasal fluid, but also by urine, feces, lacrimal fluid, and vaginal discharge of infected horses
2. **Venereal transmission** from stallions to susceptible (seronegative) mares

#### Horizontal Transmission

Through infected nasal discharge and body fluid, horizontal transmission is effective and is the means of disease spread in outbreaks in racing stables, and among mares and foals at breeding farms. The virus is found in respiratory secretions for 7 to 14 days and in other tissues for 28 days. Close contact between horses is probably required for transmission of the virus—it has been reported to spread after contact of horses across a fence. The duration of viability of the virus in the environment has not been reported, but the potential for spread of infection on fomites including clothing and tack should be considered when dealing with an outbreak.

#### Venereal Transmission

**Stallions** are infected by horizontal transmission of the virus, subsequently excrete the virus in semen, and infect susceptible mares at the time of mating. Clinically normal stallions are also capable of transmitting the virus horizontally to other stallions in a breeding operation, demonstrating the potential for horizontal spread of infection from stallions in the absence of clinical disease or sexual contact. This is demonstrated by the high frequency of infection in stallions sharing a stable and infection of semen in a virgin stallion.<sup>15</sup> Between 30% and 60% of infected stallions excrete the virus in semen for weeks to months. Some stallions excrete virus for years, and lifelong infection and virus excretion can occur. Prolonged infection of stallions is associated with mutation of the virus and secretion by the stallion of viral strains that vary over time.<sup>21</sup> However, disease resulting from transmission of infection from a stallion to a mare, and subsequent spread of infection to other horses, is associated with a single viral strain. In other words, stallions can excrete a variety of strains of the virus during their lifetime, but outbreaks of disease are associated with an initial single viral strain that evolves slowly, if at all, during the weeks or months of the outbreak but that can develop into multiple viral strains.<sup>5,6</sup> For

instance, at least 22 strains of EAV were detected in the 2007 outbreak in France, with the original inciting virus having developed in a stallion persistently infected before 2002.<sup>5,6,10</sup>

Prolonged excretion of the virus in semen is likely important in the maintenance of the virus in populations of horses. Introduction of a **persistently infected stallion** into a naive population, insemination of seronegative mares with semen from an infected stallion, and emergence of a virulent strain of EAV from a persistently infected stallion have been implicated as the cause of outbreaks of viral arteritis.<sup>5,10,13,18</sup> The carrier stallion infects mares at mating; the mares then develop disease and shed the virus in nasal and other body fluids and infect in-contact susceptible horses and foals by horizontal transmission.

Artificial breeding practices in which large numbers of mares, often over geographically dispersed areas, are inseminated within a short time or single season from an infected stallion can result in widespread outbreaks. This situation occurred among Quarter horses in the United States in 2006 to 2007 and in draft breed horses in France in 2007.<sup>5,6</sup> Furthermore, transfer of EAV-infected embryos to EAV serologically negative recipient mares can result in infection of the recipients, although this has only been demonstrated experimentally and has not been identified as a means of EAV spread in the field.<sup>25</sup>

The possibility of fomite spread on veterinary instruments, clothing, or personnel, as was possibly the case in France, should be considered.<sup>5</sup>

### Immunity

Vaccination or recovery from natural infection results in the development of a strong serum antibody virus-neutralizing response, which is thought to be important in clearance of the virus and resistance to infection. The humoral immune response to EAV includes development of complement-fixing and virus-specific neutralizing antibodies. Complement-fixing antibodies develop 1 to 2 weeks after infection, peak after 2 to 3 weeks, and disappear by 8 months, whereas virus-neutralizing antibodies are detected within 1 to 2 weeks after exposure, peak at 2 to 4 months, and persist for at least 3 years.<sup>4</sup>

Naive pregnant mares infected by horizontal transmission may abort or, less commonly, give birth to infected foals that subsequently die, whereas foals of immune mares are resistant to infection. Viral neutralization antibodies are present in mare's colostrum and foal's serum after sucking, with persistence of the antibodies to the age of 2 to 6 months in the foals. Persistence of passive immunity in foals has important implications for resistance to infection and for timing of administration of modified live vaccines.

### Animal Risk Factors

There are clear differences in susceptibility of individual horses to infection and disease, with the clinical outcome of EAV infection determined by host genetic factors. Horses can be segregated into susceptible and resistant phenotypic groups based on the in vitro susceptibility of CD3+ T-lymphocytes to EAV infection.<sup>26-28</sup> A genetically dominant haplotype associated with the in vitro susceptible phenotype has been identified in four horse breeds studied and is located in the region of ECA11, based on genome-wide association studies.<sup>26</sup> There are several proteins associated with virus attachment and entry, cytoskeletal organization, and NF- $\kappa$ B pathways encoded by this region of ECA1.<sup>26</sup> There does not appear to be an association between polymorphisms in major histocompatibility antigens (the equine lymphocyte antigen) and susceptibility to EAV infection.<sup>29</sup>

Horses of all age groups are susceptible to infection, but adult horses are generally resistant to disease. In the 2007 outbreak in France, deaths were recorded of one fetus, 5 young foals, and 2 mature horses.<sup>5</sup>

### Economic Importance

The chief impact of the disease on breeding farms is the loss of foals through abortion and the cost of quarantine and control measures. The systemic illness can be severe, but the mortality rate is low. The outbreak in western France in 2007 affected 18 (index, 8 primary and 9 secondary) premises in five counties in western France. Eight mortality cases were observed, including one fetus, five young foals and two mature horses. During outbreaks at race tracks, the economic impact is a result of lost opportunities for training and racing sick or convalescing horses and the effect of quarantine and control measures. Additional costs are incurred by the inconvenience and cost of vaccinating mares to be bred to stallions infected with the virus and import regulations controlling movement of horses and semen, including the inability to export mares, fillies, and noncarrier stallions that are seropositive (perhaps as a result of vaccination), and the limited opportunities for export of semen from infected stallions or export of the stallions themselves.

### PATHOGENESIS

The clinical manifestations of EVA result from vascular injury; the pathogenesis of EVA has not yet been comprehensively defined but involves infection of CD3+ T-lymphocytes.<sup>9</sup> The highly virulent, horse-adapted *Bucyrus* strain of EAV causes death in horses by severe vascular damage. The pathogenesis of disease associated with horizontal transmission of EAV has been elucidated. After inhalation of the virus, it binds to the respiratory epithelium and infects alveolar macrophages and is detectable in

bronchial lymph nodes by 48 hours after infection. Three days after infection, the virus is detectable in circulating monocytes, with subsequent systemic distribution of infection. The virus has localized in vascular endothelium and medial myocytes by days 6 to 9, and there is significant damage to blood vessels by day 10. The virus infects renal tubular epithelium and can persist there for up to 2 weeks. Medial necrosis of blood vessels might cause anoxia of associated tissues. The virus is not detectable in any tissue by 28 days after infection, with the exception of accessory sex glands in intact male horses.

Abortion is caused by a severe necrotizing myometritis and presumed consequent reduction in fetal blood flow. There are usually no lesions in the fetus, although the fetus is infected with the virus, sometimes at titers higher than those in the dam. The mechanism underlying abortion of foals from EAV-infected mares is unclear.<sup>4</sup>

### CLINICAL FINDINGS

Infection by EAV is usually **clinically inapparent**, especially after venereal infection of mares. **Abortion** is not necessarily associated with clinical disease in the mare. Systemic disease is usually mild to moderate and self-limiting, with recovery in 5 to 9 days in the vast majority of horses.

**Systemic disease is characterized** by an incubation period of 1 to 6 days followed by the appearance of fever (39–41°C [102–106°F]). A serous nasal discharge presents that may become purulent and be accompanied in some horses by congestion and petechiation of the nasal mucosa, urticaria, conjunctivitis, excessive lacrimation developing to purulent discharge, keratitis, palpebral edema, and blepharospasm. Opacity of the aqueous humor and petechiation of the conjunctiva may also occur. Signs of pulmonary disease, such as respiratory distress and coughing, are attributable to pulmonary edema and congestion but are uncommon. The appetite is reduced or absent; in severe cases, there may be abdominal pain, diarrhea, and jaundice. Edema of the limbs is common and more marked in stabled horses than those at pasture. In stallions, edema of the ventral abdominal wall may extend to involve the prepuce and scrotum. Depression is usual and varies in degree with the severity of the syndrome. The disease is acute and severe, and deaths may occur without secondary bacterial invasion. In these cases dehydration, muscle weakness, and prostration develop quickly. It must be emphasized that the disease may be much milder than that described previously.

**Clinical disease in neonatal foals** is characterized by fever, profound depression, weakness, limb and facial edema, and respiratory distress.<sup>30</sup> Severely affected foals usually die. Foals can be affected at birth or

be born apparently normal and develop disease 1 to 19 days after birth.

**Abortion** occurs within a few days of the onset of clinical illness, although it is not usually associated with clinically apparent disease. Abortions may occur in 10% to 60% of at-risk mares during an outbreak and during the 3rd through 10th months of gestation. Abortion occurs 12 to 30 days after exposure. The abortion is not foreshadowed by premonitory signs, and the placenta is not retained.

### CLINICAL PATHOLOGY

**Hematologic examination** of adults and foals during the acute phase of the systemic disease is characterized by leukopenia and thrombocytopenia.

**Antemortem** confirmation of infection has historically been achieved by serology or virus isolation. However, modern diagnostic techniques involving PCR and genetic sequencing technology have greatly facilitated prompt diagnosis of infection, monitoring for the presence of EAV in semen (fresh or for artificial insemination), and genetic epidemiology of infection to track the source of the outbreak and its progression.<sup>5,6,10-12</sup> PCR tests are described for detection of the EAV.<sup>31,32</sup> Recommended use of testing is described in Table 21-4.

**Serologic confirmation of infection** is achieved using complement fixation, serum neutralization, and ELISA tests.<sup>33-36</sup> Seroconversion occurs within 1 week of infection, and demonstration of a rising antibody titer, based on acute and convalescent serum samples, or seroconversion is considered evidence of recent infection. False-positive results for the virus neutralization test have occurred using OIE prescribed rabbit kidney (RK-13) indicator cells when testing serum from horses vaccinated with an EHV1/4 tissue cultured derived vaccine. The false-positive results are likely a result of vaccine-induced antibody response against the RK-13 cells.

**Virus isolation** from blood, body fluids, and fetal or placental tissue is readily achieved during the acute phase of the disease. Appropriate samples for virus isolation include nasopharyngeal or conjunctival swabs and anticoagulated whole blood (heparin, EDTA, or citrate are suitable anticoagulants). Virus is continuously excreted in the semen of infected stallions and is readily isolated from the sperm-rich fraction of the semen. A nested PCR can detect the presence of virus in naturally infected semen at concentrations as low as 2.5 plaque-forming units per mL with a specificity of 97% and a sensitivity of 100%, and may be useful for the rapid diagnosis of EAV shedding stallions.

Antemortem diagnosis of EVA disease can be achieved by examination of skin samples using monoclonal antibody immunoperoxidase histochemistry. Examination

Table 21-4 Test methods available for the diagnosis of equine viral arteritis and their purpose

Method	PURPOSE					
	Population freedom from infection	Individual animal freedom from infection	Efficiency of eradication policies	Confirmation of clinical cases	Prevalence of infection—surveillance	Immune status in individual animals or populations postvaccination
Virus isolation	—	+++	—	+++	—	—
Agar gel immunodiffusion	—	—	—	—	—	—
Complement fixation	—	—	—	+++	—	—
Enzyme-linked immunosorbent assay	+	++	+	++	+++	+
Polymerase chain reaction	—	+++	—	+++	—	—
Virus neutralization	+	+++	+	+++	+++	+++

Key: +++ = recommended method; ++ = suitable method; + = may be used in some situations, but cost, reliability, or other factors severely limit its application; — = not appropriate for this purpose.

Although not all of the tests listed as category +++ or ++ have undergone formal standardization and validation, their routine nature and the fact that they have been used widely, without dubious results, makes them acceptable.

of skin samples obtained by biopsy reveals edema and vasculitis and presence of intracytoplasmic EAV antigen.

### NECROPSY FINDINGS

Gross lesions include edema of the eyelids and petechiation of the upper respiratory tract and the serosae of the abdominal and thoracic viscera. There is an abundant serofibrinous pleural and peritoneal effusion with generalized edema of the lungs, mediastinum, and abdominal mesenteries. A hemorrhagic enterocolitis and hemorrhage and infarction in the spleen may be noted. Characteristic histologic changes are found in the small arteries and include **fibrinoid necrosis of the tunica media and karyorrhexis of the infiltrating leukocytes**. Fluorescent antibody or immunohistochemical staining demonstrates viral antigen within the endothelial cells of these blood vessels. An immunoperoxidase method has also revealed viral antigen within endothelial cells and macrophages of an aborting mare and her fetus and within skin biopsies of animals exhibiting a maculopapular rash. Serologic tests performed on samples collected at necropsy can also be used to confirm that exposure to the virus has occurred.

The virus can be isolated from the lung and spleen of aborted fetuses, but no consistent, specific lesions are present. Necrotizing arteritis, similar to that in the mare, may be detectable.

### Samples for Confirmation of Diagnosis

- **Virology**—chilled lung, spleen, and thymus (virus isolation, PCR, fluorescence antibody test)
- **Serology**—heart-blood serum or fetal thoracic fluid (virus neutralization, ELISA, complement fixation)
- **Histology**—fixed lung, spleen, adrenal, jejunum, colon, and heart (light microscopy, immunohistochemistry)

### DIFFERENTIAL DIAGNOSIS

Definitive diagnosis is based on isolation of EAV from affected cases, or the demonstration of seroconversion or an increase in serum antibody titer.

The systemic disease must be differentiated from that associated with equine herpesvirus type 1 (EHV1) or type 4 (EHV-4) infection, equine influenza, strangles (see Tables 12-13 and 12-14—Infectious respiratory diseases of horses), infection with Getah virus in Japan, equine infectious anemia, African horse sickness, and purpura hemorrhagica, equine infectious anemia, equine encephalosis virus infection, Hendra virus infection, Getah virus infection, and toxicosis caused by hoary alyssum (*Berteroa incana*).

Abortion should be differentiated from that associated with EHV1, *Salmonella abortusequi*, leptospirosis, mare reproductive loss syndrome, and congenital malformations.

Similar disease in neonates can be associated with EHV1, immaturity or premature birth, and bacterial septicemia.

### TREATMENT AND CONTROL

There is no specific treatment for equine viral arteritis. Most horses recover without specific care. Severely affected foals require intensive care.

**Control** of EAV infection is based on the strong **immunity** induced by natural infection or vaccination with a modified live virus and an understanding of the role of carrier stallions in the disease. The following practices are suggested:

1. Isolate all new arrivals (and returning horses) to farm or ranch for 3 to 5 weeks.
2. If possible, segregate pregnant mares from other horses.
3. Blood test all breeding stallions for EAV antibodies.

4. Check semen of any unvaccinated, antibody-positive stallions for EAV to identify carriers before breeding.
5. Once tested negative for EAV antibodies, vaccinate all breeding stallions annually.
6. Physically isolate any EAV carrier stallions.
7. Restrict breeding EAV carrier stallions to vaccinated mares or mares that test positive for naturally acquired antibodies to the virus.
8. Vaccinate mares against EVA at least 3 weeks before breeding to a known carrier stallion.
9. Isolate mares vaccinated for the first time against EVA for 3 weeks following breeding to an EAV carrier stallion.
10. In breeds or areas with high rates of EAV infection, vaccinate all intact males between 6 to 12 months of age.

**Testing of mares and stallions** permits identification of serologically negative, and therefore at-risk, animals. Seronegative mares should not be mated with infected stallions nor inseminated with fresh or frozen semen from infected stallions because of the risk of transmission of infection to the mare. Seropositive mares, or mares that have been vaccinated for at least 3 weeks, can safely be bred to stallions that have serologic evidence of infection. Seropositive mares should be separated from seronegative mares for at least 3 weeks after mating to a seropositive stallion. Seropositive stallions that have not been vaccinated should have their semen cultured to determine whether they are excreting the virus. Stallions excreting virus in their semen should be kept isolated from susceptible horses but can be bred to seropositive mares, as described previously. Because the virus survives cooling and freezing, similar principles should be applied to the use of artificial insemination in horses. One control program requires that all

stallions be vaccinated with a modified live virus vaccine 28 days before the beginning of each breeding season.

**Vaccination with a modified live virus vaccine** induces strong immunity, although revaccination is necessary to ensure continuing immunity. The vaccine protects mares exposed to stallions shedding the virus in semen and has been used to control outbreaks of the respiratory form of the disease at racetracks. The modified live virus vaccine is regarded as safe, although there is mild fever and leukopenia, and there is evidence that the vaccine virus replicates in the vaccines. A killed-virus vaccine is also available and is used to vaccinate Thoroughbred stallions in the United Kingdom.<sup>37</sup> Antibodies induced by the vaccine cannot be differentiated from those resulting from natural infection, a situation that may be problematic when import restrictions require the horse to be seronegative, presumably as proof of lack of exposure to virulent EAV.

Vaccination of foals from immune mares results in good protection, provided that the timing of vaccination is delayed until maternal antibodies to EAV are no longer present in the foal.

Control of an outbreak of EVA involves cessation of all movement on and off the farm and all breeding to control both horizontal and venereal transmission. All cases and contacts should be traced, sampled, and isolated. All horses on the affected premises should be screened and grouped according to infectious status. Testing and screening should continue on all possible affected premises until the end of the outbreak, seropositive animals and pregnant mares should be isolated for 4 weeks after first sampling, and stallions must have their shedding status determined. It is critical that all breeding of stallions is stopped and that concerted efforts are made to control horizontal spread of infection to stallions.

For breeds that permit use of assisted breeding technologies, all semen and embryos should be traced and recipients informed of the situation.

A protocol for managing an outbreak of EVA on a breeding facility is as follows (modified from the Horserace Betting Levy Board<sup>38</sup>):

1. Stop mating, teasing, and collection/insemination of semen, and stop movement of horses on and off the premises immediately.
2. Notify the appropriate regulatory authority.
3. Isolate and treat clinical cases.
4. Group the in-contacts away from other horses on the premises and take samples for virus detection (preferably RT-PCR). When the results are available, separate any healthy horses that have tested negative away from those that have tested positive. Horses

that have tested positive should be kept in isolation until freedom from active infection is confirmed.

5. Screen all other horses at the premises to determine their serologic status (EAV positive or negative). If any of these return positive results, they should be separated from those with negative results and kept in isolation until freedom from active infection is confirmed by RT-PCR testing.
6. Arrange for one straw from each ejaculate of stored semen from infected stallions and their in-contacts to be tested by a laboratory. If any straw is infected, all straws from that ejaculate should be destroyed.
  - Inform the following of infection:
    - owners (or persons authorized to act on their behalf) of horses at, and soon to arrive at, the premises;
    - owners (or persons authorized to act on their behalf) of horses which have left the premises;
    - recipients of semen from the premises;
    - the national breeders' association, if applicable.
7. Clean and disinfect stables; equipment, including that used for semen collection and processing; and vehicles used for horse transport.
8. Good hygiene must be exercised. If possible, separate staff should be used for each different group of horses to prevent indirect transmission of infection between the groups.
9. Repeat the serologic testing after 14 days and again every 14 days until freedom from active infection is confirmed. Use the same laboratory for repeat samples as for the first samples. If any of the previously healthy or seronegative horses become ill or seropositive, they should be moved into the appropriate group. Testing of these horses should continue until freedom from active infection is confirmed. Seropositive stallions and teasers must be investigated to determine whether they are shedders. Those that prove to be shedders must be kept in strict isolation until their future is decided and must not be used for breeding activities during this time.
10. Do not resume any breeding activities or movement on and off the premises until freedom from active infection is confirmed in all infected and in-contact horses.
11. Pregnant mares must be isolated for at least 28 days after leaving the premises. Those remaining on the premises should be kept in isolation for at least 28 days after active infection has stopped.

12. Any mares that became infected after their pregnancy began should be foaled in isolation.

## AFRICAN HORSE SICKNESS

### SYNOPSIS

**Etiology** African horse sickness virus.

**Epidemiology** Infectious, noncontagious, arthropod-borne disease of horses, donkeys, and mules endemic to sub-Saharan Africa. Epizootics occur in the Iberian Peninsula, Mediterranean coast, Middle East, and Indian subcontinent. Heightened concern over risk of spread to areas, particularly western Europe, that are currently free of the disease.

*Continued*

**Clinical signs** *Pulmonary form*: fever, respiratory distress, frothy nasal discharge, death. *Cardiac form*: fever, edema of the head and ventral chest, hydropericardium. *Mixed form* has characteristics of both pulmonary and cardiac forms. *Horse fever*: mild fever, often inapparent infection.

**Clinical pathology** Leukopenia; disseminated intravascular coagulation. Serology often negative in horses that die acutely. Detection of viral genome by polymerase chain reaction (PCR).

**Lesions** Pulmonary edema, hydropericardium, ascites, edema of the gastrointestinal tract.

**Diagnostic confirmation** Histopathology. Detection of virus by cultivation or reverse-transcription PCR (RT-PCR) in blood or tissues.

**Differential diagnosis list:**

- Pulmonary form—rupture of cordae tendineae of mitral valve (single horse), acute bacterial pneumonia, anthrax, piroplasmosis
- Cardiac form—intoxication with monensin or similar ionophore.

**Treatment** None. Supportive care.

**Control specific** *Enzootic area*: vaccination, reduce exposure to biting insects. Quarantine and eradication in nonenzootic areas.

African horse sickness is an important disease of horses and mules in southern and central Africa and, during epizootics, in northern Africa (including Ethiopia)<sup>1</sup> and the Arabian and Iberian peninsulas. The disease in southern Africa occurs as frequent, intermittent small outbreaks and as periodic epidemics that kill large numbers of horses. An epidemic during 1854 to 1855 killed over 17,000 horses, 40% of the horse population, in the Western Cape region. During premechanized exploration and development of southern and central Africa and during the Boer War, the disease had a major economic and military impact. For example, during a single campaign in the Boer War, of 1732 British horses involved, 323 died of African horse sickness within a 17-day period in late April of 1901. An outbreak that extended through northern Africa into the Indian subcontinent from 1959 to 1961 resulted in the death of 300,000 horses.

## ETIOLOGY

African horse sickness (AHS) is associated with a viscerotropic orbivirus (RNA, family Reoviridae), of which nine antigenic strains (serotypes) are recognized. The genome of AHS virus (AHSV), which is available,<sup>2</sup> is composed of 10 double-stranded RNA segments, which encode seven structural proteins (VP1-7) and four nonstructural proteins.<sup>3,4</sup> Proteins VP2 and VP5 form the outer capsid of the virion, and proteins VP3 and VP7 are the major inner capsid proteins.

Proteins VP1, VP4, and VP6 constitute minor inner capsid proteins. The NS3 proteins are the second most variable AHSV proteins and are associated with viral release from cells and total viral yield.<sup>3,5</sup>

The serotypic differences are attributable to variations in the capsid proteins, predominantly VP2 and to a lesser extent VP5. VP2 contains the predominant neutralizing epitopes, although antibodies to VP5 are one of the earliest serologic markers of infection and have neutralizing activity. Lineages are also evident within serotypes, and the resultant clades are grouped geographically, at least for the serotypes studied. Identification of clades facilitates epidemiologic studies. There are also variants of each serotype with attenuated virulence. No new serotypes have been identified since 1960, and virtually all epidemics outside of southern Africa before 1987 were caused by serotype 9. Since then, outbreaks attributable to AHSV-4 (Iberian Peninsula 1987–1990); AHSV2, -4, -6, -8, and -9 in Ethiopia since 2007 (although AHSV-9 is endemic and was the serotype isolated from ~80% of cases)<sup>6</sup>; and AHSV-2 in Nigeria, Ghana, Senegal, Morocco, and neighboring countries from 2007 (again, with AHSV-9 being endemic in some of this region) have occurred.<sup>7,8</sup> Serotype 7 has been reported to cause disease in equids in Ethiopia but was not detected during 2007 to 2010.<sup>1</sup>

An avirulent form of AHSV 9 circulates in the Gambia, with 96% of clinically normal unvaccinated horses and donkeys seropositive for the serotype. The avirulent strain of AHSV-9 is identical to a vaccinal strain, raising the suggestion that the virus circulating in the Gambia region is highly likely to have derived from a live-attenuated AHSV-9 vaccine.<sup>9</sup> Passage of AHSV-7 through cell lines to produce an attenuated strain does not reduce its infectivity for midges, indicating the potential for vector-borne spread of avirulent strains of the virus.<sup>10</sup> The practice of vaccinating horses with polyvalent, avirulent vaccines has led to concerns about reassortment of the virus and reversion to virulence. However, although reassortment of vaccine virus occurs *in vivo*, there is currently no evidence that the reassortants are pathogenic, noting the limitation on this conclusion imposed by the small number of horses studied and the short duration of the study.<sup>11</sup>

There have been three outbreaks of AHS in the AHS-controlled zone near the Cape of Good Hope in South Africa since the zone was established in 1997. Serotypes involved in these outbreaks were serotype 1 (2004 and 2011) and serotype 7 in 1999. The 1999 and 2004 outbreaks were traced to unauthorized movement of horses into the zone. The source of the 2011 outbreak is unknown.<sup>12</sup>

There is real concern among AHS-free countries, including those in Europe, the Americas, and Australia, that AHS will gain entry, either by movement of midges, through introduction of subclinically infected equids

(likely mules, donkeys, or zebras), or through fraudulent (unauthorized) importation of equids. Recognition of this risk, which appears to be increasing with global warming and climate change and is exemplified by the emergence of Bluetongue and Schmallenberg viruses in Europe,<sup>8,13,14</sup> has resulted in many countries developing contingency plans for exclusion of the virus or management plans should it emerge.<sup>8,14-19</sup>

The virus is similar to other animal orbiviruses, including bluetongue virus, enzootic hemorrhagic disease virus, and equine encephalosis virus. The host range includes equids (horses, donkeys, mules, zebra), elephants, camels, sheep, goats, and predatory or scavenging carnivores. Infection produces disease in horses and mules, and less commonly African donkeys, but rarely in the other herbivorous hosts.<sup>3</sup> The disease occurs in dogs, although apparently rarely, and can occur in dogs that have not had known access to infected meat.<sup>20</sup>

The virus is inactivated by heating at 50°C (122°F) for 3 hours or 60°C (140°F) for 15 minutes, is stable at 4°C (39°F), and survives for 37 days at 37°C. It remains viable at pH of 6 to 12, but it is inactivated by acid and in 48 hours by 0.1% formalin or phenol, sodium hypochlorite, and iodophors.

Infection with African horse sickness virus is listed by the World Organization for Animal Health (OIE).<sup>21</sup>

## EPIDEMIOLOGY

African horse sickness is an **infectious but not contagious** disease of Equidae. It is spread by the bite of blood-feeding insects.

## Occurrence

The disease is **enzootic in sub-Saharan Africa**, causing clinical disease in horses, donkeys, mules, and dogs and infecting zebras, elephants, and perhaps other wildlife. The disease occurs from Senegal through sub-Saharan Africa to Somalia and Ethiopia. The disease makes occasional incursions into Iran, Pakistan, India, Turkey, and the eastern Mediterranean and Cyprus. The virus occurs in the Middle East, including Saudi Arabia and Yemen. It does not appear to be enzootic to Saudi Arabia, although the long-term status of this region is uncertain. In 1987 the disease recurred in Spain through introduction of infected zebras into a game park. By 1990 the disease had spread throughout Spain and Portugal but was eliminated by 1991.

Sero-epidemiologic surveys in Ethiopia indicate a prevalence rate of 10.4%, 29.7%, and 10.3% in horses, donkeys, and mules, respectively, with some regions having 51% seroprevalence in donkeys, 30% in mules, and 28% in horses, with an overall seroprevalence of 33%.<sup>1</sup>

## South Africa

The disease has been recognized in South Africa since shortly after introduction of

domesticated horses in the 1600s. The disease occurred throughout what is now South Africa in the nineteenth and early twentieth centuries, but as an enzootic disease became restricted to the northeastern areas of the country in the middle and later part of the twentieth century. The geographic contraction of disease was associated with elimination of large herds of wild zebra from all except the game parks of the northeastern areas of the country. Elimination of zebra, the reservoir of infection, reduced the occurrence of the disease dramatically. Outbreaks of disease outside of the endemic areas in the northeastern areas of South Africa are associated with introductions of virus from endemic areas at times of high abundance of *Culicoides* spp., the vector. The disease does not overwinter in the essentially zebra-free nonendemic areas. Serotype 9 causes enzootic disease in central Africa in the absence of zebra; the wildlife host has not been identified.

African horse sickness occurred in 1999 in the surveillance zone of the Cape Province of South Africa surrounding the disease-free area of Cape Town. The virus (serotype 7) was of a clade identical to that found in Kwazulu Natal Province, and its introduction was by the movement of infected horses from that region into the Cape Province.

### Transmission of Infection

African horse sickness virus (AHSV) is transmitted by the **bite of hematophagous insects**, including midges (*Culicoides* spp.), ticks (*Hyalomma dromadarii* and the brown dog tick, *Rhipicephalus sanguineus*), and mosquitoes (various species in laboratory studies). **Midges** are by far the most important vector in the spread of the spontaneous disease. The source of virus for midges is blood of infected horses, donkeys, mules, and zebra. Horses and mules have clinical signs of disease while viremic, but donkeys are often and, most important, zebra are always, apparently uninfected. Zebras may remain viremic for 6 weeks, donkeys for 12 days, and horses for 18 to 21 days. Dogs are usually infected by eating infected animals, although transmission to and from dogs by ticks can occur.<sup>20</sup>

Transmission of the virus to areas where it does not usually exist occurs both by movement of infected animals, such as zebras and horses, and by transportation of midges by wind or in aircraft.<sup>7,8</sup> Mechanical transmission of the virus on contaminated surgical instruments and needles should be considered a possibility.

### Zebra

In areas in which the disease is enzootic, the virus persists by cycling between the mammalian host, the zebra, and vectors year round. Zebra in enzootic areas can seroconvert during any month of the year, indicating that persistence of the virus is associated

with sequential infection of zebra within a herd or region. Persistence of the virus in a region is attributable to the long period of viremia in zebra and the presence of a herd of sufficient size to support cycling of infection among animals. The minimum size of a zebra population to maintain an enzootic infection is unknown. However, in areas in which the disease is not enzootic, the virus does not persist over the cooler winter months, when viremic animals recover and the vectors die. Concern exists that reintroduction of zebra to areas of the country currently free of enzootic AHS might permit reestablishment of the virus and disease in horses.

### Midges

Knowledge of the ecology of midges (*Culicoides* spp.), and which of them can be vectors for AHSV, is critical to developing an understanding of the risk of introduction and spread of infection in disease-free areas.<sup>22,23</sup> Although much is known about the ecology of midges, it is unclear which species, apart from *C. imicola* and *C. bolitinos*, can be vectors for AHSV and the capacity of these potential vectors to spread disease. A number of species of *Culicoides* that feed on horses, and other herbivores, are present in rural and urban regions of the southeastern United Kingdom and could be potential vectors for AHSV.<sup>23,24</sup> And being present and capable of being infected by AHSV, midges must feed on horses with sufficient frequency to spread the infection. The frequency with which midges feed on horses could be influenced by the host preference of midges—they might prefer to feed on other herbivores, thereby reducing the risk of spread of infection between horses.<sup>25</sup> Whether midges have this preference, and the influence of variable densities of alternative hosts on midge feeding, is unclear at this time.<sup>25</sup>

Finally, the risk of introduction and establishment of breeding populations of species of midges to areas in which they are not currently present must be considered.<sup>8,15</sup> Such introductions could be by wind or aircraft. The biosecurity risks of African horse sickness viruses need to be reevaluated in regions where the vector's niche is suitable as a result of climate change or human manipulation of local ecosystems, such as by irrigation.<sup>26</sup> Under some likely climate change scenarios the distribution of *C. imicola* could expand northward in the Northern Hemisphere. The risk of spread of African horse sickness virus is likely to increase as the climate suitability for *C. imicola* shifts poleward, especially in Western Europe.<sup>26</sup> The range of *C. imicola* in Africa might well decrease as a result of a warming climate.<sup>26</sup> Other human activities, such as irrigations programs and alterations in herbivore populations, that alter the ecology of local areas in such a way as to provide an ecological niche and environment where midges exotic to the

area can thrive will influence the risk of introduction of AHSV.

Midges are infected with AHSV; that is, they are not mechanical vectors, but rather the virus infects and replicates in the midge,<sup>27</sup> although transovarian transmission of infection between generations of midges does not occur. *C. imicola* is the primary vector responsible for the transmission of AHSV within its enzootic area and during epizootics. *C. bolitinos* is also a vector of AHSV in southern Africa, whereas a number of other *Culicoides* spp. are unlikely to be vectors because they are unable to maintain infection with the virus 10 days after ingesting a meal of infected blood. At least 11 species of *Culicoides* from South Africa can be infected by a variety of AHSV serotypes after feeding on infected blood meals in a laboratory setting. There are evident complex relationships between species of *Culicoides* and serotype of AHSV affecting viral infection and titer in the vectors.<sup>10</sup> However, *C. varipennis*, *C. pulicaris*, and *C. obsoletus* are competent and likely important vectors because of their ability to maintain infection over the winter, as demonstrated in Portugal.

The abundance of midges can be predicted from measures of soil moisture content and land surface temperature. Midges breed in damp soils that are rich in organic material, such as irrigated pastures, that provide soil moisture adequate for completion of the life cycle (at least 7–10 days). Higher temperatures increase the rates of infection of midges, virogenesis within midges, and transmission rate but decrease midge longevity. Replication of AHSV in midges does not occur at temperatures less than 15°C (59°F), although midges continue to be active at 12°C (54°F). The absence of AHSV in the midges during winter in parts of South Africa can be ascribed to their relatively low numbers, low infection prevalence, low virus replication rates, and low virus titers in the potentially infected midges.<sup>28</sup>

Midges can be transported by winds for up to 700 km.

### Risk Factors

#### Environment Factors

The incidence of the disease is often **seasonal** because of the seasonal variations in the number of *Culicoides* spp. present and possibly other weather-related factors such as host (zebra) behavior (Fig. 21-2). Vector activity is favored by temperatures between 12.5° and 29°C (54.5° and 84°F), and it is likely that several cool or cold episodes, rather than one “killing frost,” are necessary to kill all or most vectors. Local factors, including topography, influence the distribution of midges within their overall range, and therefore the disease has a geographic distribution: the areas most severely affected are low lying and swampy.

Epizootics of AHS occur in southern Africa in association with variations in the El

**Fig. 21-2 Seasonal occurrence of outbreaks of African horse sickness in central Ethiopia (2007–2010).**<sup>1</sup> (Reproduced with permission from Aklilu N, Batten C, Gelaye E, et al: African Horse Sickness Outbreaks Caused by Multiple Virus Types in Ethiopia. *Transboundary & Emerging Diseases* 2014;61:185-192.)

Niño/Southern Oscillation. Epizootics of the disease occur in years in which the oscillation produces drought followed by heavy rains. The reason for this association, which was first anecdotally reported in the 1800s, is unknown but could be related to congregation of zebra around water holes during the drought. Congregation of large numbers of zebra might increase the infection rate among midges, which then disseminate the infection when rains produce widespread conditions favorable to their reproduction.

### Animal Factors

Natural infection occurs in Equidae, the most severe disease occurring in horses, with mules, donkeys, and zebras showing lesser degrees of susceptibility, in that order. The risk of death is greatest in weanlings but for all horses does not appear to be related to sex of the animal. The case-fatality rate varies depending on the severity of disease (see under “Clinical Signs”) but can be as high as 90% in susceptible horses,<sup>12,29</sup> but it is lower in mules and donkeys.

Elephants seroconvert when exposed to infection but are probably not an important reservoir. White rhinoceros sampled in Kruger National Park in 1989 had a 60% seroprevalence to AHSV, whereas in 2007 the seroprevalence was zero. The reasons for this difference are unclear.<sup>30</sup>

**Vaccination** is effective in reducing risk of the disease (odds ratio for risk of death ~0.1 [0.04 to 0.4]).<sup>29</sup> After natural infection or vaccination, immunity to that strain, but not to heterologous strains, is solid. The development of immunity is slow and may require 3 weeks to be appreciable; titers may continue to rise for 6 months after infection.

Foals from immune dams derive passive immunity, the titer of which varies depending on the mare's titer, the serotype, and the time after ingestion of colostrum. Mare titers before foaling and foal serum titers after suckling are highly correlated regardless of serotype.<sup>31</sup> Mare serum titers for some

serotypes (1, 4, 6, and 9) are higher than for other serotypes, and this is mirrored in the titers in foal serum. Estimated mean half-life for neutralizing antibodies in foals to all 9 serotypes was 20.5 ( $\pm 2.6$  standard deviation) days, with a range from 15.4 days for serotype 8 to 22.6 days for serotype 3. The estimate for the mean time until the serum neutralization test became negative at a 1:10 dilution, considered absence of protection from infection, was 96 days for all nine serotypes, with a range from 62 days for serotype 5 to 128 days for serotypes 3 and 4.<sup>31</sup>

### Economic Importance

The disease was of tremendous economic concern in southern Africa when horses were important for transportation and as draft animals. The disease is currently an economic concern because of the costs associated with preventive measures in enzootic areas, monitoring for introduction of disease in unaffected areas, and restrictions on importation of horses from countries in which the disease is enzootic. The high case-fatality rate and morbidity of the disease in outbreaks is another source of loss. The cost of disease epizootics can be large, as demonstrated by the outbreak in the Iberian Peninsula, where control of the disease in Portugal in 1990 to 1991 was achieved at a cost of US\$2,000,000. Direct costs of managing the 2011 outbreak in the AHS-controlled zone in South Africa were at least R850,000, with estimated export losses of greater than R20,000,000.<sup>12</sup>

### Zoonotic Disease

African horse sickness caused encephalitis and chorioretinitis in eight workers in an AHS vaccine factory. Infection was likely to be through inhalation of freeze-dried virus.

### PATHOGENESIS

AHSV affects vascular endothelium and monocytes/macrophages.<sup>32</sup> The tissue tropism of the infecting serotype determines

which organs are most severely affected, although all serotypes infect the heart and lungs and, to a lesser extent, the spleen.<sup>32</sup> After infection, the virus multiplies in local lymph nodes, and a primary viremia ensues, with dissemination of infection to endothelial cells and intravascular macrophages of lung, spleen, and lymphoid tissues. Viral multiplication then results in a secondary cell-associated (red cell and white cell) viremia in horses of up to 9 days in duration. Fever and viremia occur at the same time, and resolution of the viremia is associated with defervescence. Localization of antigen depends on the form of the disease—horses with horse sickness have most of the antigen in the spleen, whereas horses with the more severe cardiopulmonary form have abundant antigen in cardiovascular and lymphatic systems.

Infection of endothelial cells results in degenerative changes, increases in vascular permeability, impaired intercellular junctions, loss of endothelium, subendothelial deposition of cell debris and fibrin, and evidence of vascular repair. Edema, hemorrhage, and microthrombi are associated with the vascular lesions. Abnormalities in the lungs include development of alveolar and interstitial edema, sequestration of neutrophils and platelet aggregates, and formation of fibrinous microthrombi. Combined, these changes likely result in coagulopathy, systemic inflammatory response syndrome, edema, impaired cardiovascular and pulmonary function, and hypovolemia.

### CLINICAL FINDINGS

The **incubation period** in natural infections is about 5 to 7 days. Three or four clinical forms of the disease occur, an acute or pulmonary form, a cardiac or subacute form, a mixed form, and a mild form known as “horse sickness fever.” An intermittent fever of 40° to 41° C (105–106° F) is characteristic of all forms.

### Acute (Pulmonary) Horse Sickness (Dunkop)

Acute horse sickness is the most common form in epizootics and has a case-fatality rate of 95%. Fever is followed by labored breathing, severe paroxysms of coughing, and a **profuse nasal discharge** of yellowish serous fluid and froth. Profuse sweating, profound weakness, and a staggering gait progress to recumbency. Death usually occurs after a total course of 4 to 5 days, although it can be so acute as to be without observed premonitory signs in some horses. Severe respiratory distress persists for many weeks in surviving animals. This is the form of the disease that occurs naturally in dogs.

### Subacute (Cardiac) Horse Sickness (Dikkop)

Subacute (cardiac) horse sickness is most common in horses in enzootic areas and has

a case-fatality rate of 50%. The incubation period may be up to 3 weeks, and the disease has a more protracted course than does the acute, pulmonary form. There is **edema** in the head, particularly in the temporal fossa, the eyelids, and the lips, and the chest, which may not develop until the horse has been febrile for a week. The oral mucosa is bluish in color, and petechiae may develop under the tongue. Examination of the heart and lungs reveals evidence of **hydropericardium**, endocarditis, and pulmonary edema. Restlessness and mild abdominal pain and paralysis of the esophagus, with inability to swallow and regurgitation of food and water through the nose, is not uncommon. Recovery is prolonged. A fatal course may last as long as 2 weeks.

A **mixed form** of the disease, with both pulmonary and cardiac signs, is evident as an initial subacute cardiac form that suddenly develops acute pulmonary signs. Also, a primary pulmonary syndrome may subside, but cardiac involvement causes death. This mixed form is not common in field outbreaks.

### Horse Sickness Fever

A mild form of horse sickness fever, which may be easily overlooked, is common in enzootic areas. The disease occurs in horses with some immunity or infection by serotypes of low virulence. This is the only form of the disease that occurs in zebras. The temperature rises to 40.5°C (105°F) over a period of 1 to 3 days but returns to normal about 3 days later. The appetite is poor, and there is slight conjunctivitis and moderate respiratory distress.

### CLINICAL PATHOLOGY

**Leukopenia** with lymphopenia, neutropenia and a left shift, mild thrombocytopenia, and hemoconcentration are characteristic of the acute forms of AHS. **Serum biochemical abnormalities** include increases in creatine kinase, lactate dehydrogenase, and alkaline phosphatase activities and creatinine and bilirubin concentrations. There is evidence of activation of coagulation cascade and fibrinolysis, although disseminated intravascular coagulation is unusual.

**Confirmation** of diagnosis is based on seroconversion (in horses that survive) or presence of AHSV in horses with compatible clinical or epidemiologic characteristics of the disease.<sup>3</sup> Detection of the virus can be made by demonstration of viral genome by one or more of a variety of PCR tests.<sup>3,33-41</sup> Each of these tests has its particular advantages, but all have the advantage of rapidity of diagnosis, often within hours of the sample being delivered to the laboratory, and many allow prompt identification of the serotype involved. Type-specific gel-based RT-PCR and real-time RT-PCR using hybridization probes for identification and differentiation AHSV genotypes provides a rapid typing

method for AHSV in tissue samples and blood.<sup>34,37,39,42</sup> ELISA tests provide rapid detection of AHSV antigen in blood, spleen, and supernatant from cell culture. The virus neutralization (VN) assay was formerly the “gold standard” for typing and identifying virus isolates, but because it takes 5 days and culture of the virus, it has been replaced by PCR assays.<sup>3</sup> The virus can be cultured in baby hamster kidney-21 (BHK-21), monkey stable (MS) or African green monkey kidney (Vero), or insect cells (KC); intravenously in embryonated eggs; or intracerebrally in newborn mice.<sup>3</sup>

**Serologic diagnosis** of the acute disease may be difficult because many horses die before they mount a detectable antibody response. In horses that survive for at least 10 days, agar gel immunodiffusion (AGID), indirect fluorescent antibody (IFA), complement fixation (CF), VN and ELISA tests are all effective in detecting antibody to the virus. An indirect ELISA (I-ELISA) is more sensitive in detecting early immunologic responses to vaccination or infection and the declining immunity in foals. However, in outbreaks of disease early and accurate diagnosis of disease and identification of the serotype involved is important to guide selection of vaccine and thereby control spread of the disease. Blocking ELISA, indirect ELISA, and complement fixation are all prescribed tests in the *OIE Terrestrial Manual*.<sup>3</sup> Suitable samples are blood collected into heparin during the febrile stage of the disease or lung, spleen, or lymphoid tissue collected at necropsy.

Tests approved for testing horses for international trade include a complement fixation test and an indirect sandwich ELISA.

### DIFFERENTIAL DIAGNOSIS

The fulminant disease in groups of horses is characteristic, although acute intoxication by monensin, salinomycin, or similar compounds can produce similar signs. Individual horses affected with purpura hemorrhagica and groups of horses affected with equine viral arteritis can have signs similar to horses with African horse sickness (AHS). Piroplasmiasis (*B. caballi* or *T. equi*) and trypanosomiasis cause fever and depression. Anthrax can cause acute deaths in solitary horses or groups of horses.

### NECROPSY FINDINGS

Gross findings in acute cases include **severe hydrothorax and pulmonary edema** and moderate ascites. The liver is acutely congested, and there is edema of the bowel wall. The pharynx, trachea, and bronchi are filled with yellow serous fluid and froth. In cases of cardiac horse sickness there is marked hydropericardium, endocardial hemorrhage, and myocardial degeneration. Edema of the head and neck is common, especially of the supraorbital fossa and nuchal ligament. Microscopic lesions are minimal in the acute

form; pulmonary edema may be present but no obvious vascular injury. Myocardial damage, including foci of necrosis, hemorrhage, and mild leukocytic infiltrates, may be seen during histologic examination of many cardiac (subacute) cases. An immunoperoxidase test is sensitive in detecting viral antigen in formalin-fixed, paraffin-embedded tissues.<sup>43</sup>

### Samples for Confirmation of Diagnosis

- **Virology**—chilled spleen, lung, lymph node (PCR, VIRUS ISOLATION)
- **Histology**—fixed lung, heart (light microscopy, immunohistochemistry)

### TREATMENT

There is no specific treatment for AHS. Supportive care and treatment of complication of the disease should be provided.

### CONTROL

The **principles of control** in enzootic areas are **vaccination** and **reduction of exposure** of horses to biting insects, whereas in **non-enzootic** areas the aim is to **prevent introduction** of the disease and **eradication** if it is introduced. The objectives of a control program for African horse sickness are as follows:

- Prevention of introduction of infection by clinically ill or apparently uninfected animals
- Slaughter of viremic animals where animal welfare and economic considerations permit this course of action
- Management changes to reduce exposure to midges
- Vector control
- Induction of active immunity in animals at risk of disease

### Prevention of Introduction

Many countries now have specific plans to prevent introduction of AHSV-infected equids and emergency management of introduction of the virus or occurrence of the disease.<sup>8,13,14,16,17,19,44</sup>

Infection can be introduced into an area free of AHSV by infected animals or midges. Control of midges is discussed later in the chapter. Infected animals can be horses incubating the disease; clinically ill animals; or animals, including donkeys and zebras, that have no clinical signs of illness but are infected and viremic, as was the case of the Portuguese epizootic. Appropriate control measures to prevent movement of animals at risk of being infected should be instituted and include the following:<sup>3</sup> completion of a vaccination protocol effective against all important serotypes at least 42 to 60 days before introduction of the horse, positive identification of all horses by microchipping and passport documenting vaccination status, and a veterinary certificate confirming

health and issued no more than 48 hours before introduction. Equids imported from areas in which the disease is enzootic, or from neighboring regions, should be housed in isolation in insect-proof enclosures for 60 days. Recommendations that call for vaccination of all equids within 10 miles (16 km) of imported horses are not appropriate for most countries to which the disease is exotic.

### Slaughter of Sick or Viremic Animals

The extreme measure of slaughter is appropriate in controlling infection recently introduced into areas previously free of the disease. It is an effective adjunct in control of spread of infection, as demonstrated in Portugal. There are obvious economic, animal welfare, and public relations aspects to this practice, especially in areas where horses have high intrinsic worth or are companion animals.

### Reduce Exposure to Biting Midges<sup>22</sup>

Horses should be housed in insect-proof buildings or, at a minimum, buildings that limit exposure of horses to midges by closure of doors and covering of windows with gauze. Impregnation of gauze with an insecticide further reduces biting rates. Stables should be situated in areas, such as on hill-tops or well-drained sites, that have minimal midge populations. Midge numbers on individual farms should be reduced by habitat alteration, and thus areas of damp, organically enriched soils are eliminated. Widespread use of insecticides is unlikely to be environmentally acceptable.

The feeding pattern of midges is such that housing of horses during the crepuscular periods and at night will significantly reduce biting rates and likelihood of infection. Horses kept at pasture should have insect repellents applied regularly and especially to provide protection during periods of high-insect-biting activity. DEET (*N,N*-diethyl-m-toluamide) is the only commercially available repellent with documented activity against *Culicoides* spp. Application of deltamethrin (10 mL of 1% solution) to skin of horses did not reduce the frequency of midge feeding in an experimental trial in the United Kingdom.<sup>24</sup> Installation of alphacypermethrin impregnated mesh to jet stalls reduced the attach rate by *Culicoides* species by 6- to 14-fold and markedly reduced the number of *Culicoides* collected from horses housed in the stalls compared with sentinel horses, suggesting that this might be a useful means of reducing exposure of housed horses to midges.<sup>15</sup>

### Vaccination

Vaccination is effective in reducing both morbidity and mortality from AHSV infection in horses in enzootic areas and to control epizootics of the disease.<sup>7,29</sup> Vaccination is used in two circumstances: in areas in which the disease is endemic and in regions with an

epizootic of the disease. Vaccination can be used in enzootic or neighboring regions to provide active immunity of all resident equids because of the continual risk of the disease in these areas. Vaccination in this instance is initiated as soon as foals no longer have passive immunity to the virus, and it continues annually throughout the horse's life. Alternatively, vaccination can be used in the face of an epizootic to induce active immunity in horses in contact or in regions surrounding the outbreak. In this instance vaccination is stopped when the infection is eradicated from the area.

Early attenuated virus vaccines, although effective in preventing AHS, were associated with significant adverse effects, such as encephalitis. More recent vaccines of virus attenuated by passage through tissue culture are effective in preventing disease but do not prevent viremia. They were used to control the most recent outbreak in Spain and Portugal. Currently available vaccines are polyvalent or monovalent preparations containing attenuated strains of the virus. Protection against heterologous serotypes is usually weak, and most vaccines are polyvalent.

The polyvalent vaccines contain serotypes 1, 3, and 4 or serotypes 2, 6, 7, and 8, respectively. AHSV-9 is not included because serotype 6 is cross-protective.<sup>46</sup> A monovalent vaccine containing attenuated serotype 9 is used in western Africa, where this was, until recent emergence of AHSV-2, the only serotype present.<sup>7</sup> Vaccination of foals with either monovalent or polyvalent vaccine did not affect the serologic response to each serotype; that is, the response to vaccination with a monovalent vaccine did not differ to the response to that serotype when it was delivered in a polyvalent vaccine.<sup>47</sup> Foals have markedly varying serologic responses to differing serotypes, similar to the situation in adult horses,<sup>31</sup> and they fail to develop protective immunity to some serotypes.<sup>47</sup>

Inactivated vaccines are effective in preventing viremia in most animals and disease without adverse effects. Inactivated vaccines are no longer available.

A number of recombinant canary-pox or vaccinia subunit vaccines have been trialed experimentally and provide protective immunity against challenge exposure of horses or appear to be effective using guinea pig models of the disease. The remaining challenge is to ensure that vaccines provide protection against all 9 serotypes.<sup>48-52</sup>

The recommended vaccination program for horses in South Africa that all race horses shall be vaccinated against African horse sickness using a registered, nonexpired, polyvalent horse sickness vaccine (e.g., Horse Sickness Vaccine I [AHS I] and Horse Sickness Vaccine II [AHS II]) according to the manufacturers' recommendations including two times as foals between the ages of 6 and 18 months, not less than 90 days

apart and, where possible, between June 1 and October 31, and thereafter every year between June 1 and October 31.<sup>53</sup> Foals are not vaccinated until they are at least 6 months of age to prevent any effect of colostral passive immunity on efficacy of vaccination. Horses resident in the AHS controlled area may not be vaccinated without written permission from authorities.

**Immunity** after vaccination is protective for at least 1 year, but annual revaccination of all horses, mules, and donkeys is recommended.

There is concern over the use of attenuated virus vaccines in epizootic situations, that is, in regions where AHSV is not enzootic. These reasons include the lack of vaccines approved for use in the European Community; the availability of only two types of polyvalent vaccines and one type of monovalent vaccine; delays in availability of vaccine for emergency vaccination; introduction of the virus, even attenuated virus, into regions in which it is not present; attenuated-virus viremia in some vaccinated horses; and reversion of vaccine strains to virulence.<sup>9,11,54</sup> These concerns have heightened the need for availability of inactivated virus or subunit vaccines.

## EQUINE ENCEPHALOSIS

### ETIOLOGY

The equine encephalosis virus is an insect-borne orbivirus, transmitted by a variety of *Culicoides* spp., that is closely related to bluetongue and epizootic hemorrhagic disease viruses.<sup>1,3</sup> It has characteristics in cell culture similar to African horse sickness (see “African Horse Sickness”). There are multiple serotypes of equine encephalosis virus that infect equids of southern, eastern, and western Africa, with serologic evidence of infection or virus isolation from equids in Kenya, Botswana, Namibia, South Africa, Ghana, the Gambia region, and Ethiopia, but not Morocco. Seven serotypes have been identified as circulating among equids in South Africa, with additional phylogenetically distinct isolates from horses in Israel.<sup>1,4,5</sup> The virus was detected in horses in Israel in 2008, in which it caused a mild febrile illness in large numbers of horses, and there is serologic evidence of its presence in Israel since 2001.<sup>5</sup> The virus isolated from horses in Israel was phylogenetically distant to those serotypes circulating in South Africa and similar to an isolate obtained from horses in Ghana.<sup>5</sup>

### EPIDEMIOLOGY

Horses, donkeys, and zebra in southern, western, and eastern Africa frequently have antibodies to the virus, indicating widespread infection of these equidae. Seventy-seven percent of 1144 horses, 57% of 518 horses, 49% of 4875 donkeys, and up to 88% of zebra in South Africa have antibody to EEV. All of 144 equids (horses and donkeys)

sampled in the Gambia region, 129 of 159 (81%) in Ghana, and 206 of 220 in Ethiopia had serologic evidence of infection by equine encephalosis virus.<sup>6</sup> None of 120 horses sampled in Morocco had serologic evidence of infection. An intensive study of all 127 foals on a single stud farm in South Africa revealed that 94% of the 93 foals that had a pyrexia episode were infected with EEV, despite 34% having maternally acquired antibodies soon after birth.<sup>7</sup> Zebra foals develop antibodies to the virus within months of losing their maternally acquired passive immunity. Elephants seldom have antibodies to EEV.

Seroprevalence in Thoroughbred yearlings has varied in South Africa markedly from year to year. Seroprevalence varies between 17.5 and 34.7% (of approximately 500 sampled each year) in most years but can be as low as 3.6%.<sup>1</sup>

The virus replicates in midges, although the rate differs depending on species of midge and strain of the virus. The genetic and phenotypic stability of strains of the virus are unknown, and there exists the potential for emergence of new strains or recognition of currently undetected strains, as demonstrated by the recent isolation of a phylogenetically distinct form of the virus from horses in Israel and Ghana. Variations in pathogenicity are not recognized but might exist. There is independent persistence of virus serotypes in a maintenance cycle based on observation of increased rates of seasonal seroconversion to a specific serotype with ongoing low level of infection by other serotypes. For example, infection by serotype 1 is most common (60%), whereas that by serotype 2 is uncommon (0.7%), despite the latter having been first documented as infecting horses in 1967.<sup>1</sup>

### CLINICAL SIGNS

The clinical importance of the virus is uncertain, and three syndromes are described: asymptomatic infection, clinical disease, and, on less evidence, encephalitis. Seroconversion in closely managed horses without evidence of clinical disease suggests that in most instances infection by the virus is asymptomatic. Whereas 94% of foals experiencing a pyrexia episode had virus recovered from their blood, only ~50% of foals from which virus was recovered had pyrexia, indicating that asymptomatic infections are common.<sup>7</sup> Most infections are subclinical based on the high seroprevalence rate and lack of reports of outbreaks of the disease. Clinical signs commonly attributed to EEV infection include fever, lassitude, edema of the lips, and congesta mucosal membranes, as reported in horses in Israel in 2008 and 2009. The virus was originally isolated from a horse with signs of neurologic disease—hence the name. However, the disease associated with infection by EEV is poorly documented, and, given the high prevalence

of infection, EEV might be falsely incriminated as the cause of more severe disease in some situations. Acute neurologic disease, abortion, and enteritis are anecdotally reported. In an outbreak report in late 2008 in Israel, the morbidity rate on 60 premises varied from 2% to 100%.<sup>4,5</sup> No horses died of the disease during that outbreak. Disease associated with EEV has not been recorded in donkeys or zebra.

### CLINICAL PATHOLOGY

Characteristic abnormalities in serum biochemistry or hematology are not reported. Antibodies to the virus are detected by serum neutralization assays and ELISA, both of which are group specific.<sup>8</sup> Complement fixation and agar gel immunodiffusion tests have been used to detect group-specific antibodies. A group-specific, indirect sandwich ELISA detects EEV antigen and does not cross react with African horse sickness virus, bluetongue virus, or epizootic hemorrhagic disease virus. A competitive ELISA suitable for use with serum from horses, donkeys, or zebras detects antibodies to all seven equine encephalosis virus serotypes but does not detect antibodies to other orbiviruses (such as African horse sickness or bluetongue).

### NECROPSY FINDINGS

Necropsy examination reveals cerebral edema, localized enteritis, degeneration of cardiac myofibers, and myocardial fibrosis but whether these abnormalities are attributable to EEV is unclear.<sup>3</sup> Definitive diagnosis of individual animals is difficult at the current time because of the high prevalence of seropositive animals and the ill-defined clinical and necropsy characteristics of the disease. Detection of seroconversion and/or virus isolation associated with clinical signs consistent with the disease in groups of horses permits detection of outbreaks of the disease, such as occurred in Israel. There are no recognized measures for treatment, control, or prevention. There is no vaccine.

## GETAH VIRUS INFECTION

### ETIOLOGY

Getah virus is an alphavirus within the Semliki Forest complex of togaviruses. These are small enveloped viruses with a single-stranded, positive-sense RNA genome. Getah virus causes disease in horses and

pigs, and this occurs in Japan, Hong Kong, China, Southeast Asia, Korea, and India. Reports from the 1960s document antibodies to Getah virus in animals in Australia, but the presence of this virus in Australia has not been confirmed using modern techniques that are able to differentiate antibodies to Getah virus from those of the related Ross River virus and other viruses in this complex. There are no reports of disease caused by Getah virus in Australia. There is considerable sequence homology between Getah and Ross River virus genomes. There is temporal, but not geographic, variability among isolates of Getah virus from Southeast Asia and Japan.<sup>1,2</sup>

### EPIDEMIOLOGY

Getah virus is arthropod-borne, and infection is through the bite of an infected mosquito. The life cycle of Getah virus has not been completely explicated. The virus is maintained in the mosquito-vertebrate-mosquito host cycle typical of arboviruses. The definitive, amplifying vertebrate host for Getah virus is unknown, although a number of vertebrates, including horses, cattle, and pigs, can be infected by the virus. Antibodies to the virus have been detected in humans. Horses and pigs become viremic and presumably can infect mosquitoes, although this does not appear to have been confirmed experimentally. The virus is assumed to be maintained in a mosquito-pig-mosquito cycle in those areas in which there is mosquito activity year round. Persistence of the virus in areas in which mosquito activity is seasonal has not been explained, and whether transovarial or transtadial transmission occurs within the mosquito population is not reported.

There is suspicion that during outbreaks of disease Getah virus is spread by horse-to-horse contact, based on the rapidity of spread among horses, the short duration of the outbreak, and the lack of mosquito activity at the time that some horses developed the disease. However, experimental evidence suggests that this route of spread is likely of limited importance in propagation of epidemics because of the low concentration of the virus in nasal and oral secretions of infected horses and the large inoculum required to cause disease in horses by the intranasal route.

A recent outbreak in Japan saw 75 of 2000 Thoroughbred race horses develop a pyrexial episode, with Getah virus isolated from 25 of the 49 blood samples collected.<sup>3,4</sup> This contrasts with the 770 of 1900 horses affected in a 1974 outbreak at the same facility in Japan.<sup>3</sup> The prevalence of serologic evidence of infection of horses by Getah virus in Japan ranges from 8% to 93%, depending on the region of the country in which the samples were collected and the disease history of the band or stable of horses. Seroprevalence was 17% in India,

12.4% in Thoroughbred racehorses in Korea (with 28% of horses > 6 years of age positive), and 25% in Hong Kong.<sup>5</sup> These results confirm the widespread incidence of subclinical infection of horses by Getah virus in endemic areas.

Disease of humans caused by Getah virus has not been documented.

### CLINICAL SIGNS

Disease associated with Getah virus infection is characterized by pyrexia, edema of the limbs, and an abnormal gait, often described as “stiffness.” Eruptions of the skin, urticaria, and submandibular lymphadenopathy are reported in some horses with the disease in Japan, but not in India. The clinical disease persists for 7 to 10 days. Abortion is not a feature of the disease, and foals born of mares that have had the disease during gestation are normal. Subclinical infection is very common in endemic areas. However, Getah virus has been isolated from aborted swine fetuses.

Hematologic abnormalities induced by Getah virus infection in horses include lymphopenia. Increases in serum activity of muscle-derived enzymes, such as creatine kinase, are not characteristic of the disease. Affected horses can have mild to moderate hyperbilirubinemia secondary to inappetence.

Diagnosis of disease caused by Getah virus is achieved by detection of clinical signs consistent with the disease, isolation of the virus from blood of affected horses, and seroconversion to the virus. Interpretation of serologic data from horses in Japan is hindered by the widespread use of a vaccine against Getah disease that induces detectable antibodies to Getah virus in serum. A multiplex RT-PCR is available for use on samples from pigs.<sup>6</sup>

### NECROPSY FINDINGS

Reports of postmortem examination of horses with disease caused by Getah virus are limited to experimental studies because the disease is typically not fatal. Horses with disease induced by inoculation with pathogenic Getah virus typically have mild changes, including atrophy of splenic and lymphoid tissue with destruction of lymphocytes, and perivascular and diffuse infiltration of focal skin lesions by lymphocytes, histiocytes, and eosinophils. Lesions in the central nervous system are equivocal and limited to mild perivascular cuffing in the cerebrum and small hemorrhagic foci in the spinal cord.

### TREATMENT

Treatment of affected horse is supportive. Affected horses might benefit from administration of analgesics and antipyretics such as phenylbutazone. Administration of antimicrobials is not indicated in uncomplicated cases.

### CONTROL

An inactivated virus vaccine is available in Japan for immunization of horses against disease caused by Getah virus. The vaccine, which is combined with that for Japanese encephalitis, is considered effective. Race horses are vaccinated every 6 months.<sup>4</sup> Minimizing the exposure of horses to infected mosquitoes is prudent, although the efficacy of this technique in preventing infection is unknown. During outbreaks of disease caused by Getah virus, it is prudent to isolate affected horses, given the potential for horse-to-horse spread of the virus.

### CLASSICAL SWINE FEVER (HOG CHOLERA)

Hog cholera, also known as classical swine fever (CSF), is a highly infectious pestivirus infection of pigs. At one time it was characterized clinically by an acute highly fatal disease and pathologically by lesions of a severe viremia. It is now known that chronic or inapparent disease also occurs, including persistent congenital infection in newborn pigs infected during fetal life. In many countries where it is endemic, clinical ability will diagnose it more often than laboratory skills.

Swine can also be affected by ruminant pestiviruses (BVD and BD); these seldom cause disease in pigs, but there are exceptions.<sup>1</sup> The risk factors for these are large numbers of cattle or sheep and goats sharing the same accommodation and watering facilities.<sup>2</sup> Knowledge of these viruses is important for the interpretation of diagnostic tests for CSF because BVDV can transmit between pigs and may prevent the transmission of CSF.<sup>3</sup>

### SYNOPSIS

**Etiology** Hog cholera virus, a pestivirus belonging to the genus *Flaviviridae* and related to the bovine virus diarrhea virus.

**Epidemiology** Affects domestic pig of all ages; causes major economic losses interfering with trade when outbreaks occur in pig-raising countries. Occurs in Europe, South America, and the Far East. Highly virulent virus causes high morbidity high mortality; less virulent strains cause milder form. Transmitted by direct contact, feeding of uncooked pork products. Neutralizing antibodies provide protection.

**Signs** Sudden onset of peracute deaths first indication in herd. Many pigs affected within days. Severe depression, fever, anorexia, purplish discoloration of skin, ocular discharge, nervous signs, and death in few days. Nervous form may predominate. Reproductive failure in pregnant sows (abortions, mummification, stillbirths, birth of persistently infected pigs).

**Clinical pathology** Leukopenia. Detection of virus in tissues and serologic testing.

**Lesions** Diffuse hemorrhages subcapsular of kidney, lymph nodes, bladder, larynx, swollen lymph nodes, splenic infarcts, congestion of liver and bone marrow, button ulcers in colon, nonsuppurative encephalitis. Hydropic degeneration and proliferation of vascular endothelium.

**Diagnostic confirmation** Detection of virus in tissues and serologic tests.

**Differential diagnosis list:**

- African swine fever
- Erysipelas
- Salmonellosis

**Treatment** None

**Control** Eradication in hog cholera-free countries by slaughter of all in-contact and affected pigs. Use of vaccines in endemic areas. Eradication in countries where endemic by use of vaccination followed by test and slaughter, quarantine farms.

## ETIOLOGY

It is a small, enveloped positive-sense, single-stranded, RNA virus in the genus *Pestivirus* of the family *Flaviviridae*. A new virus, Bungowannah virus, found in two herds in Australia, is also a pestivirus.<sup>4</sup> Most are non-cytopathogenic in culture, but there are some CSF and BVD that are cytopathogenic.<sup>5</sup>

It is antigenically and genetically diverse, with recombination possible between strains.<sup>6</sup> There is considerable antigenic variability. There are four structural proteins (C, E<sup>ns</sup>, E1, and E2) and eight nonstructural proteins. Genetic typing is most commonly based on E2 glycoprotein because abundant sequence data are available. The E2 glycoprotein of CSF is a virulence determinant in swine.<sup>7</sup> There are three major groups, each with three of four subgroups.<sup>8</sup> Typing used full-length encoding sequences of E2, which proved to be the most reliable for significant phylogeny and were proved to be useful in recent outbreaks in Lithuania.

**Group 1** types are present in South America and Russia. There have been subgroups 1.1, 1.2, and 1.3 in the past, but now it is proposed that there is a group 1.4 found in Cuba.<sup>9</sup>

**Group 2** types were isolated from Europe<sup>10</sup> and some Asian countries.<sup>11</sup> It has been shown that there is the possibility of a long-term persistence of genotype 2.3 CSF virus strains in affected areas at an almost

undetectable level even after long-term oral vaccination campaigns.<sup>12</sup>

**Group 3** types are confined to Asia. Four genetic groups are found in China (1.1, 1.2, 2.2, and 2.3), and a recent study has shown the wide range of antigenic differences in 21 strains.<sup>13</sup>

The virus is an enveloped virus and thus is susceptible to detergents and lipid solvents. High or low pH and temperature above 60°C (140°F) will inactivate the virus, but this depends on the substances in which the virus is contained.

There is evidence of natural recombination in CSF virus.<sup>6</sup> A sequence database allowing automated genotyping has been established.<sup>14</sup>

Classification of virulence has been based on a clinical and pathologic score and extended further by additional parameters such as case-fatality rate, antibody production, and leukocyte count to provide a modified clinical score<sup>15</sup> that gives a more reliable classification of virulence.

## EPIDEMIOLOGY

Although eradicated in many parts of the world, the countries that are free are always open to reinfection from illegal imports of fresh products, tourism, hunting, and illegal swill feeding.<sup>136</sup>

## Occurrence

The pig is the only domestic animal species naturally infected by the virus. Wild boar are also affected. Antibodies against CSF virus in fecal samples from wild boar in Korea have been described.<sup>16</sup>

A study of common warthogs and bush-pigs in South Africa showed that they were capable of supporting CSF infection and could transmit to other pigs that were in contact.<sup>17</sup> The warthogs did not develop clinical signs, but the bushpigs did.<sup>18,19</sup> CSF of the type 1.1 cluster has also been described in pygmy hogs in India at a conservation center.<sup>20</sup> All breeds and ages are susceptible, and adults are more likely to survive an acute infection. The disease is found in eastern Europe, Southeast Asia, Central and South America, and in parts of Europe in wild boar.

Canada, Australia, New Zealand, and South Africa have not experienced the disease for many years. A mild form of the disease occurred in Australia in 1960 to 1961. The disease was eradicated from the United Kingdom during the period 1963 to 1967, and the United States was declared free of the disease in 1978.

Outbreaks of acute hog cholera have occurred occasionally in other countries but were quickly controlled by a rigorous policy of slaughter and quarantine. The disease occurred in the United Kingdom in 1986 in which three primary outbreaks were identified; all outbreaks were attributed to the feeding of unprocessed waste feed containing imported pig meat products. A similar

origin was suspected for the outbreak in the United Kingdom in 2000. In this outbreak an interesting feature was the transport of infected pig carcasses from a site where bodies were dumped for quite long distances by scavenging foxes, infecting new outside pig arks across fields as they went.

Between 1982 and 1984 epidemics occurred in Germany, the Netherlands, Belgium, France, Italy, Greece, and the Iberian Peninsula. As of 1985, six countries in Europe were free of classical swine fever: Denmark, Ireland (including Northern Ireland), Norway, Sweden, Finland, and Switzerland.

There were three outbreaks of CSF in France between 2002 and 2011, one in wild boar and a pig herd in 2002 in Moselle, and a further one in wild boar in 2003 in Bas-Rhin, and they appeared to be from two lineages in wild boar in Germany. The wild boar in Bas-Rhin remained infected until 2007.<sup>21</sup> The role of wild boar in France has been described.<sup>22</sup>

The costs are astronomical (the Belgian outbreak of 1997 cost an estimated €11 million), and the 1997 to 1998 outbreak in the Netherlands was very serious. The disease has also concentrated in certain parts of Europe where the pig populations are intense and live in close proximity to wild boar and feral pig populations. For instance, outbreaks occurred regularly between 1997 and 2001 in Croatia. One source was imported pig meat; the other was strains reaching domestic pigs from wild boar. The wild boar areas include parts of Germany and Poland and probably most of eastern Europe. The outbreak in Spain in 2001 to 2002 was related to wild boar.<sup>23</sup>

In Europe, the disease, together with ASF, is endemic in the central highlands of Sardinia. Many outbreaks of classical swine fever occurred in Germany between 1993 and 1995, and major outbreaks occurred in 1996 to 1997 in Germany and the Netherlands. The risk factors for Germany have been described. In these countries, over the past 25 years, the disease occurred as a series of epidemics in which many swine herds in a geographic area were affected within a few months.

Infection with the classical swine fever virus has also occurred in the wild boar population in Tuscany in Italy, Germany, France, Austria, Czechoslovakia, and Croatia. Serologic surveys of wild boar in Sardinia found an overall prevalence of 11%, and seropositive boars were found not only in areas where they share their habitat with free-ranging domestic pigs but also in areas of the island where contacts between wild and domestic pigs are unlikely to occur. Thus there may be transmission and persistence of the virus within the wild boar population. This has occurred with the low-virulence strain in Germany. The persistence of infection in a wild boar population in the

Brandenburg region of Germany provided optimum conditions for the establishment of a CSF epidemic in Germany.

The disease is currently endemic in most countries of South America and the Far East except Japan and Korea. In Asia the problem is the backyard pig that is not vaccinated and is always a reservoir. Here extension services, appropriate vaccination schemes, and regulatory control are difficult to implement, but it may be time to try for worldwide eradication. In the Philippines, the disease is endemic on many large-scale swine farms. In spite of vaccination of the sows and boars every 6 months and piglets at 6 to 8 weeks of age, the disease causes suboptimal performance in 10% to 30% of pigs between 7 and 16 weeks of age.

### Morbidity and Case Fatality

The disease usually occurs in epidemics, often with a morbidity of 100% and a case-fatality rate approaching 100%, when a virulent strain of the virus infects a susceptible population. However, in recent years, outbreaks of a relatively slowly spreading, mild form of the disease have caused great concern in many countries. The disease associated with strains of low virulence may be unnoticed in growing and adult pigs, but the infection can be associated with perinatal mortality, abortions, and mummified fetuses. In a recent outbreak a mild form given experimentally to sows only produced a mild viremia with widespread antigen distribution, but without clinical signs, except lesions of hemorrhagic dermatitis. It did, however, produce an antibody response and transplacental infection.

### Methods of Transmission

The source of virus is always an infected pig or its products, and the infection is usually acquired by ingestion; inhalation is also a possible portal of entry. Direct animal-to-animal contact is the most important method of spread. Infected pigs shed a large amount of the virus in all secretions and excretions of pigs infected with highly or moderately virulent strains.<sup>24</sup> The effect of strain and inoculation dose of CSF on within-pen transmission has been described.<sup>25</sup> It is excreted in the urine for some days before clinical illness appears and for 2 to 3 weeks after clinical recovery.

Virus spread via excretions is more important in early stages of an outbreak. Highly contagious by direct contact, it is likely to be transmitted by aerosol only when all the pigs in the same airspace are viremic, and even then only for a distance of 1 meter. Viral RNA and infectious virus were detected in air samples in 2008.<sup>26</sup> It has been spread experimentally by aerosol, which followed the pattern of air currents,<sup>25</sup> but the importance under field conditions is not known. The higher the dose of virus or the more virulent the virus strain, the sooner the virus

should be detected in air samples in experimental infections.<sup>26</sup> Analysis of the 1997 to 1998 outbreak in the Netherlands suggested that it did not occur over long distances but did occur within a holding or within a radius of less than 500 meters. The transmission of CSF depends on the clinical course of infection, which is determined by the levels of high or low levels of virus excretion.<sup>27</sup> Different strains of the virus can differ in the relative contribution of secretions and excretions to the transmission of the virus, although blood is a high risk for spreading infection from pig to pig.<sup>28</sup>

Infected boars can shed the virus in semen. Rats and mice are unlikely to be involved in the spread.

Silent circulation of CSF occurs before the first outbreak is detected. The most severely affected animals have a higher infectivity than the less affected ones. Three transmission experiments suggested that the most severely affected animals could play a prominent role in CSF transmission.<sup>29</sup>

Sick pigs excrete virus until they die, or until after recovery. The resistance and high infectivity of the virus make spread of the disease by inert materials, especially uncooked meat, a major problem. The UK virus in the 2000 outbreak probably came from an infected pork product, imported illegally and fed to an outdoor pig. Outside pens, in warm weather and exposed to sunlight, lose their infectivity within 1 to 2 days. The ability of the virus to survive in the environment in more favorable situations is uncertain. However, it is probable that it can survive for considerable periods because the virus is quite resistant to chemical and physical influences. Transmission from neighboring units is very easy. One of the major features of the recent Dutch outbreak was the proof that transmission from boar studs (AI) was possible because infected boars excreted virus in semen, and the virus probably infects spermatogonia. It was shown that following insemination with semen containing CSF antibodies, infection could occur as early as 7 days; all pigs were positive by 14 days. The transmission rates in the Dutch outbreak have been calculated.

In areas free of the disease, introduction is usually by the importation of infected pigs or the feeding of garbage containing uncooked pork scraps. Hopefully, in Europe the ban on swill feeding will prevent further cases of infected meat causing the problems. Movement of pigs that are incubating the disease or are persistently infected is the most common method of spread. The infection usually originates directly from infected breeding farms. Birds and humans may also act as physical carriers of the virus. In endemic areas, transmission to new farms can occur in feeder pigs purchased for finishing, indirectly by flies and mosquitoes, or on bedding, feed, boots, automobile tires, or transport vehicles. Farmers, veterinarians,

and vaccination teams can transmit the virus by contaminated instruments and drugs, but recent evidence suggests that mechanical transmission may have been overestimated. People can spread the virus.<sup>30</sup>

Farmers can spread the virus within a herd by treating sick animals or employing routine health management procedures such as iron injections of newborn pigs. The common practice of not changing syringes and needles between farm visits constitutes a major risk when viremic animals are present. The most common cause of dissemination occurs through the movement and sale of infected or carrier pigs through communal sale yards when there is ample opportunity for infection of primary and secondary contacts. Transmission of excretions without direct contact from pig to pig may have been overestimated.

When the disease is introduced into a susceptible population, an epidemic usually develops rapidly because of the resistance of the virus and the short incubation period. In recent years, outbreaks have been observed in which the rate of spread is much reduced, and this has delayed field diagnosis. It is not spread by dogs, cats, or rats, and bird transmission is unlikely.

### Risk Factors

Following the 1997 to 1998 severe epizootic in the Netherlands, analysis showed that there were five major increased risk factors identified: (i) presence of commercial poultry on the farm, (ii) visitors to the units not being provided with protective clothing, (iii) drivers of lorries using their own clothes rather than protective clothing provided by the premises they were visiting, (iv) larger size, and (v) aerosols produced by high-pressure hosing. Reduced risk was associated with (i) over 30 years of experience in farming and (ii) additional lorry cleaning before being allowed on to the farm.

### Animal Risk Factors

It has been shown at least experimentally that the virulence of the strain can influence the dynamics of the virus spread.<sup>29</sup> Pigs infected with such a virus excrete significantly more virus than pigs infected with moderately or low virulent virus. The exception was the chronically infected pig, which, over the period of its disease, excreted significantly more virus. It showed the importance of virus type and excretion data in modeling studies.<sup>28</sup>

Historically, infection with the hog cholera virus rapidly resulted in severe clinical disease. It is now recognized that with less virulent strains, a carrier state can occur, at least for a period of time. Following exposure to these strains, pigs may become infected without showing overt signs of the disease, and although they may eventually develop clinical disease, this latent period is of importance in dissemination of infection

when such pigs are sold and come in contact with others. In recent outbreaks in high-pig-density areas in Belgium, the interval between the first occurrence of clinical signs and the report of a suspect herd was shorter when the disease was first diagnosed in finishing pigs rather than in sows, boars, or nursing piglets. The proportion of clinically affected animals was positively correlated with the proportion of serologically positive animals.

Susceptible pregnant sows, if exposed to less virulent strains of the virus, may remain clinically healthy, but infection of the fetuses in utero is common, and the virus may be introduced into susceptible herds by way of these infected offspring. The sow with "carrier sow syndrome" can give birth to normal, healthy-appearing piglets that are persistently infected and immuno-tolerant; these pigs, along with those with chronic infections, are responsible for the perpetuation of the virus in the pig population. A fully virulent virus may also be transmitted in this manner if the sows are treated with inadequate amounts of antiserum at the time of exposure or if they are exposed following inadequate vaccination. Piglets infected in utero, if they survive, may support a viremia for long periods after birth.

During outbreaks of classical swine fever in Germany between 1993 and 1995, differing clinical courses were observed, ranging from mild clinical signs to severe typical disease. The genotype of pigs may influence the outcome of hog cholera virus infection. In certain pig breeds the chronic form of the disease is more likely to occur, and these pigs may excrete the virus over prolonged periods. Experimental inoculation of purebred pigs resulted in acute fatal infections, whereas crossbred pigs experienced acute, chronic, and transient infections.

### Pathogen Risk Factors

#### *Virulence Characteristics*

The most virulent strains produce clinical disease in pigs of all ages. But there are differences in the clinical and pathologic features between strains of the virus and in their virologic characteristics. The less virulent strains cause only mild clinical disease or disease restricted primarily to fetal and newborn piglets. It is probable that this variation has always occurred in field strains of the virus, but the use of inadequately attenuated live virus vaccines is also a contributory factor. The occurrence of variation in virulence and antigenicity has been recognized as a cause of failure of vaccination and "vaccine breakdowns." It is equally important in causing problems with the diagnosis of hog cholera in eradication programs when infection is manifest in patterns not traditionally associated with this disease.

Genetic analysis of isolates of the virus for a series of epidemics of swine fever in Italy

affecting both domestic pigs and wild boar has provided useful epidemiologic information. The isolates were divided into three subgroups, and it is suggested that there have been at least two separate introductions of classical swine fever over a 7-year period and that the virus has been transmitted between domestic pigs and wild boar. Molecular analysis can aid in tracing the transmission of the virus from domestic pigs to wild pigs and back to domestic pigs.

In the outbreaks of hog cholera in England in 1986, affected pigs in the first outbreak exhibited clinical signs and necropsy lesions indicative of a virulent strain of the virus. However, in subsequent outbreaks, clinical disease was much milder and case-fatality rates low. Experimental infection of pigs with a field isolate of the virus resulted in variations in clinical response, from acute illness to inapparent infection, including minimal changes visible at necropsy, all of which indicate that genotype may influence the pathogenesis of the disease. High titers of virus were found in several tissues of one experimental pig that was recovering, even in the presence of serum-neutralizing antibodies. It is clear that some infected pigs may pass through an abattoir without detection because of the absence of lesions.

### Resistance of Virus

Survival of the virus is very dependent on the strain of the virus.<sup>26</sup> The CSF virus (CSFV) is destroyed by boiling, 5% cresol, or 2% sodium hydroxide and by sunlight, but it persists in meat that is preserved by salting, smoking, and particularly by freezing. It is able to survive in cool, moist protein-rich environments for 2 weeks at 20°C (68°F) but for 6 weeks at 4°C. The virus can be inactivated in at least 80% of pork hams after exposure to a flash temperature of 71°C (159°F). It can survive in infected uncooked ham pork for at least 84 days and 140 days in diced ham or sausage; it can survive in bacon for 27 days after traditional curing processes and for at least 102 days in hams cured in salt concentrations of up to 17.4%, which is much higher than that normally used in curing bacon. The use of lower-salt concentrations in curing solutions and the decreased time between slaughter and consumption as a result of modern abattoir practices increase the risk of disease transmission. It survives pH ranges from 3 to 11. Persistence in frozen meat has been observed after 4.5 years. The virus persists for 3 to 4 days in decomposing organs and for 15 days in decomposing blood and bone marrow.

### Immune Mechanisms

Maternal antibodies may interfere with the production of viral-specific cell-mediated immunity. Neutralizing antibodies occur as early as 9 days after infection in recovering pigs and after 15 days in fatally infected pigs. Neutralizing antibodies are the most

important antibodies in terms of protection. The maximum antibody response occurs 3 to 4 weeks after infection, and levels may persist indefinitely but last at least 6 months. In chronic hog cholera, neutralizing antibodies may be transiently detectable during the phase of partial recovery between 3 and 6 weeks after infection. Low-virulence strains of hog cholera may cause inapparent infections and are described as poorly immunogenic but in some instances may induce considerable titers of neutralizing antibodies in immunocompetent pigs. Cellular immunity mechanisms are probably very important in that it has been shown that there is CSFV-specific IFN- $\gamma$  formed early after antigen exposure. These mechanisms produce a higher response after intranasal or oral vaccination than after IM vaccination, and therefore vaccines should be looked at for their potential to induce higher T-cell responses. Intrauterine infection of piglets with the virus may induce a state of specific immunologic unresponsiveness. The piglets are persistently viremic and may continue to live for several weeks or months, but the majority die within the first 3 weeks of life. Piglets with PRRSV infections have been shown to produce a poorer response.

### Economic Importance

Hog cholera has been responsible for large economic losses in the swine industry worldwide. It is considered to be the most important disease of pigs in the European Union, and a common program of eradication in the member states is in effect. The magnitude of the economic importance of the disease is directly proportional to the size of the pig population and the standards of the swine industry. In countries with intensified systems of pig production, such as the Netherlands, it is estimated that the direct costs of transport and destruction of infected herds, disinfection of premises, indemnities to farmers, vaccination, and identification and registration of pigs on behalf of the control of the disease amounted to a large percentage of the gross slaughter value. The additional indirect damage as a result of loss of production on infected farms, standstill of pig movements in affected areas or regions, and restrictions on export is difficult to evaluate. Losses as a result of the death of pigs are aggravated by the high cost of vaccination programs in enzootic areas and by the problem that vaccination may not be completely effective in controlling epidemics. Recovered or partially recovered pigs are very susceptible to secondary infections, and exacerbations of existing chronic infections such as enzootic pneumonia are likely to occur during the convalescent period.

### PATHOGENESIS

The tonsil is the primary site of virus invasion following oral exposure. Primary multiplication of the virus occurs in the tonsils,

beginning within several hours after infection. It then spreads to the peripheral lymph nodes. The virus is first found in plasma before the mononuclear cell populations. The primary cell in the peripheral blood to be infected is the mixed granulocyte. The virus then moves through lymphatic vessels and enters blood capillaries, resulting in an initial viremia at approximately 24 hours. At this time the virus is present in the spleen and other sites such as peripheral and visceral lymph nodes, bone marrow, and Peyer's patches. The virus exerts its pathogenetic effect on endothelial cells, lymphoreticular cells and macrophages, and epithelial cells. In particular, B-lymphocytes, T-helper cells, and cytotoxic T cells are affected, and these changes take place before the RT-PCR picks up the virus in the blood.

The changes in gene expression of 148 genes during the first 48 hours following infection have been described.<sup>31</sup> Mutations in CSF nonstructural protein NS4B affect the virulence of CSF.<sup>32</sup>

The enhanced pathogenicity of some strains is associated with the presence of residues in E2 and NS4B of CSFV that can act synergistically to influence viral replication efficiency *in vitro* and pathogenicity in pigs.<sup>33</sup>

CSF virus is accompanied by depression of cellular immune defenses,<sup>34</sup> particularly innate responses mediated by interferon.<sup>35</sup> CSFV is not often found in apoptotic cells, so there are other mechanisms that cause this apoptosis. CSFV appears to be able to inhibit apoptotic signaling at multiple levels, and by supporting viral replication, endothelial cells may promote the pathogenesis of CSF.<sup>36</sup> A B-lymphocyte deficiency associated with viral destruction of germinal centers in lymphoid tissues is the most significant patho-immunologic consequence of acute hog cholera infection. This lymphocyte apoptosis, which is activation-induced programmed cell death, is one of the key features of CSF infections. CSF affects cellular antiviral activity, which suggests that the lesions may have an immunopathologic component, possibly through the infection of dendritic cells<sup>37</sup> and possibly by damaging the interferon production.<sup>38</sup> It is likely that CSFV up-regulates some of the adhesion molecules, such as integrin- $\beta 3$  in vascular endothelial cells, which may alter hemostatic balance in CSF.<sup>39</sup>

Certain virus infections are associated with high levels of IFN-1 (type 1), which is a potent antiviral defense mechanism. Despite the presence of viral anti-IFN-1, inhibitors the plasmacytoid dendritic cells can continue to produce IFN-1. CSFV prevents IFN-1 secretion in its main target cells (macrophages, monocytes, and endothelial cells) by interacting with interferon regulatory factor.<sup>40</sup> The ability to activate dendritic cells, the ability to spread systemically, and the tropism for lymphoid tissues also contribute strongly to a raised IFN-1 response.

There is a novel virulence determinant within the E2 structural glycoprotein of CSFV.<sup>41</sup> In highly and moderately virulent strains of CSF there was a decrease in antiviral and apoptotic gene expression, and this coincided with higher levels of virus in these immune tissues (spleen, tonsil, retropharyngeal lymph nodes).<sup>42</sup>

In recovered pigs (from infection with a moderately severe strain) it was found that antiviral defense mechanisms were rapidly activated, whereas in chronically affected pigs several genes with the power to inhibit production of type 1 interferons were up-regulated. The chronic pigs failed to activate NK or cytotoxic T-cell pathways, and they also showed reduced gene activity in antigen-presenting monocytes/macrophages.<sup>43</sup> A highly virulent CSF virus produced significant changes in the mononuclear cell proteome in porcine peripheral blood, with 66 protein spots showing altered expression; 44 of these were identified as 34 unique proteins.<sup>44</sup>

CSFV can evade the immune response and establish chronic infection, and in an *in vitro* study it was shown that immune response genes were generally down-regulated.<sup>45</sup> The gene transcriptional profiles in peripheral blood mononuclear cells following a virulent strain of CSF have been studied. Many genes were up-regulated and many down regulated.<sup>46</sup> CSFV strains may exacerbate the alpha-response, leading to bystander killing of lymphocytes and lymphopenia, the severity of which might be attributable to the host's loss of control of IFN production and downstream effectors regulation.<sup>47</sup>

Most of the lesions are produced by hydropic degeneration and proliferation of vascular endothelium, which results in the occlusion of blood vessels. This effect on the vascular system results in the characteristic lesions of congestion, hemorrhage, and infarction from changes in arterioles, venules, and capillaries. Thrombosis of small and medium-sized arteries is another feature. Vascular changes are most severe in the lymph nodes, spleen, kidneys, and gastrointestinal tract. Lesions related to the effects on the endothelial cells also occur in the adrenals, central nervous system, and eyes. Atrophy of the thymus, depletion of lymphocytes and germinal follicles in peripheral lymphoid tissues, renal glomerular changes, and splenitis are characteristic. Leukopenia is common in the early stages, followed by leukocytosis in some animals, and anemia and thrombocytopenia occur. The thrombocytopenia may be caused by massive platelet activation and subsequent phagocytosis of platelets secondarily to the release of platelet activating factors by activated macrophages. Disseminated intravascular coagulation is common with microthrombi in small vessels, particularly of the kidney, liver, spleen, lymph nodes, lung, intestine, and intestinal

lymph nodes. The end stage of a lethal infection in the natural host is associated with a marked depletion preferentially of B-lymphocytes in the circulatory system and in the lymphoid tissues. Macrophage activation, and subsequent release of proinflammatory cytokines, plays an important role in the development of the classical signs of CSF. This is particularly true for the pulmonary intravascular macrophages.

It has been shown that there is a significant expression of TNF- $\alpha$  in virus infected lymph nodes. It may be that commitment to apoptosis may depend on the IFN production. In these lymph nodes lymphocyte death occurred by apoptosis, and some of the cells were positive on IHC for both TNF- $\alpha$  and apoptosis. It may be that the release of the TNF- $\alpha$  may induce the apoptosis in the uninfected bystander cells. Early immunosuppression is an important feature of the development of CSF, with the depression of CD1+, CD4+, and CD8+ common thymocytes. It has recently been shown that CSF can replicate in the dendritic cells and control IFN type 1 responses without interfering with immune reactivity. It is still not clear, even though it is known that there is clear targeting of macrophages and monocytes, how these cells produce this immunosuppression and account for the death of the T-lymphocytes. It is known that the dendritic cells are the sentinels of the immune system and respond to easy viral contact. They then develop the effective immune responses by migrating into the lymphoid tissue to present the processed viral antigens to the T-lymphocytes. However, in both CSF and BVD infections there is no activation of the dendritic cells, and this may be a feature of pestivirus infections and enable them to evade the immune response. At the same time, there is no interference with the maturation of the dendritic cells. The virus induces proinflammatory cytokine production (IL-1, IL-6, and IL-8) by 3 hours, and even further at 24 hours postinfection, and also increases the coagulation factors, tissue factor, and vascular endothelium cell growth factor. Endothelial cells that were chronically infected were unable to produce IFN type 1, and these cells were also protected from apoptosis. This establishes a long-term infection of endothelial cells with virus replication and increasing levels of IL-1, IL-6, and IL-8. It shows that there has been long-term interference with cellular antiviral defenses, possibly by targeting interferon regulating factor 3, as BVDV does, or by increased binding of NF- $\kappa B$ , which modulates an apoptotic pathway controlling several anti-apoptotic genes.

CSFV infections significantly increased the mRNA expression of IL-10 and tumor necrosis factor (TNF) alpha, and they inhibited IL-12 expression, with little effect on IFN- $\alpha$  and IFN- $\gamma$  expression. CSFV suppresses maturation and modulates functions

of monocyte-derived dendritic cells without activating nuclear factor kappa B, which is involved in immune regulation, inflammatory response, and antiapoptosis effect.<sup>48</sup>

In many cases, secondary bacterial infection occurs and plays an important part in the development of lesions and clinical signs.

The experimental disease is characterized by a biphasic temperature elevation at the 2nd and 6th day after inoculation, a profound leukopenia and an appreciable anemia 24 hours after inoculation, diarrhea at the 7th day, and anorexia and death on the 4th to 15th day in slaughter pigs. The anemia can be explained by the infection of 2% to 9% of the megakaryocytes 2 to 9 days after infection.

The inoculation of pregnant sows with a low-virulence field strain of hog cholera virus at various stages of pregnancy results in prenatal mortality in litters from sows infected at pregnancy day 40 and postnatal death at 65 days. The later that infection occurs in pregnancy, the greater the number of uninfected piglets born in infected litters. Transplacental infection of the porcine fetus with both field and vaccine strains of the virus may induce a spectrum of abnormalities, including hypoplasia of the lungs, malformation of the pulmonary artery, micrognathia, arthrogryposis, fissures in the renal cortex, multiple septa in the gallbladder, and malformations of the brain. Infection of the fetus at a critical stage of gestation (30 days) induces retardation in growth and maturation of the brain, resulting in microencephaly. The teratogenicity of the virus clearly depends on the stage of gestation. In general, the earlier the infection occurs, the more severe the abnormalities are likely to be. The virus can be found in the ovaries because the blood vessels deliver peripheral macrophages to the ovaries through atretic follicles.

One of the sequelae of transplacental hog cholera virus infection of the fetus is congenital persistent virus infection with the evolution of a runt-like syndrome during the first few months of life. At birth, affected piglets appear normal, although they are viremic; the viremia persists throughout life of the animals. The first evidence of clinical disease may occur at about 10 weeks of age, but it may be delayed until 4 months of age. Growth retardation, anorexia, depression, conjunctivitis, dermatitis, intermittent diarrhea, and locomotor disturbance with posterior paresis occur. At necropsy, the most remarkable lesion is atrophy of the thymus gland, and lesions of classical hog cholera are not present. In experimental congenital persistent hog cholera infection, the earlier the infection occurs in pregnancy, the greater the number of persistent infections in piglets born alive with immunologic tolerance. The immunologic tolerance is specific to the virus because affected piglets respond to other selected antigens.

The experimental infection of pregnant goats with the hog cholera virus on days 64 to 84 of gestation can result in transplacental infection, with the virus replicating and persisting in the fetuses for at least 40 to 61 days. The virus is highly pathogenic for goat fetuses, and serum antibodies may be present in the precolostral sera of the kids.

It appears that disseminated intravascular coagulation does not play a major role in the pathogenesis of CSF.<sup>49</sup>

### CLINICAL FINDINGS

The early identification of clinical signs would facilitate diagnosis and control, but a recent paper on experimental infections with a type 2.1 genotype virus and a genotype 3.3 virus that is genetically divergent from European viruses has shown differences in outcome.<sup>50</sup> The UK 2001 virus was similar to other European type 2 viruses, but the 3.3 virus produced fewer and delayed clinical signs, notably with little fever, making it more difficult to recognize in the field. Another complicating factor is that it poorly recognized by the CSF-specific antibody.

Six uncharacterized CSFV isolates from 1996 to 2007 were examined<sup>51</sup> and assessed in animal experiments for their clinical virulence. They were assessed as either moderately or highly virulent.

### Diagnosis

Nearly always, the detection is too late because it has been missed. The clinical signs are often nonspecific, but the score system suggested by the Dutch may help to suggest it. The differences in the four most recent German outbreaks in terms of clinical and pathologic signs were minimal. In former times, most of the European outbreaks were associated with the virulent genotype 1 of the virus, but now there are types 2:1, 2:2, and 2:3, which are much less virulent and produce a milder clinical course that is much more difficult to recognize over the first 14 days postinfection. In a recent set of experiments (with a strain of virus SF0277) all the pigs died, but in other experiments some of the pigs survived.

A recent report has suggested that the occurrence of PRRS does not appear to potentiate the clinical outcome of CSF in young pigs, but this has been disputed.

Simultaneous infection with *Trypanosoma evansi* does seem to produce a poor response to CSF vaccination.

As a result of the recent outbreak in the Netherlands, a quantitative retrospective analysis was made of the clinical signs, which suggested that the clinical inspection was the most important part of detection but was not very specific. Moderate-virulence and low-virulence strains cause a mild disease that may be so mild that clinical disease is not suspected.

Differential diagnosis should include PRRS, PDNS, ASF, salmonellosis, and coumarin poisoning.

### Peracute and Acute Disease

In the acute form the disease is characterized by anorexia, lethargy, conjunctivitis, respiratory signs, and constipation.<sup>51,52</sup> Diagnosis on clinical signs is more difficult since the 1980s, and therefore the CSF may not be recognized immediately,<sup>27</sup> but nearly always the major clinical sign is pyrexia. Clinical signs usually appear 5 to 10 days after infection, but incubation periods up to 35 days or more are recorded. At the beginning of an outbreak, young pigs may die in a peracute state without evidence of clinical signs having occurred. Acute cases are the most common. Affected pigs are depressed, do not eat, and stand in a drooped position with their tails hanging. They are disinclined to move and, when forced, do so with a swaying movement of the hindquarters. They tend to lie down and burrow into the bedding, often piled one on top of the other. Before the appearance of other signs, a high temperature (40.5–41.5°C [105–107°F]) is usual. In recent European outbreaks, respiratory signs have not been common. Constipation followed by diarrhea and vomiting also occurs. Later, a diffuse purplish discoloration of the abdominal skin occurs. Small areas of necrosis are sometimes seen on the edges of the ears, tail, and lips of the vulva. A degree of conjunctivitis is usual, and in some pigs the eyelids are stuck together by dried, purulent exudate. Nervous signs often occur in the early stages of illness and include circling, incoordination, muscle tremor, and convulsions. Death can be expected 5 to 7 days after the commencement of illness. Infection with *Salmonella* Choleraesuis may also be potentiated by hog cholera infection, and the two diseases in combination can result in high mortality.

### Nervous Manifestations

A form of the disease in which nervous signs predominate is attributed to a variant strain of the virus. The incubation period is often shorter and the course of the disease more acute than usual. Pigs in lateral recumbency show a tetanic convulsion for 10 to 15 seconds followed by a clonic convulsion of 30 to 40 seconds. The convulsion may be accompanied by loud squealing and may occur constantly or at intervals of several hours, often being followed by a period of terminal coma. In some cases, convulsions do not occur, but nervous involvement is manifested by coarse tremor of the body and limb muscles. Apparent blindness and stumbling have also been observed.

### Chronic Disease

Low-virulence strains of virus result in less severe disease syndromes. A chronic form occurs in field outbreaks and occasionally

after serum–virus simultaneous vaccination. The incubation period is longer than normal, and there is depression; anorexia; persistent mild fever; unthriftiness; and the appearance of characteristic skin lesions, including alopecia, dermatitis, blotching of the ears, and a terminal, deep-purple coloration of the abdominal skin. Pigs may apparently recover following a short period of illness but subsequently relapse and die if stressed.

Pigs infected with the low-virulence strains of the virus appear more susceptible to intercurrent bacterial disease. The changeable nature of this combination is such that hog cholera should be suspected in a herd or area where there is an increase in mortality from any apparent infectious cause that either does not respond, or responds only temporarily, to therapeutic ploys that are usually effective.

### Reproductive Failure

Reproductive failure can be a significant feature and may occur without other clinical evidence of disease within the herd. It may occur when inadequately protected pregnant sows are exposed to virulent virus or when susceptible pregnant sows are vaccinated with live attenuated vaccines or exposed to low-virulent field strains. Infection of the sow can occur at any stage of pregnancy and may result in no clinical signs other than a mild pyrexia, but it may be followed by a high incidence of abortion, low litter size, and mummification, stillbirth, and anomalies of piglets. Piglets infected at 50 to 70 days may be clinically normal at birth and then waste away and may develop tremors; such cases are said to be late-onset CSF. They are like BVDV cases in that they shed virus and are persistently affected for months. Live-born pigs, although carriers, may be weak or clinically normal. Persistent congenital infection is characterized by persistent viremia, continuous virus excretion, and late onset of disease, with death occurring 2 to 11 months after birth. No antibodies to the virus are present in spite of the persistent infection; affected pigs have a normal immune response to other antigens, but they do not respond to the hog cholera virus. Cell-mediated immunity appears to be normal. A high incidence of myoclonia congenita (congenital trembles) associated with cerebellar hypoplasia has been observed in some outbreaks where prenatal infection with hog cholera virus has occurred, and this syndrome has been reproduced experimentally. The prevalence of any one of these manifestations appears to vary with the strain of the virus and the stage of gestation at the time of infection.

## CLINICAL PATHOLOGY

### Hematology

A valuable antemortem diagnostic test is the total and differential leukocyte count. In the early stages of the disease there is marked

leukopenia, with the total count falling from a normal range of 14,000 to 24,000 cells/ $\mu$ l to 4000 to 9000 cells/ $\mu$ l. This is specifically granulocytopenia caused by bone-marrow atrophy. It is a result of apoptosis or necrosis, from 1 to 3 days postinfection, probably as a result of cytokine interaction. Depletion of the lymphocyte subpopulations occurs 1 to 4 days before the virus can be detected by RT-PCR on serum. If a virulent form, depletion is evident by 2 days.

B-lymphocytes, T-helper cells, and cytotoxic T cells are the most affected by the virus. The loss of the circulating B-lymphocytes is consistent with the failure to generate a circulating neutralizing antibody. Virulent strains produce greater reduction in B-lymphocytes than do mild forms. This can be of value in differentiation from bacterial septicemias, but it should not be used as the sole method of differentiation. In the late stages of hog cholera, leukocytosis as a result of secondary bacterial invasion may develop. Piglets less than 5 weeks of age normally have low leukocyte counts.

In a study of CSFV in 6- and 11-week-old pigs,<sup>53</sup> it was found that although only the mild disease resulted, there were depletions in B-cell numbers and a number of T-cell populations in peripheral blood, which were most marked in the 6-week-old pigs. A population of large granulocytes developed in the peripheral blood before the start of viremia.

### Diagnostic Tests

A comparison of diagnostic tests shows that the best results are detected by RT-PCR (98.9%), which is earlier than virus isolation (VI) on blood, which gives only a result of 94.5%. RT-PCR is expensive and labor intensive. The antigen-ELISA gives a later detection and the worst results. The leukocyte count gives the earliest pointer to CSF infection but of course does not confirm the disease.

The advent of eradication programs has resulted in the development of diagnostic tests for hog cholera. These tests must be accurate and rapid so that control measures can be rapidly instituted or lifted as required. Diagnosis by virus isolation is slow, the cytopathic effect may be minimal, and some strains have low infectivity and limited growth in tissue culture. This method is seldom used as a primary diagnostic method. Animal inoculation tests still provide an excellent method for the diagnosis of hog cholera and involve the challenge of susceptible and immune pigs with suspect material followed by subsequent challenge at a later date with fully virulent hog cholera virus. However, this test is time consuming and costly, and although it is used for the final confirmatory test for the presence of hog cholera infection in various situations, it is not satisfactory for a rapid diagnostic test.

### Detection of Virus

The more rapid tests rely on the detection of antigen in infected pig tissues or the detection of antibody following infection.

### Fluorescent Antibody Techniques

This technique allows the rapid detection of antigen in frozen sections of tissue or impression smears and in infected tissue cultures, and these methods have been adopted as a primary test in the eradication program in the United States. Antigen can be detected up to 2 days after death, and this method has been considered more reliable than the agar gel precipitation test. The method is capable of detecting virus carriers among vaccinated pigs.

### Antigen-Capture ELISA

The antigen-capture ELISA can detect the virus antigens in blood and tissues from experimentally infected pigs at 4 to 6 days after infection with a moderate- to high-virulence strain (Weybridge virus) and 7 to 9 days after infection with a low-virulence strain (New South Wales virus). The technique does not require tissue culture and takes less than 36 hours for a definitive result.

### Agar Gel Precipitation Test

The agar gel precipitation test detects antigen in tissue by means of a precipitin formed with immune sera. Usually pancreas from suspect pigs is tested. This test was used widely in the UK eradication program and is the standard primary test in many countries.

### Differentiation of Swine Fever Virus From Other Pestiviruses

#### PCR Tests

A PCR assay can be used to differentiate classical swine fever virus from ruminant pestiviruses. An international reference panel of monoclonal antibodies for the differentiation of hog cholera virus from other pestiviruses has been developed. Restriction endonuclease cleavage of PCR amplicons can distinguish between vaccine strains and European field viruses. The RT-PCR can also detect CSF in boar semen. A RT-PCR was then described. Rapid detection of CSF using a portable real-time RT-PCR (TaqMan) has been described. Further modifications have been described, and thus the test can be performed in a single tube with all the ingredients. It can then be used as a pen-side test and detects virus in nasal and tonsil scrapings 2 to 4 days before the onset of clinical signs. A further modification of RT-PCR and ISH has been that they can be used on formalin-fixed sections. A multiplex PCR is available to separate BVD from CSF.

A multiplex RT-PCR for the simultaneous detection of both ASFV and CSFV has been described,<sup>133</sup> with a diagnostic

sensitivity of 100% for both viruses and 100% specificity for CSFV and 97.3% for ASFV. The inclusion of a heterologous internal control allowed the detection of false negatives.

### Serologic Tests

Antibody can be detected by the fluorescent antibody neutralization test, tissue culture serum neutralization test, or an indirect ELISA. Serologic tests are less satisfactory for detection of hog cholera in the acute phase and are of limited value in vaccinated animals. They are of value in the detection in sows of the subclinical infection of hog cholera associated with reproductive failure and for survey studies to determine the prevalence of hog cholera infection. BVDV may infect pigs, especially those in close contact with cattle, and may give false-positive serologic reactions. The incidence rates of these false-positive reactions may be high, and they pose a problem for hog cholera identification in eradication programs. The neutralizing peroxidase-linked antibody assay is a highly sensitive and specific test for hog cholera and will distinguish between pigs infected with different strains of the hog cholera virus and BVDV. The complex, trapping, blocking ELISA is sensitive, specific, and reliable for screening purposes for early identification of infected herds and their elimination in an eradication program. A peroxidase-labeled antibody assay can be used to detect swine IgG antibodies to hog cholera and BVDVs. Monoclonal antibodies to pestiviruses are also available to discriminate between both viruses. A competitive ELISA using a truncated E2 recombinant protein has been described, which can be used when a large number of samples are to be tested.

### Samples for Laboratory

When hog cholera is suspected, tissues submitted for examination should include the brain and sections of intestine and other internal organs in formalin, and pancreas, lymph node, and tonsil unpreserved in sealed containers. Local regulations and requirements should be followed. The viral antigens are densely distributed in the skin and tongue of infected pigs, and biopsies of the ear may be useful for diagnosis on a herd basis.

### NECROPSY FINDINGS

In many cases the single most important diagnostic aid is the postmortem examination, although in the Dutch outbreaks it was thought that the contribution to the detection of CSF was limited. The reason for this is that there is a tremendous individual variation in necropsy findings. In the outbreak in the United Kingdom in 2000, there were few lesions in fetuses or in neonates; in the sows, lesions were often restricted to conjunctivitis and lesions in the hepatic and

splenic lymph nodes, even though 15 animals in each group were examined. The age group showing relatively consistent lesions were the growers, and in these the lesions were similar to those that are reported in the classical outbreaks.

In peracute cases, there may be no gross changes at necropsy. In the more common acute form, there are many submucosal and subserosal hemorrhages, but these are inconsistent; to find them, it may be necessary to examine several carcasses from an outbreak. The hemorrhage results from erythrodiapedesis and increased vascular permeability, probably aided by mast cell degranulation. The hemorrhages are most noticeable under the capsule of the kidney, near the ileocecal valve, in the cortical sinuses of the lymph nodes, and in the bladder and larynx. The hemorrhages are usually petechial and rarely ecchymotic. The lymph nodes are enlarged, and the spleen may contain marginal infarcts. Infarction in the mucosa of the gallbladder is a common but not constant finding and appears to be an almost pathognomonic lesion. There is congestion of the liver and bone marrow and often of the lungs. Circular, raised button ulcers in the colonic mucosa are usual but cannot be distinguished from those of salmonellosis. Although these gross necropsy findings are fairly typical in cases of hog cholera, they cannot be considered as diagnostic unless accompanied by the clinical and epizootiological evidence of the disease. They can occur in other diseases, particularly salmonellosis. A recent study found that the lymph nodes had the highest score for lesions and that the fewest lesions were found in the spleen and tonsil because infection of these organs was also rare. The most common lesions were also in the lymph nodes, around the ileocecolic junction, and around the blood vessels of the brain. Atypical bronchiolar cilia have been reported.

There are characteristic microscopic lesions of a nonsuppurative encephalitis in most cases, and a presumptive diagnosis of hog cholera can be made if they are present. It is thought that the most common lesion in chronic CSF is the mononuclear cell cuff in the CNS. Here ISH is capable of detecting viral nucleic acid even when viral antigen is not detected. Histologically, the main site of tissue injury is the reticuloendothelial system. There is always a progressive lymphoid depletion and mucosal necrosis. The depletion is probably caused by apoptosis but not by direct apoptosis. Atrophy of the thymic cortex and loss of thymocytes is also a feature and may be related to synthesis of the cytokines, TNF- $\alpha$  and IL-1 $\alpha$  in particular, which may increase the apoptosis of the thymocytes.

Fibrinoid necrosis of the tunica media combined with hydropic degeneration and proliferation of the vascular endothelium causes occlusion of blood vessels. The

more virulent "neurotropic" strains produce lesions of a similar nature but greater severity.

In the intestinal tract mucosa there are large, usually infected macrophages. The gut-associated lymphoid tissue areas are lymphocyte depleted, usually because of massive lymphocyte apoptosis, particularly in the B-cell areas. These changes are possibly attributable to the large amounts of TNF $\alpha$  and IL-1 $\alpha$  released from the infected macrophages. They also showed that the macrophages in the splenic marginal zone were among the first cells to be infected. The infection, mobilization, and apoptosis of splenic macrophages play a very important role in the course of the infection through cytokine release. An unusual manifestation of CSF infection is the onset of metaphyseal bone formation caused by the partly thrombosed vessels in the bone, with strong CSF viral specific fluorescence.

Histology showed swelling and vacuolation of megakaryocytes in the bone marrow 2 days after infection, and they were necrotic 4 days after infection. Severe swelling and necrosis of endothelial cells in the vascular endothelium were observed 3 days after infection. It was concluded that the thrombocytopenia resulting from direct viral damage to MKC and endothelial damage can cause hemorrhagic diathesis, whereas coagulation disorders are not involved in early stages of the disease.

In the chronic form of the disease, ulceration of the mucosa of the large intestine is usual. Secondary pneumonia and enteritis commonly accompany the primary lesions of hog cholera.

Infection of the fetus produces a persistent immunologically tolerant noncytolytic infection, often with little evidence of cell necrosis or inflammatory reaction to suggest the presence of a virus. Aborted fetuses show nondiagnostic changes of petechial hemorrhage and ascites. Malformations such as microcephaly, cerebellar hypoplasia, pulmonary hypogenesis, and joint deformity appear as a result of inhibition of cell division and function in these areas. Antibody is not detected in fetal blood when infection occurs early in fetal life. In pigs showing signs of myoclonia congenita, cerebellar hypoplasia is highly suggestive of hog cholera infection.

An immune complex glomerulonephritis has been described in which there is macrophage infiltration of the mesangium with immune complex deposits of IgM, IgG, and Clq in mesangial, subepithelial, and subendothelial areas from 10 days postinfection, and by 14 days neutrophils had also congregated.

This is a disease of major economic importance, and confirmation of the diagnosis is usually performed in specialized governmental laboratories. Virus isolation and fluorescent antibody tests are most commonly used, but other techniques, including

immunoperoxidase staining of cryostat sections, are available. The demonstration of viral antigen in the crypts of the tonsils, tubular epithelial cells of the kidney, bronchiolar mucosal gland cells, and the pancreatic epithelial cells has been shown to be possible even after 18 years in formalin.

## DIAGNOSIS

The European Union Reference laboratory in Hanover is responsible for the testing in the European Union. A survey of pig farmers and practitioners in the Netherlands investigated their attitudes regarding CSF and found there were six sets of problems identified:<sup>54</sup>

1. Lack of knowledge of CSF
2. Guilt, shame, and prejudice
3. Negative opinion of control measures
4. Dissatisfaction with postreporting procedures
5. Lack of trust in government bodies
6. Uncertainty about and lack of transparency in reporting procedures

The authors recommended procedures to deal with these problems. Diagnostic methods for CSF have been reviewed.<sup>55,56</sup>

## Detection of Antigen

Virus isolation is the sensitive, highly specific, time-consuming, and labor-intensive method to find CSF.

For the rapid detection of viral antigen, immunofluorescence and ELISAs are being used. The former uses thin sections of tissues (lymph node, spleen, tonsils, and other organs); the specificity is good, but the sensitivity is not so good. In the early stages of infection there may be false-negative results because there may not be high levels of virus.

The RT-PCR is considered the most sensitive and most specific tool for the detection of CSFV.

A real time RT-PCR is available for differentiating vaccine and field virus, and this will probably become available as a field test.<sup>136,137</sup> Next-generation technology allows the full genome of CSFV to be identified and is the best basis for high-resolution phylogenetic studies.<sup>138</sup>

Pyrexia is one of the key indicators for CSFV, together with high mortality.

## Samples for Confirmation of Diagnosis

Laboratory diagnosis is always required. Fresh tonsil can be used for polyclonal direct fluorescent antibody, which also detects BVDV and BDV, and can then be used for additional tests. The sensitivity of this test was shown to be only 78%, so to give a 99% chance of infection being detected five post-mortems would need to be performed. Even when suffering from tissue degradation, tonsil and spleen will still yield infectious virus and RNA.<sup>64</sup>

A comparative study of the signs and lesions produced by six field strains of CSF

virus<sup>51</sup> showed that the most characteristic lesions were found in the lymph nodes, followed by necrotic lesions in the ileum and hyperemia of the brain. Splenic infarction and necrotic tonsils when they occur are spectacular but are less frequent, and respiratory signs are also less frequent than was reported in the last century.

A one-step gel-based RT-PCR assay with comparable performance to RT-PCR for detection of CSF virus has been described.<sup>57</sup>

Two RT-PCR assays of CSF were developed for genetic differentiation of naturally infected from vaccinated wild boars.<sup>58</sup>

C-strain "Riems" or other vaccinated animals can be differentiated from infected animals using a RT-PCR.<sup>59</sup>

Two new E<sup>ms</sup>-based ELISAs allow differentiation of infected from marker-vaccinated animals and discrimination of pestivirus antibodies.<sup>60</sup>

Meat juice ELISA can be used as a suitable substrate for diagnosis of CSF.<sup>61</sup> Viral RNA was detected in meat juice at a lower level than in serum.<sup>62</sup> Sensitivity was calculated to be 91% and specificity to be 97%. Difficulties were encountered when there were low-virulence strains involved and when samples were taken very early in infections.

Pan-pestivirus assays will detect the pestivirus, and then CSF specific assays are required. qRT-PCR is routinely used. Specific assays for CSF include VI, fluorescence antibody test (FAT), and ELISAs.

Irrespective of virulence, whole-blood and tonsil scrapings are the samples of choice for the early detection of CSF.<sup>63</sup> At least eight RT-PCRs have been developed for detection of wild-type CSF,<sup>65-69</sup> and some are used routinely.<sup>70,71</sup>

A loop-mediated isothermal amplification assay for detection of wild-type CSF was described<sup>72</sup> and proved to be a simple, rapid, and sensitive tool for detection of wild-type CSFV under field conditions.

A multiplex nested RT-PCR for the differentiation of wild-type viruses from the C-strain vaccine of CSF was developed.<sup>73</sup>

Multiplex PCRs for the simultaneous detection and differentiation of CSFV field strains and the C-strain vaccine virus have been developed.<sup>59,68</sup>

A multiplex RT-PCR assay for the rapid and differential diagnosis of CSF and other pestiviruses was developed<sup>74</sup> and was shown to be rapid, highly sensitive, and cost effective.

A triplex TaqMan RT-PCR assay for differential detection of wild-type and hog cholera lapinized vaccine strains of CSF and BVDV type 1 has also been devised.<sup>75</sup>

Most CSF reference laboratories use more than one test (virus isolation, antigen ELISA, RT-PCR for detection and confirmation). It has been shown<sup>70</sup> that the RT-PCR is 100% sensitive but VI only about 72% and antigen ELISA only 39%.

A novel RT-PCR assay based on primer-probe energy transfer has also been developed.<sup>58,76</sup> This has been shown to be a highly sensitive and specific confirmatory tool.

The qRT-PCRs have high specificity and sensitivity.<sup>71,77,78</sup> Viral RNA can be detected in samples where the virus is in tissues that are autolysed.<sup>79</sup> Viral RNA can be detected in animals that have recovered.<sup>80</sup> The qRT-PCR can also be used to differentiate between virus species BD, BVD and CSF, and strains of CSF. It can also be used to differentiate infected from vaccinated animals (DIVA).<sup>81</sup> There are some tests that are specific for wild-type virus<sup>58,68</sup> irrespective of the vaccination status of the animal. A negative RT-PCR generally means that the animal is not infectious, but a positive RT-PCR does not mean that it is infectious.<sup>82</sup> Antigen-capture ELISA is recommended for animals with clinical signs or lesions.

A primer-probe energy transfer RT-PCR assay for CSF was described<sup>83</sup> and can differentiate between wild-type CSFV and certain C-strain vaccines. A one-step RT-PCR detection of CSFV using a minor groove binding probe was described<sup>84</sup> and was found to be rapid and of high specificity and sensitivity.

A reverse transcription multiplex RT-PCR was developed for the detection and genotyping of CSF.<sup>85</sup> It was said to be a rapid, sensitive, reproducible, sensitive, and specific genotyping tool. RT-PCR was able to detect CSF 2 days earlier than virus isolation and 2 to 4 days earlier than with antigen ELISA.<sup>86</sup> A high-speed RT-PCR was able to detect FMD, CSF, and SIV-A,<sup>87</sup> and it took only about 28 minutes.

A gold-nanoparticle-based oligonucleotide microarray for the simultaneous detection of seven swine viruses, including CSF, has been described.<sup>88</sup>

- **Histology**—formalin-fixed brain, spleen, lymph nodes, colon, cecum, ileum, kidney, tonsil, skin, tongue (LM). Tissue sections can also be used for ISH and IHC.
- **Virology**—lymph nodes, tonsil, spleen, distal ileum, skin, tongue, brain (FAT, ISO, IHC, PCR); heparinized blood. Virus can be isolated from tissue, serum, plasma, buffy coat, or whole blood in heparin.<sup>89</sup>

## Serology

The gold standard is the virus neutralization test. However, ELISAs in microtiter are easy to perform, rapid, and automated. Differentiation between pestiviruses is possible and depends on the design of the test, and detection of DIVA vaccines is also possible.<sup>60</sup>

The immuno-chromatographic strip or lateral flow device<sup>139</sup> can be used as a penside test.

The evaluation of assays<sup>90</sup> showed that the Chekit CSF-Sero and the HerdChek CSFV

Ab were both practical and had highest sensitivity. The PrioCHECK (Rcircle) CSFV<sup>ms</sup> was the only ELISA suitable for use in DIVA but is less sensitive and cannot be recommended.

ELISAs for the detection of anti-CSF antibodies are useful for epidemiologic surveys and for monitoring CSF-free areas. These antibodies occur 10 to 15 days postinfection, the same as for neutralizing antibodies.

A recombinant E2-based indirect ELISA for the detection of specific IgM antibody responses to CSF has been shown to detect antibodies 2 weeks after vaccination.<sup>91</sup>

An immunochromatographic strip for rapid detection of antibodies to CSF was described<sup>92</sup> and was found to be 97% sensitive and 100% specific and could be performed within 5 minutes.

#### DIFFERENTIAL DIAGNOSIS

A positive diagnosis of hog cholera is difficult to make without laboratory confirmation. This is particularly true of the chronic, less dramatic forms of the disease. A highly infectious, fatal disease of pigs with a course of 5 to 7 days in a group of unvaccinated animals should arouse suspicion of hog cholera, especially if there are no signs indicative of localization in particular organs. Nervous signs are probably the one exception. The gross necropsy findings are also nonspecific, and reliance must be placed on the leukopenia in the early stages and the nonsuppurative encephalitis visible on histologic examination. Both of these bacterial infections, particularly salmonellosis, may be present.

The major diseases that resemble hog cholera include the following:

- **Salmonellosis**, usually accompanied by enteritis and dyspnea.
- **Erysipelas**, in which there are characteristic diamond skin lesions, and the subserous hemorrhages are likely to be ecchymotic rather than petechial.
- **Pasteurellosis**, in which respiratory signs predominate and lesions of pleuropneumonia at necropsy are characteristic.

Epidemiologic considerations and hematologic and bacteriologic examination will usually differentiate these conditions.

Recently, hemorrhagic septicemia in a pig caused by extraintestinal *E. coli* has been suggested as a differential diagnosis.<sup>93</sup>

In the United Kingdom, many of the cases reported as suspected classical swine fever (CSF) have turned out to be *Purpura hemorrhagica*.

**Other encephalitides**, particularly **viral encephalomyelitis** and **salmonellosis**, cause similar nervous signs.

**African swine fever**, apart from its greater severity, is almost impossible to differentiate from hog cholera without laboratory testing.

#### TREATMENT

Hyperimmune serum is the only available treatment and may be of value in the very early stages of the illness if given in doses of 50 to 150 mL. It has more general use in the protection of in-contact animals. A concentrated serum permitting the use of much smaller doses is now available.
